- If  $1.12\sqrt{\frac{Ek}{F_{yw}}} < \frac{D}{t_w} \leq 1.40\sqrt{\frac{Ek}{F_{yw}}}$ , then:

$$C = \frac{1.12}{\frac{D}{t_w}} \sqrt{\frac{Ek}{F_{yw}}} \quad (6.10.9.3.2-5)$$

- If  $\frac{D}{t_w} > 1.40\sqrt{\frac{Ek}{F_{yw}}}$ , then:

$$C = \frac{1.57}{\left(\frac{D}{t_w}\right)^2} \left( \frac{Ek}{F_{yw}} \right) \quad (6.10.9.3.2-6)$$

in which:

$k$  = shear-buckling coefficient

$$= 5 + \frac{5}{\left(\frac{d_o}{D}\right)^2} \quad (6.10.9.3.2-7)$$

Otherwise, the nominal shear resistance shall be taken as follows:

$$V_n = V_p \left[ C + \frac{0.87(1-C)}{\sqrt{1 + \left(\frac{d_o}{D}\right)^2 + \frac{d_o}{D}}} \right] \quad (6.10.9.3.2-8)$$

### 6.10.9.3.3—End Panels

The nominal shear resistance of a web end panel shall be taken as:

$$V_n = V_{cr} = CV_p \quad (6.10.9.3.3-1)$$

in which:

$$V_p = 0.58 F_{yw} D t_w \quad (6.10.9.3.3-2)$$

where:

Therefore, previous provisions related to the effects of moment-shear interaction are not required in these Specifications.

The coefficient,  $C$ , is equal to the ratio of the elastic buckling stress of the panel, computed assuming simply-supported boundary conditions, to the shear yield strength assumed to equal  $F_{yw}/\sqrt{3}$ . Eq. 6.10.9.3.2-6 is applicable only for  $C$  values not exceeding 0.8 (Basler, 1961). Above 0.8,  $C$  values are given by Eq. 6.10.9.3.2-5 until a limiting slenderness ratio is reached where the shear-buckling stress is equal to the shear yield strength and  $C = 1.0$ . Eq. 6.10.9.3.2-7 for the shear-buckling coefficient is a simplification of two exact equations for  $k$  that depend on the panel aspect ratio. The coefficients within Eqs. 6.10.9.3.2-4 through 6.10.9.3.2-6 have been modified slightly from the values given in previous Specifications to correct minor round-off errors.

Because the slenderness of webs without longitudinal stiffeners is limited to 150 according to the provisions of Article 6.10.2.1.1, the separate handling requirement given in previous Specifications for web panels without longitudinal stiffeners is not required and is omitted in these Specifications.

### C6.10.9.3.3

The shear in end panels adjacent to simple supports is limited to either the shear-yielding or shear-buckling resistance given by Eq. 6.10.9.3.3-1 in order to provide an anchor for the tension field in adjacent interior panels. The shear-buckling coefficient,  $k$ , to be used in determining the constant  $C$  in Eq. 6.10.9.3.3-1 is to be calculated based on the spacing from the support to the first stiffener adjacent to the support, which may not exceed  $1.5D$ .

$C$  = ratio of the shear-buckling resistance to the shear yield strength determined by Eqs. 6.10.9.3.2-4, 6.10.9.3.2-5, or 6.10.9.3.2-6 as applicable

$V_{cr}$  = shear-buckling resistance (kip)

$V_p$  = plastic shear force (kip)

The transverse stiffener spacing for end panels with or without longitudinal stiffeners shall not exceed  $1.5D$ .

## 6.10.10 Shear—Connectors

### 6.10.10.1—General

In composite sections, stud or channel shear connectors shall be provided at the interface between the concrete deck and the steel section to resist the interface shear.

Simple span composite bridges shall be provided with shear connectors throughout the length of the span.

Straight continuous composite bridges should normally be provided with shear connectors throughout the length of the bridge. In the negative flexure regions, shear connectors shall be provided where the longitudinal reinforcement is considered to be a part of the composite section. Otherwise, shear connectors need not be provided in negative flexure regions, but additional connectors shall be placed in the region of the points of permanent load contraflexure as specified in Article 6.10.10.3.

Where shear connectors are omitted in negative flexure regions, the longitudinal reinforcement shall be extended into the positive flexure region as specified in Article 6.10.1.7.

Curved continuous composite bridges shall be provided with shear connectors throughout the length of the bridge.

### C6.10.10.1

Shear connectors help control cracking in regions of negative flexure where the deck is subject to tensile stress and has longitudinal reinforcement.

Shear connectors are to be provided in regions of negative flexure in curved continuous bridges because torsional shear exists and is developed in the full composite section along the entire bridge. For bridges containing one or more curved segments, the effects of curvature usually extend beyond the curved segment. Therefore, it is conservatively specified that shear connectors be provided along the entire length of the bridge in this case as well.

#### 6.10.10.1.1—Types

Stud and channel shear connectors shall be designed by the provisions of this Article.

Shear connectors should be of a type that permits a thorough compaction of the concrete to ensure that their entire surfaces are in contact with the concrete. The connectors shall be capable of resisting both horizontal and vertical movement between the concrete and the steel.

The ratio of the height to the diameter of a stud shear connector shall not be less than 4.0.

Channel shear connectors shall have fillet welds not smaller than 0.1875 in. placed along the heel and toe of the channel.

### 6.10.10.1.2—Pitch

The pitch of the shear connectors shall be determined to satisfy the fatigue limit state, as specified in Article 6.10.10.2 and 6.10.10.3. The resulting number of shear connectors shall not be less than the number required to satisfy the strength limit state as specified in Article 6.10.10.4.

The pitch,  $p$ , of shear connectors shall satisfy:

$$p \leq \frac{nZ_r}{V_{sr}} \quad (6.10.10.1.2-1)$$

in which:

$V_{sr}$  = horizontal fatigue shear range per unit length (kip/in.)

$$= \sqrt{(V_{fat})^2 + (F_{fat})^2} \quad (6.10.10.1.2-2)$$

$V_{fat}$  = longitudinal fatigue shear range per unit length (kip/in.)

$$= \frac{V_f Q}{I} \quad (6.10.10.1.2-3)$$

$F_{fat}$  = radial fatigue shear range per unit length (kip/in.) taken as the larger of either:

$$F_{fat1} = \frac{A_{bot} \sigma_{flg} \ell}{wR} \quad (6.10.10.1.2-4)$$

or:

$$F_{fat2} = \frac{F_{rc}}{w} \quad (6.10.10.1.2-5)$$

where:

$\sigma_{flg}$  = range of longitudinal fatigue stress in the bottom flange without consideration of flange lateral bending (ksi)

$A_{bot}$  = area of the bottom flange ( $\text{in.}^2$ )

$F_{rc}$  = net range of cross-frame or diaphragm force at the top flange (kip)

$I$  = moment of inertia of the short-term composite section ( $\text{in.}^4$ )

### C6.10.10.1.2

At the fatigue limit state, shear connectors are designed for the range of live load shear between the deck and top flange of the girder. In straight girders, the shear range normally is due to only major-axis bending if torsion is ignored. Curvature, skew and other conditions may cause torsion, which introduces a radial component of the horizontal shear. These provisions provide for consideration of both of the components of the shear to be added vectorially according to Eq. 6.10.10.1.2-2.

The parameters  $I$  and  $Q$  should be determined using the deck within the effective flange width. However, in negative flexure regions of straight girders only, the parameters  $I$  and  $Q$  may be determined using the longitudinal reinforcement within the effective flange width for negative moment, unless the concrete deck is considered to be effective in tension for negative moment in computing the range of the longitudinal stress, as permitted in Article 6.6.1.2.1.

The maximum longitudinal fatigue shear range,  $V_{fat}$ , is produced by placing the fatigue live load immediately to the left and to the right of the point under consideration. For the load in these positions, positive moments are produced over significant portions of the girder length. Thus, the use of the full composite section, including the concrete deck, is reasonable for determining the stiffness used to determine the shear range along the entire span. Also, the horizontal shear force in the deck is most often considered to be effective along the entire span in the analysis. To satisfy this assumption, the shear force in the deck should be developed along the entire span. For straight girders, an option is permitted to ignore the concrete deck in computing the shear range in regions of negative flexure, unless the concrete is considered to be effective in tension in computing the range of the longitudinal stress, in which case the shear force in the deck must be developed. If the concrete is ignored in these regions, the maximum pitch specified at the end of this Article must not be exceeded.

The radial shear range,  $F_{fat}$ , typically is determined for the fatigue live load positioned to produce the largest positive and negative major-axis bending moments in the span. Therefore, vectorial addition of the longitudinal and radial components of the shear range is conservative because the longitudinal and radial shears are not produced by concurrent loads.

Eq. 6.10.10.1.2-4 may be used to determine the radial fatigue shear range resulting from the effect of any curvature between brace points. The shear range is taken as the radial component of the maximum longitudinal range of force in the bottom flange between brace points, which is used as a measure of the major-axis bending moment. The radial shear range is distributed over an effective length of girder flange,  $w$ . At end supports,  $w$  is halved. Eq. 6.10.10.1.2-4 gives the same units as  $V_{fat}$ .

- $\ell$  = distance between brace points (ft)
- $n$  = number of shear connectors in a cross-section
- $p$  = pitch of shear connectors along the longitudinal axis (in.)
- $Q$  = first moment of the transformed short-term area of the concrete deck about the neutral axis of the short-term composite section (in.<sup>3</sup>)
- $R$  = minimum girder radius within the panel (ft)
- $V_f$  = vertical shear force range under the applicable fatigue load combination specified in Table 3.4.1-1 with the fatigue live load taken as specified in Article 3.6.1.4 (kip)
- $w$  = effective length of deck (in.) taken as 48.0 in., except at end supports where  $w$  may be taken as 24.0 in.
- $Z_r$  = shear fatigue resistance of an individual shear connector determined as specified in Article 6.10.10.2 (kip)

For straight spans or segments, the radial fatigue shear range from Eq. 6.10.10.1.2-4 may be taken equal to zero. For straight or horizontally curved bridges with skews not exceeding 20 degrees, the radial fatigue shear range from Eq. 6.10.10.1.2-5 may be taken equal to zero.

The center-to-center pitch of shear connectors shall not exceed 24.0 in. and shall not be less than six stud diameters.

#### 6.10.10.1.3—Transverse Spacing

Shear connectors shall be placed transversely across the top flange of the steel section and may be spaced at regular or variable intervals.

Stud shear connectors shall not be closer than 4.0 stud diameters center-to-center transverse to the longitudinal axis of the supporting member.

The clear distance between the edge of the top flange and the edge of the nearest shear connector shall not be less than 1.0 in.

#### 6.10.10.1.4—Cover and Penetration

The clear depth of concrete cover over the tops of the shear connectors should not be less than 2.0 in. Shear connectors should penetrate at least 2.0 in. into the concrete deck.

Eq. 6.10.10.1.2-5 will typically govern the radial fatigue shear range where torsion is caused by effects other than curvature, such as skew. Eq. 6.10.10.1.2-5 is most likely to control when discontinuous cross-frame or diaphragm lines are used in conjunction with skew angles exceeding 20 degrees in either a straight or horizontally curved bridge. For all other cases,  $F_{rc}$  can be taken equal to zero. Eqs. 6.10.10.1.2-4 and 6.10.10.1.2-5 yield approximately the same value if the span or segment is curved and there are no other sources of torsion in the region under consideration. Note that  $F_{rc}$  represents the resultant range of horizontal force from all cross-frames or diaphragms at the point under consideration due to the factored fatigue load plus impact that is resisted by the shear connectors. In lieu of a refined analysis,  $F_{rc}$  may be taken as 25.0 kips for an exterior girder, which is typically the critical girder.  $F_{rc}$  should not be multiplied by the factor 0.75 discussed in Article C6.6.1.2.1.

Eqs. 6.10.10.1.2-4 and 6.10.10.1.2-5 are provided to ensure that a load path is provided through the shear connectors to satisfy equilibrium at a transverse section through the girders, deck, and cross-frame or diaphragm.

#### C6.10.10.1.4

Stud shear connectors should penetrate through the haunch between the bottom of the deck and the top flange, if present, and into the deck. Otherwise, the haunch should be reinforced to contain the stud connector and develop its load in the deck.

### 6.10.10.2—Fatigue Resistance

The fatigue shear resistance of an individual stud shear connector,  $Z_r$ , shall be taken as:

For stud type shear connectors:

- Where the projected 75-year single lane Average Daily Truck Traffic ( $ADTT_{SL}$ ) is greater than or equal to 960 trucks per day, the Fatigue I load combination shall be used and the fatigue shear resistance for infinite life shall be taken as:

$$Z_r = 5.5d^2 \quad (6.10.10.2-1)$$

- Otherwise, the Fatigue II load combination shall be used and the fatigue shear resistance for finite life shall be taken as:

$$Z_r = \alpha d^2 \quad (6.10.10.2-2)$$

in which:

$$\alpha = 34.5 - 4.28 \log N \quad (6.10.10.2-3)$$

For channel-type shear connectors:

- Where the projected 75-year single lane Average Daily Truck Traffic ( $ADTT_{SL}$ ) is greater than or equal to 1850 trucks per day, the Fatigue I load combination shall be used and the fatigue shear resistance for infinite life shall be taken as:

$$Z_r = 2.1w \quad (6.10.10.2-4)$$

- Otherwise, the Fatigue II load combination shall be used and the fatigue shear resistance for finite life shall be taken as:

$$Z_r = Bw \quad (6.10.10.2-5)$$

in which:

$$B = 9.37 - 1.08 \log N \quad (6.10.10.2-6)$$

where:

$(ADTT)_{SL}$  = single-lane  $ADTT$  as specified in Article 3.6.1.4.2

$d$  = diameter of the stud (in.)

$N$  = number of cycles specified in Article 6.6.1.2.5

$w$  = length of the channel measured transverse to the direction of the flange (in.)

### C6.10.10.2

For the development of this information, see Slutter and Fisher (1966).

The pitch shall be determined from Eq. 6.10.10.1.2-1 using the value of  $Z_r$  and the shear force range  $V_{sr}$ .

The effect of the shear connector on the fatigue resistance of the flange shall be investigated using the provisions of Article 6.6.1.2.

### 6.10.10.3—Special Requirements for Points of Permanent Load Contraflexure

For members that are noncomposite for negative flexure in the final condition, additional shear connectors shall be provided in the region of points of permanent load contraflexure.

The number of additional connectors,  $n_{ac}$ , shall be taken as:

$$n_{ac} = \frac{A_s f_{sr}}{Z_r} \quad (6.10.10.3-1)$$

where:

$A_s$  = total area of longitudinal reinforcement over the interior support within the effective concrete deck width (in.<sup>2</sup>)

$f_{sr}$  = stress range in the longitudinal reinforcement over the interior support under the applicable Fatigue load combination specified in Table 3.4.1-1 with the fatigue live load taken as specified in Article 3.6.1.4 (ksi)

$Z_r$  = fatigue shear resistance of an individual shear connector determined as specified in Article 6.10.10.2 (kip)

The additional shear connectors shall be placed within a distance extending one-third of the effective flange width specified in Article 4.6.2.6 from each side of the point of steel dead load contraflexure. The center-to-center pitch of all connectors, including the additional connectors, within that distance shall satisfy the maximum and minimum pitch requirements specified in Article 6.10.10.1.2. Field splices should be placed so as not to interfere with the shear connectors.

### C6.10.10.3

The purpose of the additional connectors is to develop the reinforcing bars used as part of the negative flexural composite section.

### 6.10.10.4—Strength Limit State

#### 6.10.10.4.1—General

The factored shear resistance of a single shear connector,  $Q_r$ , at the strength limit state shall be taken as:

$$Q_r = \phi_{sc} Q_n \quad (6.10.10.4.1-1)$$

where:

$Q_n$  = nominal shear resistance of a single shear connector determined as specified in Article 6.10.10.4.3 (kip)

$\phi_{sc}$  = resistance factor for shear connectors specified in Article 6.5.4.2

At the strength limit state, the minimum number of shear connectors,  $n$ , over the region under consideration shall be taken as:

$$n = \frac{P}{Q_r} \quad (6.10.10.4.1-2)$$

where:

$P$  = total nominal shear force determined as specified in Article 6.10.10.4.2 (kip)

$Q_r$  = factored shear resistance of one shear connector determined from Eq. 6.10.10.4.1-1 (kip)

#### 6.10.10.4.2—Nominal Shear Force

For simple spans and for continuous spans that are noncomposite for negative flexure in the final condition, the total nominal shear force,  $P$ , between the point of maximum positive design live load plus impact moment and each adjacent point of zero moment shall be taken as:

$$P = \sqrt{P_p^2 + F_p^2} \quad (6.10.10.4.2-1)$$

in which:

$P_p$  = total longitudinal force in the concrete deck at the point of maximum positive live load plus impact moment (kip) taken as the lesser of either:

$$P_{1p} = 0.85 f_c' b_s t_s \quad (6.10.10.4.2-2)$$

or

$$P_{2p} = F_{yw} D t_w + F_{yt} b_{ft} t_{ft} + F_{yc} b_{fc} t_{fc} \quad (6.10.10.4.2-3)$$

$F_p$  = total radial force in the concrete deck at the point of maximum positive live load plus impact moment (kip) taken as:

$$F_p = P_p \frac{L_p}{R} \quad (6.10.10.4.2-4)$$

#### C6.10.10.4.2

Composite beams in which the longitudinal spacing of shear connectors has been varied according to the intensity of shear and duplicate beams where the number of connectors were essentially uniformly spaced have exhibited essentially the same ultimate strength and the same amount of deflection at service loads. Only a slight deformation in the concrete and the more heavily stressed connectors are needed to redistribute the horizontal shear to other less heavily stressed connectors. The important consideration is that the total number of connectors be sufficient to develop the nominal longitudinal force,  $P_n$ , on either side of the point of maximum design live load plus impact moment.

The point of maximum design live load plus impact moment is specified because it applies to the composite section and is easier to locate than a maximum of the sum of the moments acting on the composite section.

For continuous spans that are noncomposite for negative flexure in the final condition, points of zero moment within the span should be taken as the points of steel dead load contraflexure.

For continuous spans that are composite for negative flexure in the final condition, sufficient shear connectors are required to transfer the ultimate tensile force in the reinforcement from the concrete deck to the steel section. The number of shear connectors required between points of maximum positive design live load plus impact moment

where:

$b_s$  = effective width of the concrete deck (in.)

$L_p$  = arc length between an end of the girder and an adjacent point of maximum positive live load plus impact moment (ft)

$R$  = minimum girder radius over the length,  $L_p$  (ft)

$t_s$  = thickness of the concrete deck (in.)

For straight spans or segments,  $F_p$  may be taken equal to zero.

For continuous spans that are composite for negative flexure in the final condition, the total nominal shear force,  $P$ , between the point of maximum positive design live load plus impact moment and an adjacent end of the member shall be determined from Eq. 6.10.10.4.2-1. The total nominal shear force,  $P$ , between the point of maximum positive design live load plus impact moment and the centerline of an adjacent interior support shall be taken as:

$$P = \sqrt{P_T^2 + F_T^2} \quad (6.10.10.4.2-5)$$

in which:

$P_T$  = total longitudinal force in the concrete deck between the point of maximum positive live load plus impact moment and the centerline of an adjacent interior support (kip) taken as:

$$P_T = P_p + P_n \quad (6.10.10.4.2-6)$$

$P_n$  = total longitudinal force in the concrete deck over an interior support (kip) taken as the lesser of either:

$$P_{In} = F_{yw} D t_w + F_{yt} b_{ft} t_{fi} + F_{yc} b_{fc} t_{fc} \quad (6.10.10.4.2-7)$$

or:

$$P_{2n} = 0.45 f_c' b_s t_s \quad (6.10.10.4.2-8)$$

$F_T$  = total radial force in the concrete deck between the point of maximum positive live load plus impact moment and the centerline of an adjacent interior support (kip) taken as:

$$F_T = P_T \frac{L_n}{R} \quad (6.10.10.4.2-9)$$

and the centerline of an adjacent interior support is computed from the sum of the critical forces at the maximum positive and negative moment locations. Since there is no point where moment always changes sign, many shear connectors resist reversing action in the concrete deck depending on the live load position. However, the required number of shear connectors is conservatively determined from the sum of the critical forces at the maximum moment locations to provide adequate shear resistance for any live load position.

The tension force in the deck given by Eq. 6.10.10.4.2-8 is defined as 45 percent of the specified 28-day compressive strength of the concrete. This is a conservative approximation to account for the combined contribution of both the longitudinal reinforcement and also the concrete that remains effective in tension based on its modulus of rupture. A more precise value may be substituted.

The radial effect of curvature is included in Eqs. 6.10.10.4.2-4 and 6.10.10.4.2-9. For curved spans or segments, the radial force is required to bring into equilibrium the smallest of the longitudinal forces in either the deck or the girder. When computing the radial component, the longitudinal force is conservatively assumed to be constant over the entire length  $L_p$  or  $L_n$ , as applicable.

where:

$L_n$  = arc length between the point of maximum positive live load plus impact moment and the centerline of an adjacent interior support (ft)

$R$  = minimum girder radius over the length,  $L_n$  (ft)

For straight spans or segments,  $F_T$  may be taken equal to zero.

#### 6.10.10.4.3—Nominal Shear Resistance

The nominal shear resistance of one stud shear connector embedded in a concrete deck shall be taken as:

$$Q_n = 0.5A_{sc}\sqrt{f'_c E_c} \leq A_{sc}F_u \quad (6.10.10.4.3-1)$$

where:

$A_{sc}$  = cross-sectional area of a stud shear connector (in.<sup>2</sup>)

$E_c$  = modulus of elasticity of the deck concrete determined as specified in Article 5.4.2.4 (ksi)

$F_u$  = specified minimum tensile strength of a stud shear connector determined as specified in Article 6.4.4 (ksi)

The nominal shear resistance of one channel shear connector embedded in a concrete deck shall be taken as:

$$Q_n = 0.3(t_f + 0.5t_w)L_c\sqrt{f'_c E_c} \quad (6.10.10.4.3-2)$$

where:

$t_f$  = flange thickness of channel shear connector (in.)

$t_w$  = web thickness of channel shear connector (in.)

$L_c$  = length of channel shear connector (in.)

#### 6.10.11—Stiffeners

##### 6.10.11.1—Transverse Stiffeners

###### 6.10.11.1.1—General

Transverse stiffeners shall consist of plates or angles welded or bolted to either one or both sides of the web.

Stiffeners in straight girders not used as connection plates shall be tight fit or attached at the compression flange, but need not be in bearing with the tension flange. Single-sided stiffeners on horizontally curved girders should be attached to both flanges. When pairs of transverse stiffeners are used on horizontally curved girders, they shall be fitted tightly or attached to both flanges.

##### C6.10.10.4.3

Studies have defined stud shear connector strength as a function of both the concrete modulus of elasticity and concrete strength (Ollgaard et al., 1971). Note that an upper bound on stud shear strength is the product of the cross-sectional area of the stud times its ultimate tensile strength. Eq. 6.10.10.4.3-2 is a modified form of the formula for the resistance of channel shear connectors developed in Slutter and Driscoll (1965) that extended its use to lightweight as well as normal-weight concrete.

###### C6.10.11.1.1

When single-sided transverse stiffeners are used on horizontally curved girders, they should be attached to both flanges to help retain the cross-sectional configuration of the girder when subjected to torsion and to avoid high localized bending within the web. This is particularly important at the top flange due to the torsional restraint from the slab. The fitting of pairs of transverse stiffeners against the flanges, or attachment to both flanges, is required for the same reason.

Stiffeners used as connecting plates for diaphragms or cross-frames shall be attached to both flanges.

The distance between the end of the web-to-stiffener weld and the near edge of the adjacent web-to-flange or longitudinal stiffener-to-web weld shall not be less than  $4t_w$ , but shall not exceed the lesser of  $6t_w$  and 4.0 in.

The minimum distance between the end of the web-to-stiffener weld to the adjacent web-to-flange or longitudinal stiffener-to-web weld is specified to relieve flexing of the unsupported segment of the web to avoid fatigue-induced cracking of the stiffener-to-web welds, and to avoid inadvertent intersecting welds. The  $6t_w$ -criterion for maximum distance is specified to avoid vertical buckling of the unsupported web. The 4.0-in. criterion was arbitrarily selected to avoid a large unsupported length where the web thickness has been selected for reasons other than stability, e.g., webs of bascule girders at trunnions.

#### 6.10.11.1.2—Projecting Width

The width,  $b_t$ , of each projecting stiffener element shall satisfy:

$$b_t \geq 2.0 + \frac{D}{30} \quad (6.10.11.1.2-1)$$

and

$$16t_p \geq b_t \geq b_f / 4 \quad (6.10.11.1.2-2)$$

where:

$b_f$  = for I-sections, full width of the widest compression flange within the field section under consideration; for tub sections, full width of the widest top flange within the field section under consideration; for closed box sections, the limit of  $b_f/4$  does not apply (in.)

$t_p$  = thickness of the projecting stiffener element (in.)

#### 6.10.11.1.3—Moment of Inertia

For transverse stiffeners adjacent to web panels in which neither panel supports a shear force,  $V_u$ , larger than the factored shear buckling resistance,  $\phi_v V_{cr}$ , the moment of inertia,  $I_t$ , of the transverse stiffener shall satisfy the smaller of the following limits:

$$I_t \geq I_{t1} \quad (6.10.11.1.3-1)$$

and:

$$I_t \geq I_{t2} \quad (6.10.11.1.3-2)$$

in which:

$$I_{t1} = b t_w^3 J \quad (6.10.11.1.3-3)$$

#### C6.10.11.1.2

Eq. 6.10.11.1.2-1 is taken from Ketchum (1920). This equation tends to govern relative to Eq. 6.10.11.1.2-2 in I-girders with large  $D/b_f$ .

The full width of the widest compression flange within the field section under consideration is used for  $b_f$  in Eq. 6.10.11.1.2-2 to ensure a minimum stiffener width that will help restrain the widest compression flange. This requirement also conveniently allows for the use of the same minimum stiffener width throughout the entire field section, if desired. The widest top flange is used in Eq. 6.10.11.1.2-2 for tub sections since the bottom flange is restrained by a web along both of its edges. The limit of  $b_f/4$  does not apply for closed box sections for the same reason.

#### C6.10.11.1.3

For the web to adequately develop the shear-buckling resistance or the combined shear-buckling and postbuckling tension-field resistance, the transverse stiffener must have sufficient rigidity to maintain a vertical line of near zero lateral deflection along the line of the stiffener. For ratios of  $(d_o/D)$  less than 1.0, much larger values of  $I_t$  are required to develop the shear-buckling resistance, as discussed in Bleich (1952) and represented by Eq. 6.10.11.1.3-1. For single stiffeners, a significant portion of the web is implicitly assumed to contribute to the bending rigidity such that the neutral axis of the stiffener is located close to the edge in contact with the web. Therefore, for simplicity, the neutral axis is assumed to be located at this edge and the contribution of the web to the moment of inertia about this axis is neglected. The

$$I_{t2} = \frac{D^4 \rho_t^{1.3}}{40} \left( \frac{F_{yw}}{E} \right)^{1.5} \quad (6.10.11.1.3-4)$$

$$J = \frac{2.5}{(d_o/D)^2} - 2.0 \geq 0.5 \quad (6.10.11.1.3-5)$$

$$F_{crs} = \frac{0.31E}{\left(\frac{b_t}{t_p}\right)^2} \leq F_{ys} \quad (6.10.11.1.3-6)$$

where:

$\phi_v$  = resistance factor for shear specified in Article 6.5.4.2

$V_{cr}$  = smaller of the nominal shear-buckling resistances of the adjacent web panels, determined as specified in Article 6.10.9.2 (kip)

$V_u$  = larger of the shears in the adjacent web panels due to the factored loads (kip)

$I_t$  = moment of inertia of the transverse stiffener taken about the edge in contact with the web for single stiffeners and about the mid-thickness of the web for stiffener pairs (in.<sup>4</sup>)

$b$  = the smaller of  $d_o$  and  $D$  (in.)

$d_o$  = the smaller of the adjacent web panel widths (in.)

$J$  = stiffener bending rigidity parameter

$\rho_t$  = the larger of  $F_{yw}/F_{crs}$  and 1.0

$F_{crs}$  = local buckling stress for the stiffener (ksi)

$F_{ys}$  = specified minimum yield strength of the stiffener (ksi)

For transverse stiffeners adjacent to web panels in which the shear force,  $V_u$ , is larger than the factored shear buckling resistance,  $\phi_v V_{crs}$ , and thus the web postbuckling or tension-field resistance is required in one or both panels, the moment of inertia,  $I_t$ , of the transverse stiffeners shall satisfy:

- If  $I_{t2} > I_{t1}$ , then:

$$I_t \geq I_{t1} + (I_{t2} - I_{t1}) \left( \frac{V_u - \phi_v V_{cr}}{\phi_v V_u - \phi_v V_{cr}} \right) \quad (6.10.11.1.3-7)$$

term  $b$  in Eq. 6.10.11.1.3-1 replaces  $d_o$  in prior Specifications. This term and Eq. 6.10.11.1.3-5 give a constant value for the  $I_t$  required to develop the shear-buckling resistance for web panels with  $d_o > D$  (Kim et al., 2004).

Eq. 6.10.11.1.3-1 requires excessively large stiffener sizes as  $D/t_w$  is reduced below  $1.12\sqrt{Ek/F_{yw}}$ , the web slenderness required for  $C = 1$ , since Eq. 6.10.11.1.3-1 is based on developing the web elastic shear-buckling resistance. Inelastic buckling solutions using procedures from Bleich (1952) show that larger stiffeners are not required as  $D/t_w$  is reduced below this limit. These results are corroborated by refined FEA solutions (Kim et al., 2004).  $k$  is the shear-buckling coefficient defined in Article 6.10.9.

To develop the web shear postbuckling resistance associated with tension-field action, the transverse stiffeners generally must have a larger  $I_t$  than defined by Eq. 6.10.11.1.3-1. The  $I_t$  defined by Eq. 6.10.11.1.3-2, which for  $\rho_t = 1$  is approximately equal to the value required by Eq. 6.10.11.1.3-1 for a web with  $D/t_w = 1.12\sqrt{Ek/F_{yw}}$ , provides an accurate to slightly conservative stiffener size relative to refined FEA solutions for straight and curved I-girders at all values of  $D/t_w$  permitted by these Specifications (Kim et al., 2004). Eq. 6.10.11.1.3-2 is an approximate upper bound to the results for all values of  $d_o/D$  from an equation recommended by Kim et al. (2004), recognizing that the stiffener demands are insensitive to this parameter.

Multiple research studies have shown that transverse stiffeners in I-girders designed for tension-field action are loaded predominantly in bending due to the restraint they provide to lateral deflection of the web. Generally, there is evidence of some axial compression in the transverse stiffeners due to the tension field, but even in the most slender web plates permitted by these Specifications, the effect of the axial compression transmitted from the postbuckled web plate is typically minor compared to the lateral loading effect. Therefore, the transverse stiffener area requirement from prior Specifications is no longer specified.

- Otherwise:

$$I_t \geq I_{t2} \quad (6.10.11.1.3-8)$$

where:

$V_n$  = smaller of the nominal combined buckling and tension-field shear resistances of the adjacent web panels, determined as specified in Article 6.10.9.3.2 (kip)

Transverse stiffeners used in web panels with longitudinal stiffeners shall also satisfy:

$$I_t \geq \left( \frac{b_t}{b_\ell} \right) \left( \frac{D}{3.0d_o} \right) I_\ell \quad (6.10.11.1.3-9)$$

where:

$b_t$  = projecting width of the transverse stiffener (in.)

$b_\ell$  = projecting width of the longitudinal stiffener (in.)

$I_\ell$  = moment of inertia of the longitudinal stiffener determined as specified in Article 6.10.11.3.3 (in.<sup>4</sup>)

For girders with single-sided stiffeners, Eq. 6.10.11.1.3-9 typically requires slightly larger stiffeners than in previous Specifications for small  $D/t_w$  slightly exceeding  $1.12\sqrt{Ek/F_{yw}}$ , where the  $I_t$  requirement comparable to Eq. 6.10.11.1.3-1 governs relative to the area requirement for single-sided stiffeners given in previous Specifications. For larger  $D/t_w$  values, Eq. 6.10.11.1.3-2 typically gives comparable or smaller single-sided stiffeners compared to the area requirement in previous Specifications at  $V_u = \phi_v V_n$ . For girders with stiffener pairs, the previous Specifications substantially underestimated the required stiffener size for increasing  $D/t_w > 1.12\sqrt{Ek/F_{yw}}$ . Eq. 6.10.11.1.3-2 recognizes the fact that single- and double-sided transverse stiffeners with the same  $I_t$  exhibit essentially identical performance (Horne and Grayson, 1983; Rahal and Harding, 1990; Stanway et al., 1996; Lee et al., 2003; Kim et al., 2004).

The term  $\rho_t$  in Eq. 6.10.11.1.3-2 accounts conservatively for the effect of early yielding in transverse stiffeners with  $F_{ys} < F_{yw}$  and for the effect of potential local buckling of stiffeners having a relatively large width-to-thickness ratio  $b_t/t_p$ . The definition of the stiffener local buckling stress  $F_{crs}$  is retained from AASHTO (2004).

Eq. 6.10.11.1.3-7 accounts for the fact that the  $I_t$  necessary to develop a shear resistance greater than or equal to  $V_u$  is smaller when  $V_u$  is smaller than the full factored combined web shear buckling and post-buckling resistance,  $\phi_v V_n$  (Kim et al., 2004). For large girder depths, the philosophy of providing a stiffener flexural rigidity sufficient to develop  $V_u = \phi_v V_n$  leads to stiffener sizes that are significantly larger than typically

selected using prior AASHTO Specifications, where the former area requirement for the stiffeners was reduced when  $V_u$  was less than  $\phi_v V_n$ . Eq. 6.10.11.1.3-7 allows the calculation of a conservative but more economical stiffener size for these larger girder depths sufficient to develop a girder shear resistance greater than or equal to  $V_u$ . Eq. 6.10.11.1.3-8 addresses a small number of cases with stocky webs where  $V_n$  is approximately equal to  $V_p$ .

Lateral loads along the length of a longitudinal stiffener are transferred to the adjacent transverse stiffeners as concentrated reactions (Cooper, 1967). Eq. 6.10.11.1.3-9 gives a relationship between the moments of inertia of the longitudinal and transverse stiffeners to ensure that the latter does not fail under the concentrated reactions. This equation applies whether the stiffeners are on the same or opposite side of the web.

## 6.10.11.2—Bearing Stiffeners

### 6.10.11.2.1—General

Bearing stiffeners shall be placed on the webs of built-up sections at all bearing locations. At bearing locations on rolled shapes and at other locations on built-up sections or rolled shapes subjected to concentrated loads, where the loads are not transmitted through a deck or deck system, either bearing stiffeners shall be provided or the web shall satisfy the provisions of Article D6.5.

Bearing stiffeners shall consist of one or more plates or angles welded or bolted to both sides of the web. The connections to the web shall be designed to transmit the full bearing force due to the factored loads.

The stiffeners shall extend the full depth of the web and as closely as practical to the outer edges of the flanges.

Each stiffener shall be either milled to bear against the flange through which it receives its load or attached to that flange by a full penetration groove weld.

### 6.10.11.2.2—Projecting Width

The width,  $b_i$ , of each projecting stiffener element shall satisfy:

$$b_i \leq 0.48t_p \sqrt{\frac{E}{F_{ys}}} \quad (6.10.11.2.2-1)$$

where:

$F_{ys}$  = specified minimum yield strength of the stiffener (ksi)

$t_p$  = thickness of the projecting stiffener element (in.)

### C6.10.11.2.1

Webs of built-up sections and rolled shapes without bearing stiffeners at the indicated locations must be investigated for the limit states of web local yielding and web crippling according to the procedures specified in Article D6.5. The section should either be modified to comply with these requirements or else bearing stiffeners designed according to these Specifications should be placed on the web at the location under consideration.

In particular, inadequate provisions to resist temporary concentrated loads during construction that are not transmitted through a deck or deck system can result in failures. The Engineer should be especially cognizant of this issue when girders are incrementally launched over supports.

### C6.10.11.2.2

The provision specified in this Article is intended to prevent local buckling of the bearing stiffener plates.

### 6.10.11.2.3—Bearing Resistance

The factored bearing resistance for the fitted ends of bearing stiffeners shall be taken as:

$$(R_{sb})_r = \phi_b (R_{sb})_n \quad (6.10.11.2.3-1)$$

in which:

$(R_{sb})_n$  = nominal bearing resistance for the fitted ends of bearing stiffeners (kip)

$$= 1.4 A_{pn} F_{ys} \quad (6.10.11.2.3-2)$$

where:

$\phi_b$  = resistance factor for bearing specified in Article 6.5.4.2

$A_{pn}$  = area of the projecting elements of the stiffener outside of the web-to-flange fillet welds but not beyond the edge of the flange (in.<sup>2</sup>)

$F_{ys}$  = specified minimum yield strength of the stiffener (ksi)

### C6.10.11.2.3

To bring bearing stiffener plates tight against the flanges, part of the stiffener must be clipped to clear the web-to-flange fillet weld. Thus, the area of direct bearing is less than the gross area of the stiffener. The bearing resistance is based on this bearing area and the yield strength of the stiffener.

The specified factored bearing resistance is approximately equivalent to the bearing strength given in AISC (2005). The nominal bearing resistance given by Eq. 6.10.11.2.3-2 is reduced from the nominal bearing resistance of  $1.8A_{pn}F_{ys}$  specified in AISC (2005) to reflect the relative difference in the resistance factors for bearing given in the AISC and AASHTO LRFD Specifications.

### 6.10.11.2.4—Axial Resistance of Bearing Stiffeners

#### 6.10.11.2.4a—General

The factored axial resistance,  $P_r$ , shall be determined as specified in Article 6.9.2.1 using the specified minimum yield strength of the stiffener plates  $F_{ys}$ . The radius of gyration shall be computed about the mid-thickness of the web and the effective length shall be taken as  $0.75D$ , where  $D$  is the web depth.

#### 6.10.11.2.4b—Effective Section

For stiffeners bolted to the web, the effective column section shall consist of the stiffener elements only.

Except as noted herein, for stiffeners welded to the web, a portion of the web shall be included as part of the effective column section. For stiffeners consisting of two plates welded to the web, the effective column section shall consist of the two stiffener elements, plus a centrally located strip of web extending not more than  $9t_w$  on each side of the stiffeners. If more than one pair of stiffeners is used, the effective column section shall consist of all stiffener elements, plus a centrally located strip of web extending not more than  $9t_w$  on each side of the outer projecting elements of the group.

The strip of the web shall not be included in the effective section at interior supports of continuous-span hybrid members for which the specified minimum yield strength of the web is less than 70 percent of the specified minimum yield strength of the higher strength flange.

#### C6.10.11.2.4a

The end restraint against column buckling provided by the flanges allows for the use of a reduced effective length. The specified minimum yield strength of the stiffener plates,  $F_{ys}$ , is to be used in the calculation of the axial resistance to account for the early yielding of the lower strength stiffener plates.

#### C6.10.11.2.4b

A portion of the web is assumed to act in combination with the bearing stiffener plates. This portion of the web is not included for the stated case at interior supports of continuous-span hybrid members with  $F_{yw}$  less than the specified value because of the amount of web yielding that may be expected due to longitudinal flexural stress in this particular case. At end supports of hybrid members, the web may be included regardless of the specified minimum yield strength of the web.

For unusual cases in which  $F_{ys}$  is larger than  $F_{yw}$ , the yielding of the lower strength web is accounted for in the stiffener axial resistance by adjusting the width of the web strip included in the effective section by  $F_{yw}/F_{ys}$ .

If the specified minimum yield strength of the web is less than that of the stiffener plates, the strip of the web included in the effective section shall be reduced by the ratio  $F_{yw}/F_{ys}$ .

### 6.10.11.3—Longitudinal Stiffeners

#### 6.10.11.3.1—General

Where required, longitudinal stiffeners should consist of either a plate welded to one side of the web, or a bolted angle. Longitudinal stiffeners shall be located at a vertical position on the web such that Eq. 6.10.3.2.1-3 is satisfied when checking constructability, Eq. 6.10.4.2.2-4 is satisfied at the service limit state, and all the appropriate design requirements are satisfied at the strength limit state.

Wherever practical, longitudinal stiffeners shall extend uninterrupted over their specified length, unless otherwise permitted in the contract documents. If transverse web elements serving as stiffeners are interrupted by a longitudinal stiffener, the transverse element shall be attached to the longitudinal stiffener to develop the flexural and axial resistance of the transverse element.

The flexural stress in the longitudinal stiffener,  $f_s$ , due to the factored loads at the strength limit state and when checking constructability shall satisfy:

$$f_s \leq \phi_f R_h F_{ys} \quad (6.10.11.3.1-1)$$

where:

$\phi_f$  = resistance factor for flexure specified in Article 6.5.4.2

$F_{ys}$  = specified minimum yield strength of the stiffener (ksi)

$R_h$  = hybrid factor determined as specified in Article 6.10.1.10.1

#### C6.10.11.3.1

For composite sections in regions of positive flexure, the depth of the web in compression  $D_c$  changes relative to the vertical position of a longitudinal web stiffener, which is usually a fixed distance from the compression flange, after the concrete deck has been placed. Thus, the computed web bend-buckling resistance is different before and after placement of the deck and is dependent on the loading. As a result, an investigation of several trial locations of the stiffener may be necessary to determine a location of the stiffener to satisfy Eq. 6.10.3.2.1-3 for constructability, Eq. 6.10.4.2.2-4 at the service limit state and the appropriate design requirements at the strength limit state along the girder. The following equation may be used to determine an initial trial stiffener location for composite sections in regions of positive flexure:

$$\frac{d_s}{D_c} = \frac{1}{1 + 1.5 \sqrt{\frac{f_{DC1} + f_{DC2} + f_{DW} + f_{LL+IM}}{f_{DC1}}}} \quad (C6.10.11.3.1-1)$$

where:

$d_s$  = distance from the centerline of a plate longitudinal stiffener, or the gage line of an angle longitudinal stiffener, to the inner surface or leg of the compression-flange element (in.)

$D_c$  = depth of the web of the noncomposite steel section in compression in the elastic range (in.)

$f_{xx}$  = compression-flange stresses at the strength limit state caused by the different factored loads at the section with the maximum compressive flexural stress; i.e.,  $DC1$ , the permanent load acting on the noncomposite section;  $DC2$ , the permanent load acting on the long-term composite section;  $DW$ , the wearing surface load; and  $LL+IM$ ; acting on their respective sections (ksi). Flange lateral bending is to be disregarded in this calculation.

The stiffener may need to be moved vertically up or down from this initial trial location in order to satisfy all the specified limit-state criteria.

For composite sections in regions of negative flexure and for noncomposite sections, it is suggested than an initial trial stiffener location of  $2D_c/5$  from the inner surface of the compression flange be examined at the section with the maximum flexural compressive stress due to the factored loads at the strength limit state. Furthermore, for composite sections,  $D_c$  should be computed for the section consisting of the steel girder plus the longitudinal deck reinforcement. The stiffener may need to be moved vertically up or down from the initial trial location in order to satisfy all the specified limit-state criteria, in particular for cases where the concrete deck is assumed effective in tension in regions of negative flexure at the service limit state, as permitted for composite sections satisfying the requirements specified in Article 6.10.4.2.1.

Theoretical and experimental studies on noncomposite girders have indicated that the optimum location of one longitudinal stiffener is  $2D_c/5$  for bending and  $D/2$  for shear. Tests have also shown that longitudinal stiffeners located at  $2D_c/5$  on these sections can effectively control lateral web deflections under flexure (Cooper, 1967). The distance  $2D_c/5$  is recommended because shear is always accompanied by moment and because a properly proportioned longitudinal stiffener also reduces the web lateral deflections caused by shear. Also, because  $D_c$  may vary along the length of the span, it is recommended that the stiffener be located based on  $D_c$  computed at the section with the largest compressive flexural stress. Thus, the stiffener may not be located at its optimum location at other sections with a lower stress and a different  $D_c$ . These sections should also be examined to ensure that they satisfy the specified limit states.

In regions where the web undergoes stress reversal, it may be necessary, or desirable, to use two longitudinal stiffeners on the web.

It is preferred that longitudinal stiffeners be placed on the opposite side of the web from transverse intermediate stiffeners. Otherwise, at bearing stiffeners and connection plates where the longitudinal stiffener and the transverse web element must intersect, the longitudinal stiffener must be made continuous wherever practical, unless permitted otherwise in the contract documents, since longitudinal stiffeners are designed as continuous members. Discontinuous transverse web elements must be fitted and attached to both sides of the longitudinal stiffener with connections sufficient to develop the flexural and axial resistance of the transverse element. Should the longitudinal stiffener be interrupted, it should be similarly attached to all transverse web elements. All interruptions must be carefully designed with respect to fatigue, particularly if the longitudinal stiffener is not attached to the transverse web elements. Where the longitudinal stiffener is attached to the transverse web elements, Eq. 6.6.1.2.5-3 may apply.

For various stiffener end details and their associated fatigue details, refer to Schilling (1986). Copes should always be provided to avoid intersecting welds. Where longitudinal stiffeners are discontinued at bolted field splices, consideration should be given to taking the stiffener to the free edge of the web where the normal stress is zero.

Longitudinal stiffeners are subject to the same flexural strain as the web at their vertical position on the web. Therefore, they must have sufficient rigidity and strength to resist bend-buckling of the web, where required to do so, and to transmit the stresses in the stiffener and a portion of the web as an equivalent column (Cooper, 1967). Thus, full nominal yielding of the stiffeners is not permitted at the strength limit state and when checking constructibility as an upper bound. Eq. 6.10.11.3.1-1 serves as a limit on the validity of Eq. 6.10.11.3.3-2, which is in turn based on the axial resistance of an equivalent column section composed of the stiffener and a portion of the web plate. To account for the influence of web yielding on the longitudinal stiffener stress in hybrid members, the elastically computed stress in the stiffener is limited to  $\phi_f R_h F_{ys}$  in Eq. 6.10.11.3.1-1. For the strength limit state and constructibility checks, the corresponding value of  $R_h$  at the section under consideration should be applied in Eq. 6.10.11.3.1-1.

#### 6.10.11.3.2—Projecting Width

The projecting width,  $b_\ell$ , of the stiffener shall satisfy:

$$b_\ell \leq 0.48t_s \sqrt{\frac{E}{F_{ys}}} \quad (6.10.11.3.2-1)$$

where:

$t_s$  = thickness of the stiffener (in.)

#### 6.10.11.3.3—Moment of Inertia and Radius of Gyration

Longitudinal stiffeners shall satisfy:

$$I_\ell \geq D t_w^3 \left[ 2.4 \left( \frac{d_o}{D} \right)^2 - 0.13 \right] \beta \quad (6.10.11.3.3-1)$$

and:

$$r \geq \frac{0.16d_o \sqrt{\frac{F_{ys}}{E}}}{\sqrt{1 - 0.6 \frac{F_{yc}}{R_h F_{ys}}}} \quad (6.10.11.3.3-2)$$

#### C6.10.11.3.2

This requirement is intended to prevent local buckling of the longitudinal stiffener.

#### C6.10.11.3.3

Eq. 6.10.11.3.3-1 ensures that the stiffener will have adequate rigidity to maintain a horizontal line of near zero lateral deflection in the web panel when necessary to resist bend-buckling of the web (Galambos, 1998). Eq. 6.10.11.3.3-2 ensures that the longitudinal stiffener acting in combination with an adjacent strip of the web will withstand the axial compressive stress without lateral buckling. The moment of inertia,  $I_\ell$ , and radius of gyration,  $r$ , are taken about the neutral axis of an equivalent column cross-section composed of the stiffener and an adjacent strip of the web, as suggested by Cooper (1967). Previous Specifications required that these quantities be calculated about the edge of the stiffener in contact with the web plate. The values for  $I_\ell$  and for  $r$  calculated as suggested

in which:

$\beta$  = curvature correction factor for longitudinal stiffener rigidity calculated as follows:

- For cases where the longitudinal stiffener is on the side of the web away from the center of curvature:

$$\beta = \frac{Z}{6} + 1 \quad (6.10.11.3.3-3)$$

- For cases where the longitudinal stiffener is on the side of the web toward the center of curvature:

$$\beta = \frac{Z}{12} + 1 \quad (6.10.11.3.3-4)$$

$Z$  = curvature parameter:

$$= \frac{0.95d_o^2}{Rt_w} \leq 10 \quad (6.10.11.3.3-5)$$

where:

$d_o$  = transverse stiffener spacing (in.)

$I_\ell$  = moment of inertia of the longitudinal stiffener including an effective width of the web equal to  $18t_w$  taken about the neutral axis of the combined section (in.<sup>4</sup>). If  $F_{yw}$  is smaller than  $F_{ys}$ , the strip of the web included in the effective section shall be reduced by the ratio  $F_{yw}/F_{ys}$ .

$R$  = minimum girder radius in the panel (in.)

$r$  = radius of gyration of the longitudinal stiffener including an effective width of the web equal to  $18t_w$  taken about the neutral axis of the combined section (in.).

## 6.10.12—Cover Plates

### 6.10.12.1—General

The length of any cover plate,  $L_{cp}$ , in ft, added to a member shall satisfy:

$$L_{cp} \geq \frac{d}{6.0} + 3.0 \quad (6.10.12.1-1)$$

where:

$d$  = total depth of the steel section (in.)

by Cooper (1967) are generally smaller than the corresponding values determined as suggested in the previous Specifications. The specified procedure for calculation of  $I_\ell$  and  $r$  is consistent with the horizontally-curved I-girder provisions of AASHTO (2003) in the limit that the girder is straight. The effect of the web plate having a lower yield strength than that of the longitudinal stiffener is accommodated by adjusting the web strip that contributes to the effective column section by  $F_{yw}/F_{ys}$  in the calculation of the moment of inertia of the longitudinal stiffener.

The rigidity required of longitudinal stiffeners on curved webs is greater than the rigidity required on straight webs because of the tendency of curved webs to bow. The factor  $\beta$  in Eq. 6.10.11.3.3-1 is a simplification of the requirement in the Hanshin (1988) provisions for longitudinal stiffeners used on curved girders. For longitudinal stiffeners on straight webs, Eq. 6.10.11.3.3-5 leads to  $\beta = 1.0$ .

Eq. 6.10.11.3.3-2 is based on the model described by Cooper (1967), except that the possibility of different specified minimum yield strengths for the stiffener and compression flange is accommodated. Also, the influence of a hybrid web is approximated by including the hybrid factor,  $R_h$ , within this equation. For a nonhybrid I-section, the required radius of gyration from Eq. 6.10.11.3.3-2 is slightly larger than that required in previous Specifications. For an I-section in which  $F_{yc}/F_{ys}$  is greater than one, the required radius of gyration from Eq. 6.10.11.3.3-2 is significantly larger than required in previous Specifications. This is necessary because in these cases, the longitudinal stiffener is subjected to larger stresses compared to its resistance as an equivalent column than in an equivalent homogeneous section.

Article 6.10.9.3.1 requires that the shear resistance of the web panel be determined based on the total web depth  $D$ . Therefore, no area requirement is given for the longitudinal stiffeners to anchor the tension field.

Partial length welded cover plates shall not be used on flanges more than 0.8 in. thick for nonredundant load path structures subjected to repetitive loadings that produce tension or reversal of stress in the flange.

The maximum thickness of a single cover plate on a flange shall not be greater than two times the thickness of the flange to which the cover plate is attached. Multiple welded cover plates shall not be permitted.

Cover plates may either be wider or narrower than the flange to which they are attached.

### **6.10.12.2—End Requirements**

#### *6.10.12.2.1—General*

The theoretical end of the cover plate shall be taken as the section where the moment,  $M_u$ , or flexural stress,  $f_{bu}$ , due to the factored loads equals the factored flexural resistance of the flange. The cover plate shall be extended beyond the theoretical end far enough so that:

- The stress range at the actual end satisfies the appropriate fatigue requirements specified in Article 6.6.1.2, and
- The longitudinal force in the cover plate due to the factored loads at the theoretical end can be developed by welds and/or bolts placed between the theoretical and actual ends.

The width at ends of tapered cover plates shall not be less than 3.0 in.

#### *6.10.12.2.2—Welded Ends*

The welds connecting the cover plate to the flange between the theoretical and actual ends shall be adequate to develop the computed force in the cover plate at the theoretical end.

Where cover plates are wider than the flange, welds shall not be wrapped around the ends of the cover plate.

#### *6.10.12.2.3—Bolted Ends*

The bolts in the slip-critical connections of the cover plate to the flange between the theoretical and actual ends shall be adequate to develop the force due to the factored loads in the cover plate at the theoretical end.

The slip resistance of the end-bolted connection shall be determined in accordance with Article 6.13.2.8. The longitudinal welds connecting the cover plate to the flange shall be continuous and shall stop a distance equal to one bolt spacing before the first row of bolts in the end-bolted portion. Where end-bolted cover plates are used, the contract documents shall specify that they be installed in the following sequence:

- Drill holes,

#### *C6.10.12.2.3*

Research on end-bolted cover plates is discussed in Wattar et al. (1985).

- Clean faying surfaces,
- Install bolts, and
- Weld plates.

## 6.11—BOX-SECTION FLEXURAL MEMBERS

### 6.11.1—General

The provisions of this Article apply to flexure of straight or horizontally curved steel single or multiple closed-box or tub sections in simple or continuous bridges of moderate length. The provisions cover the design of composite, hybrid and nonhybrid, and constant and variable web depth members as defined by and subject to the requirements of Article 6.10.1.1, Articles 6.10.1.3 through 6.10.1.8, and Articles 6.11.1.1 through 6.11.1.4. The provisions of Article 6.10.1.6 shall apply only to the top flanges of tub sections.

Single box sections shall be positioned in a central position with respect to the cross-section, and the center of gravity of the dead load shall be as close to the shear center of the box as is practical. These provisions shall not be applied to multiple cell single box sections, or to composite box flanges used as bottom flanges.

All types of box-section flexural members shall be designed as a minimum to satisfy:

- The cross-section proportion limits specified in Article 6.11.2;
- The constructibility requirements specified in Article 6.11.3;
- The service limit state requirements specified in Article 6.11.4;
- The fatigue and fracture limit state requirements specified in Article 6.11.5;
- The strength limit state requirements specified in Article 6.11.6.

The web bend-buckling resistance in slender web members shall be determined as specified in Article 6.10.1.9. Flange-strength reduction factors in hybrid and/or slender web members shall be determined as specified in Article 6.10.1.10.

Internal and external cross-frames and diaphragms for box sections shall satisfy the provisions of Article 6.7.4. Top flange bracing for tub sections shall satisfy the provisions of Article 6.7.5.

### C6.11.1

Article 6.11.1 addresses general topics that apply to closed-box and tub sections used as flexural members in either straight bridges, horizontally curved bridges, or bridges containing both straight and curved segments. For the application of the provisions of Article 6.11, bridges containing both straight and curved segments are to be treated as horizontally curved bridges since the effects of curvature on the support reactions and girder deflections, as well as the effects of flange lateral bending and torsional shear, usually extend beyond the curved segments. The term moderate length as used herein refers to bridges of spans up to approximately 350 ft. The provisions may be applied to larger spans based on a thorough evaluation of the application of the bridge under consideration consistent with basic structural fundamentals. Alternative information regarding the design of long-span steel box-girder bridges is contained in FHWA (1980). For general overview on box-girder bridges, refer to Wolchuk (1997).

The five bullet items in this Article indicate the overarching organization of the subsequent provisions for the design of box-section flexural members. To avoid repetition, some of the general topics in this Article refer back to the general provisions of Article 6.10.1 for I-sections, which apply equally well to box sections. Where necessary, other Articles in Article 6.10 are referred to at appropriate points within Article 6.11.

Within these provisions, the term box flange refers to a flange plate connected to two webs.

These provisions do not apply to the use of box sections which are noncomposite in the final condition, as defined in Article 6.10.1.2, as flexural members. The concrete deck is to be assumed effective over the entire span length in the analysis for loads applied to the composite section according to the provisions of Article 6.10.1.5. Therefore, shear connectors must be present along the entire span to resist the torsional shear that exists along the entire span in all types of composite box sections in order to avoid possible debonding of the deck. Shear connectors must also be present in regions of negative flexure in order to be consistent with the prototype and model bridges that were studied in the original development of the live-load distribution provisions for box sections (Johnston and Mattock, 1967). For considerations while a composite box section is under construction, applicable provisions of Articles 6.10 and 6.11 may be utilized depending on whether the section is thought to be effectively open or quasi-box in

behavior, respectively. The flexural resistance of noncomposite closed-box sections used as compression or tension members is specified in Article 6.12.2.2.

These provisions may be applied to the use of composite closed-box sections, or sections utilizing a steel plate for the top flange that is composite with the concrete deck, as flexural members. The use of such sections has been relatively rare in the U.S. to date due to cost considerations related to the implementation of necessary safety requirements for working inside of closed boxes. These Specifications do not apply to the use of composite concrete on bottom box flanges in order to stiffen the flanges in regions of negative flexure.

The use of single-box sections is permitted in these Specifications because torsional equilibrium can be established with two bearings at some supports. Placing the center of gravity of the dead load near the shear center of single-box sections ensures minimal torsion. Items such as sound barriers on one side of the bridge may be critical on single-box sections.

These Specifications do not apply to multiple cell single box sections because there has been little published research in the U.S. regarding these members. Analysis of this bridge type involves consideration of shear flow in each cell.

In variable web depth box members with inclined webs, the inclination of the webs should preferably remain constant in order to simplify the analysis and the fabrication. For a constant distance between the webs at the top of the box, which is also preferred, this requires that the width of the bottom flange vary along the length and that the web heights at a given cross-section be kept equal. If the bridge is to incrementally launched, a constant depth box is recommended.

The provisions of Article 6.11 provide a unified approach for consideration of combined major-axis bending and flange lateral bending from any source in the design of top flanges of tub sections during construction. These provisions also provide a unified approach for consideration of the combined effects of normal stress and St. Venant torsional shear stress in closed-box and tub sections both during construction and in the final constructed condition. General design equations are provided for determining the nominal flexural resistance of box flanges under the combined effects of normal stress and torsional shear stress. The provisions also allow for the consideration of torsional shear in the design of the box-section webs and shear connectors. For straight boxes, the effects of torsional shear are typically relatively small unless the bridge is subjected to large torques. For example, boxes resting on skewed supports are usually subjected to large torques. For horizontally curved boxes, flange lateral bending effects due to curvature and the effects of torsional shear must always be considered at all limit states and also during construction.

For cases where the effects of the flange lateral bending and/or torsional shear are judged to be insignificant or incidental, or are not to be considered, the

terms related to these effects are simply set equal to zero in the appropriate equations. The format of the equations then simply reduces to the format of the more familiar equations given in previous Specifications for checking the nominal flexural resistance of box sections in the absence of flange lateral bending and St. Venant torsion.

Fundamental calculations for flexural members previously found in Article 6.10.3 of AASHTO (2004) have been placed in Appendix D6.

### 6.11.1.1—Stress Determinations

Box flanges in multiple and single box sections shall be considered fully effective in resisting flexure if the width of the flange does not exceed one-fifth of the effective span. For simple spans, the effective span shall be taken as the span length. For continuous spans, the effective span shall be taken equal to the distance between points of permanent load contraflexure, or between a simple support and a point of permanent load contraflexure, as applicable. If the flange width exceeds one-fifth of the effective span, only a width equal to one-fifth of the effective span shall be considered effective in resisting flexure.

For multiple box sections in straight bridges satisfying the requirements of Article 6.11.2.3, the live-load flexural moment in each box may be determined in accordance with the applicable provisions of Article 4.6.2.2.2b. Shear due to St. Venant torsion and transverse bending and longitudinal warping stresses due to cross-section distortion may also be neglected for sections within these bridges that have fully effective box flanges. The section of an exterior member assumed to resist horizontal factored wind loading within these bridges may be taken as the bottom box flange acting as a web and 12 times the thickness of the web acting as flanges.

The provisions of Article 4.6.2.2.2b shall not apply to:

- Single box sections in straight or horizontally curved bridges,
- Multiple box sections in straight bridges not satisfying the requirements of Article 6.11.2.3, or
- Multiple box sections in horizontally curved bridges.

For these sections, and for sections that do not have fully effective box flanges, the effects of both flexural and St. Venant torsional shear shall be considered. The St. Venant torsional shear stress in box flanges due to the factored loads at the strength limit state shall not exceed the factored torsional shear resistance of the flange,  $F_{vr}$ , taken as:

$$F_{vr} = 0.75\phi_v \frac{F_y}{\sqrt{3}} \quad (6.11.1.1-1)$$

### C6.11.1.1

Stress analyses of actual box girder bridge designs were carried out to evaluate the effective width of a box flange using a series of folded plate equations (Goldberg and Leve, 1957). Bridges for which the span-to-flange width ratio varied from 5.65 to 35.3 were included in the study. The effective flange width as a ratio of the total flange width covered a range from 0.89 for the bridge with the smallest span-to-width ratio to 0.99 for the bridge with the largest span-to-width ratio. On this basis, it is reasonable to permit a box flange to be considered fully effective and subject to a uniform longitudinal stress, provided that its width does not exceed one-fifth of the span of the bridge. For extremely wide box flanges, a special investigation for shear lag effects may be required.

Although the results quoted above were obtained for simply-supported bridges, this criterion would apply equally to continuous bridges using the appropriate effective span defined in this Article for the section under consideration.

The effective box-flange width should be used when calculating the flexural stresses in the section due to the factored loads. The full flange width should be used to calculate the nominal flexural resistance of the box flange.

Closed-box sections are capable of resisting torsion with limited distortion of the cross-section. Since distortion is generally limited by providing sufficient internal bracing in accordance with Article 6.7.4.3, torsion is resisted mainly by St. Venant torsional shear flow. The warping constant for closed-box sections is approximately equal to zero. Thus, warping shear and normal stresses due to warping torsion are typically quite small and are usually neglected.

Transverse bending stresses in box flanges and webs due to distortion of the box cross-section occur due to changes in direction of the shear flow vector. The transverse bending stiffness of the webs and flanges alone is not sufficient to retain the box shape so internal cross bracing is required. Longitudinal warping stresses due to cross-section distortion are also best controlled by internal cross bracing, as discussed further in Article C6.7.4.3.

Top flanges of tub girders subject to torsional loads need to be braced so that the section acts as a pseudo-box for noncomposite loads applied before the concrete deck hardens or is made composite. Top-flange bracing working with internal cross bracing retains the box shape and resists lateral force induced by inclined webs and torsion.

where:

$\phi_v$  = resistance factor for shear specified in Article 6.5.4.2

In addition, transverse bending stresses due to cross-section distortion shall be considered for fatigue as specified in Article 6.11.5, and at the strength limit state. Transverse bending stresses due to the factored loads shall not exceed 20.0 ksi at the strength limit state. Longitudinal warping stresses due to cross-section distortion shall be considered for fatigue as specified in Article 6.11.5, but may be ignored at the strength limit state. Transverse bending and longitudinal warping stresses shall be determined by rational structural analysis in conjunction with the application of strength-of-materials principles. Transverse stiffeners attached to the webs or box flanges should be considered effective in resisting transverse bending.

As discussed further in Article C6.11.2.3, for multiple box sections in straight bridges that conform to the restrictions specified in Article 6.11.2.3, the effects of St. Venant torsional shear and secondary distortional stresses may be neglected unless the box flange is very wide. The live-load distribution factor specified in Article 4.6.2.2.2b for straight multiple steel box sections may also be applied in the analysis of these bridges. Bridges not satisfying one or more of these restrictions must be investigated using one of the available methods of refined structural analysis, or other acceptable methods of approximate structural analysis as specified in Articles 4.4 or 4.6.2.2.4, since the specified live-load distribution factor does not apply to such bridges. The effects of St. Venant torsional shear and secondary distortional stresses are also more significant and must therefore be considered for sections in these bridges. Included in this category are all types of bridges containing single-box sections, and horizontally curved bridges containing multiple-box sections. Transverse bending stresses are of particular concern in boxes that may be subjected to large torques; e.g. single box sections, sharply curved boxes, and boxes resting on skewed supports. For other cases, the distortional stresses may be ignored if it can be demonstrated that the torques are of comparable magnitude to the torques for cases in which research has shown that these stresses are small enough to be neglected (Johnston and Mattcock, 1967), e.g., a straight bridge of similar proportion satisfying the requirements of Article 6.11.2.3 or if the torques are deemed small enough in the judgment of the Owner and the Engineer. In such cases, it is recommended that all web stiffeners be attached to both flanges to enhance fatigue performance.

In single-box sections in particular, significant torsional loads may occur during construction and under live loads. Live loads at the extreme of the deck can cause critical torsional loads without causing critical flexural moments. In the analysis, live load positioning should be done for flexure and torsion. The position of the bearings should be recognized in the analysis in sufficient completeness to permit direct computation of the reactions.

Where required, the St. Venant torsional shear and shear stress in web and flange elements can be calculated from the shear flow, which is determined as follows:

$$f = \frac{T}{2A_o} \quad (\text{C6.11.1-1})$$

where:

$A_o$  = enclosed area within the box section ( $\text{in.}^2$ )

$f$  = shear flow (kip/in.)

$T$  = internal torque due to the factored loads (kip-in.)

For torques applied to the noncomposite section,  $A_o$  is to be computed for the noncomposite box section. As specified in Article 6.7.5.3, if top lateral bracing in a tub section is attached to the webs,  $A_o$  is to be reduced to reflect the actual location of the bracing. Because shear connectors are required along the entire length of box sections according to these provisions, the concrete deck can be considered effective in resisting torsion at any point along the span. Therefore, for torques applied to the composite section in regions of positive or negative flexure,  $A_o$  is to be computed for the composite section using the depth from the bottom flange to the mid-thickness of the concrete deck. The depth may be computed using a lower bound estimate of the actual thickness of the concrete haunch, or may be determined conservatively by neglecting the thickness of the haunch.

The torsion acting on the composite section also introduces horizontal shear in the concrete deck that should be considered when designing the reinforcing steel. Article C6.11.10 suggests a procedure for determining the torsional shear in the concrete deck for closed-box sections. For tub sections, the deck should be assumed to resist all the torsional shear acting on top of the composite box section.

Previous Specifications (AASHTO, 1993) limited the nominal St. Venant torsional shear resistance of box flanges to the shear yield stress,  $F_{yf}/\sqrt{3}$ . However, at this level of shear stress, there is a significant reduction in the nominal flexural resistance of the flange. Therefore, the nominal shear resistance is limited to  $0.75 F_{yf}/\sqrt{3}$  in these provisions. Such a level of torsional shear stress is rarely, if ever, encountered in practical box-girder designs.

Where required, transverse or through-thickness bending stresses and stress ranges in the webs and flanges due to cross-section distortion can be determined using the beam-on-elastic-foundation or BEF analogy presented by Wright and Abdel-Samad (1968). In this method, the internal diaphragms or cross-frames are analogous to intermediate supports in the BEF, and the resistance to distortion provided by the box cross-section is analogous to a continuous elastic foundation. The deflection of the BEF is analogous to the transverse bending stress. Transverse stiffeners should be considered effective with the web or box flange, as applicable, in computing the flexural rigidities of these elements. Sample calculations based on the BEF analogy are presented in Heins and Hall (1981) and in AASHTO (2003). The use of finite-element analysis to determine through-thickness bending stresses as part of the overall analysis of box sections is impractical due to the mesh refinement necessary for the accurate calculation of these stresses.

Longitudinal warping stresses due to cross-section distortion can also be determined using the BEF analogy. The warping stress is analogous to the moment in the BEF. The warping stresses are largest at the corners of the box where critical welded details are often located and should be considered for fatigue (Wright and Abdel-Samad, 1968). Tests have indicated that these warping stresses do not affect the ultimate strength of box girders of typical proportions.

Since top lateral bracing contributes to the flexural stiffness of tub sections, consideration should be given to including the longitudinal component of the top-flange bracing area when computing the section properties of the tub. Where used, longitudinal flange stiffeners should also be included in the section properties of the box or tub.

#### **6.11.1.2—Bearings**

Single or double bearings may be used at supports. Double bearings may be placed either inboard or outboard of the box section webs. If single bearings narrower than the bottom flange are used, they shall be aligned with the shear center of the box, and other supports shall have adequate bearings to ensure against overturning under any load combination. If tie-down bearings are used, the resulting force effects shall be considered in the design.

#### **C6.11.1.2**

The bearing arrangement dictates how torsion is resisted at supports and is especially critical for single box sections. When a single bearing arrangement is used, torque may be removed from multiple box sections through cross-frames or diaphragms between the boxes. Two bearings under each box provide a couple to resist the torque in each box. Double bearings can be placed between the box webs or outboard of the box. Placing bearings outboard of the box reduces overturning loads on the bearings and may eliminate uplift. For the case of double bearings, uplift may be especially critical when deck overhangs are large and heavy parapets or sound barriers are placed at the edges of the overhangs. Uplift should be checked ignoring the effect of the future wearing surface.

Integral cap beams of steel or concrete are often used with box sections in lieu of bearings.

#### **6.11.1.3—Flange-to-Web Connections**

Except as specified herein, the total effective thickness of flange-to-web welds shall not be less than the smaller of the web or flange thickness.

Where two or more intermediate internal diaphragms are provided in each span, fillet welds may be used for the flange-to-web connections. The weld size shall not be less than the size consistent with the requirements of Article 6.13.3.4. If fillet welds are used, they shall be placed on both sides of the connecting flange or web plate.

#### **C6.11.1.3**

If at least two intermediate internal cross-frames or diaphragms are not provided in each span, it is essential that the web-to-flange welds be of sufficient size to develop the smaller of the full web or flange section. Full-thickness welds should be provided in this case because of the possibility of secondary flexural stresses developing in the box section as a result of vibrations and/or distortions of the cross-section. Haaijer (1981) demonstrated that the transverse secondary distortion stress range at the web-to-flange welded joint is reduced more than 50 percent in such sections when one intermediate internal cross-frame per span is introduced and more than 80 percent when two intermediate internal cross-frames per span are introduced. Thus, when two or more intermediate internal cross-frames or diaphragms are provided in each span, fillet welds on both sides of the web designed according to the requirements of Article 6.13.3.4 may be assumed to be adequate.

It is essential that the welds be placed on both sides of the connecting flange or web plate whether full penetration or fillet welds are used. This will help minimize the possibility of a fatigue failure resulting from the transverse bending stresses.

### 6.11.1.4—Access and Drainage

Access holes in box sections should be located in the bottom flange in areas of low stress. The effect of access holes on the stresses in the flange should be investigated at all limit states to determine if reinforcement of the holes is required. At access holes in box flanges subject to compression, the nominal flexural resistance of the remaining flange on each side of the hole at the strength limit state shall be determined according to the provisions of Article 6.10.8.2.2, with  $\lambda_f$  taken as the projecting width of the flange on that side of the hole divided by the flange thickness, including any reinforcement. Provisions should be made for ventilation and drainage of the interior of box sections.

### C6.11.1.4

At access holes in box flanges subject to compression, the nominal flexural resistance of the remaining flange on each side of the hole is determined using the local buckling resistance equations for I-girder compression flanges, with the flange slenderness based on the projecting width of the flange on that side of the hole.

Outside access holes should be large enough to provide easy access for inspection. Doors for exterior access holes should be hinged and provided with locks. All outside openings in box sections should be screened to exclude unauthorized persons, birds and vermin.

Consideration should be given to painting the interior of box sections a light color. Painting the interior of these sections is primarily done to facilitate inspections, and for tub sections, to prevent solar gain and to offer a minimum level of protection to the steel from the elements while the tub is temporarily open during construction. The paint quality need not match that normally used for exterior surfaces. A single-coat system should be sufficient in most cases, particularly when provisions are made for ventilation and drainage of the interior of the box.

### 6.11.2—Cross-Section Proportion Limits

#### 6.11.2.1—Web Proportions

##### 6.11.2.1.1—General

Webs may be inclined or vertical. The inclination of the web plates to a plane normal to the bottom flange should not exceed 1 to 4. For the case of inclined webs, the distance along the web shall be used for checking all design requirements. Webs attached to top flanges of tub sections shall be attached at mid-width of the flanges.

##### C6.11.2.1.1

Inclined webs are advantageous in reducing the width of the bottom flange.

Top flanges of tub sections with webs located at other than mid-width of the flange are not to be used because additional lateral flange bending effects are introduced that would require special investigation.

##### 6.11.2.1.2—Webs without Longitudinal Stiffeners

Webs shall be proportioned such that:

$$\frac{D}{t_w} \leq 150 \quad (6.11.2.1.2-1)$$

##### C6.11.2.1.2

Eq. 6.11.2.1.2-1 is discussed in Article C6.10.2.1.1.

##### 6.11.2.1.3—Webs with Longitudinal Stiffeners

Webs shall be proportioned such that:

$$\frac{D}{t_w} \leq 300 \quad (6.11.2.1.3-1)$$

##### C6.11.2.1.3

Eq. 6.11.2.1.3-1 is discussed in Article C6.10.2.1.2.

### 6.11.2.2—Flange Proportions

Top flanges of tub sections subject to compression or tension shall be proportioned such that:

$$\frac{b_f}{2t_f} \leq 12.0, \quad (6.11.2.2-1)$$

$$b_f \geq D/6, \quad (6.11.2.2-2)$$

and:

$$t_f \geq 1.1t_w \quad (6.11.2.2-3)$$

### 6.11.2.3—Special Restrictions on Use of Live Load Distribution Factor for Multiple Box Sections

Cross-sections of straight bridges consisting of two or more single-cell box sections, for which the live load flexural moment in each box is determined in accordance with the applicable provisions of Article 4.6.2.2.2b, shall satisfy the geometric restrictions specified herein. In addition, the bearing lines shall not be skewed.

The distance center-to-center of flanges of adjacent boxes,  $a$ , taken at the midspan, shall neither be greater than 120 percent nor less than 80 percent of the distance center-to-center of the flanges of each adjacent box,  $w$ , as illustrated in Figure 6.11.2.3-1. In addition to the midspan requirement, where nonparallel box sections are used, the distance center-to-center of adjacent flanges at supports shall neither be greater than 135 percent nor less than 65 percent of the distance center-to-center of the flanges of each adjacent box. The distance center-to-center of flanges of each individual box shall be the same.

The inclination of the web plates to a plane normal to the bottom flange shall not exceed 1 to 4.

The cantilever overhang of the concrete deck, including curb and parapet, shall not be greater than either 60 percent of the average distance between the centers of the top steel flanges of adjacent box sections,  $a$ , or 6.0 ft.

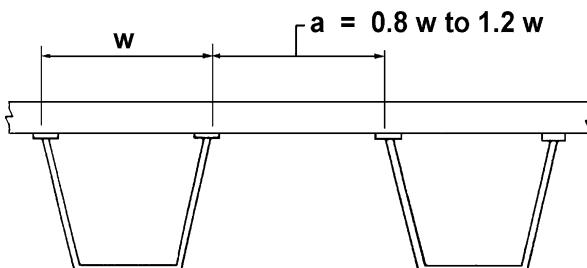

Figure 6.11.2.3-1—Center-to-Center Flange Distance

### C6.11.2.2

Eqs. 6.11.2.2-1 through 6.11.2.2-3 apply to flanges of I-sections and are also applied to a single top flange of a tub section. Eqs. 6.11.2.2-1 through 6.11.2.2-3 are discussed in Article C6.10.2.2.

Box flanges should extend at least one inch beyond the outside of each web to allow for welding of the webs to the flange. The Engineer should consider providing an option on the design plans for the fabricator to increase this distance, if necessary, to provide for greater welding access.

### C6.11.2.3

Restrictions specified in this Article for straight bridges utilizing multiple box sections are necessary in order to employ the lateral live-load distribution factor given in Article 4.6.2.2.2b for straight multiple steel box sections. The development of this distribution factor is based on an extensive study of bridges that conform to these limitations (Johnston and Mattock, 1967). The study assumed an uncracked stiffness for the composite section along the entire span.

Further, it was determined that when these restrictions are satisfied, shear due to St. Venant torsion and secondary distortional bending stress effects may be neglected if the width of the box flange does not exceed one-fifth of the effective span defined in Article 6.11.1.1. It was found from an analytical study of bridges of this type that when such bridges were loaded so as to produce maximum moment in a particular girder, and hence maximum compression in the flange plate near an intermediate support, the amount of twist in that girder was negligible. It therefore appears reasonable that, for bridges conforming to the restrictions set forth in this Article and with fully effective box flanges, shear due to torsion need not be considered in the design of box flanges for maximum compression or tension loads.

In the case of bridges with support skew, additional torsional effects occur in the box sections and the lateral distribution of loads is also affected. Although the bridge may satisfy the cross-section restrictions of this Article, these effects are not comprehended by the lateral distribution factor specified in Article 4.6.2.2.2b. Therefore, in these cases, a more rigorous analysis of stresses is necessary using one of the available methods of refined structural analysis. For straight portions of bridges that satisfy these restrictions, but that also contain horizontally curved segments, a refined analysis is also recommended. Although not required, refined structural analysis methods may also be used for bridges satisfying the restrictions of this Article, if desired.

Some limitations are placed on the variation of the distance  $a$  with respect to the distance  $w$  shown in Figure 6.11.2.3-1 when the distribution factor is used because the studies on which the live load distribution provisions are based were made on bridges in which  $a$  and  $w$  were equal. The limitations given for nonparallel box sections will allow some flexibility of layout in design while generally maintaining the validity of the provisions. For cases with nonparallel box sections where the live load distribution factor is employed, refer to the provisions of Article 4.6.2.2b.

### 6.11.3—Constructability

#### 6.11.3.1—General

Except as specified herein, the provisions of Article 6.10.3 shall apply.

The individual box section geometry shall be maintained throughout all stages of construction. The need for temporary or permanent intermediate internal diaphragms or cross-frames, external diaphragms or cross-frames, top lateral bracing, or other means shall be investigated to ensure that deformations of the box section are controlled.

#### 6.11.3.2—Flexure

For critical stages of construction, the provisions of Articles 6.10.3.2.1 through 6.10.3.2.3 shall be applied only to the top flanges of tub sections. The unbraced length should be taken as the distance between interior cross-frames or diaphragms. The provisions of Article A6.3.3 shall not be applied in determining the lateral torsional buckling resistance of top flanges of tub sections with compact or noncompact webs.

For critical stages of construction, noncomposite box flanges in compression shall satisfy the following requirements:

$$f_{bu} \leq \phi_f F_{nc} \quad (6.11.3.2-1)$$

and:

$$f_{bu} \leq \phi_f F_{crw} \quad (6.11.3.2-2)$$

where:

$\phi_f$  = resistance factor for flexure specified in Article 6.5.4.2

#### C6.11.3.1

The Engineer should consider possible eccentric loads that may occur during construction. These may include uneven placement of concrete and equipment. Temporary cross-frames or diaphragms that are not part of the original design should be removed because the structural behavior of the box section, including load distribution, may be significantly affected if these members are left in place.

Additional information on construction of composite box sections may be found in NSBA (1996) and United States Steel (1978).

For painted box sections, the Engineer should consider making an allowance for the weight of the paint. For typical structures, three percent of the steel weight is a reasonable allowance.

#### C6.11.3.2

Although the equations of Articles 6.10.3.2.1 through 6.10.3.2.3 apply to flanges of I-sections, they may also safely be applied to a single top flange of a tub section. The provisions of Article 6.10.1.6 also apply when these equations are used.

Top lateral bracing attached to the flanges at points where only struts exist between the flanges may be considered as brace points at the discretion of the Engineer.

For straight girders, lateral bending in discretely braced top flanges of tub sections, before the concrete deck has hardened or is made composite, is caused by wind and by torsion from various origins. The equations of Articles 6.10.3.2.1 and 6.10.3.2.2 allow the Engineer to directly consider the effects of the flange lateral bending, if deemed significant. When the flange lateral bending effects are judged to be insignificant or incidental, the lateral bending term,  $f_t$ , is simply set equal to zero in these equations. The format of the equations then reduces simply to the more conventional format for checking the flanges for the limit states of yielding, lateral torsional buckling or local buckling, as applicable, in the absence of flange lateral bending. For horizontally curved girders, flange

$f_{bu}$  = longitudinal flange stress due to the factored loads at the section under consideration calculated without consideration of longitudinal warping (ksi)

$F_{crw}$  = nominal bend-buckling resistance for webs specified in Article 6.10.1.9 (ksi)

$F_{nc}$  = nominal flexural resistance of box flanges in compression determined as specified in Article 6.11.8.2 (ksi). In computing  $F_{nc}$  for constructability, the web load-shedding factor,  $R_b$ , shall be taken as 1.0.

For sections with compact or noncompact webs, Eq. 6.11.3.2-2 shall not be checked.

For critical stages of construction, noncomposite box flanges in tension and continuously braced box flanges in tension or compression shall satisfy the following requirement:

$$f_{bu} \leq \phi_f R_h F_{yf} \Delta \quad (6.11.3.2-3)$$

in which:

$$\Delta = \sqrt{1 - 3 \left( \frac{f_v}{F_{yf}} \right)^2} \quad (6.11.3.2-4)$$

$f_v$  = St. Venant torsional shear stress in the flange due to the factored loads at the section under consideration (ksi)

$$= \frac{T}{2A_o t_f} \quad (6.11.3.2-5)$$

where:

$A_o$  = enclosed area within the box section (in.<sup>2</sup>)

$R_h$  = hybrid factor determined as specified in Article 6.10.1.10.1

$T$  = internal torque due to the factored loads (kip-in.)

For loads applied to a composite box flange before the concrete has hardened or is made composite, the flange shall be designed as a noncomposite box flange. The maximum vertical deflection of the noncomposite box flange due to the unfactored permanent loads, including the self-weight of the flange plus the unfactored construction loads, shall not exceed 1/360 times the transverse span between webs. The through-thickness

lateral bending effects due to curvature must always be considered during construction. For loads applied during construction once the top flanges are continuously braced, the provisions of Article 6.10.3.2.3 apply. A distinction is made between discretely and continuously braced flanges in Article 6.10.3.2 because for a continuously braced flange, lateral flange bending need not be considered. Article C6.10.1.6 states the conditions for which top flanges may be considered continuously braced. St. Venant torsional shears are also typically neglected in continuously braced top flanges of tub sections. In checking the requirements of Articles 6.10.3.2.1 through 6.10.3.2.3 for a single top flange of a tub, it is recommended that the checks be made for half of the tub section.

In checking Eq. 6.10.3.2.1-2 for I-sections in straight bridges with compact or noncompact webs, Article A6.3.3 optionally permits the lateral torsional buckling resistance of the compression flange to be determined including the beneficial contribution of the St. Venant torsional constant  $J$ . The use of these provisions is conservatively prohibited in checking top flanges of tub sections with compact or noncompact webs. The compact, noncompact and slender web definitions are discussed in Article C6.10.6.2.3. For making these checks with the section in its noncomposite condition, the categorization of the web is to be based on the properties of the noncomposite section.

One potential source of flange lateral bending due to torsion is the effect of eccentric concrete deck overhang loads acting on cantilever forming brackets placed along exterior tub sections. In lieu of a more refined analysis, the maximum flange lateral bending moments in the outermost top flange of a tub due to these eccentric loadings may be estimated using either Eq. C6.10.3.4-2 or C6.10.3.4-3 depending on how the lateral load is assumed applied to the flange.

In box sections with inclined webs, the change in the horizontal component of the web dead load shear plus the change in the St. Venant torsional dead load shear per unit length along the member acts as a uniformly distributed transverse load on the girder flanges. Additional intermediate internal cross-frames, diaphragms or struts may be required to reduce the lateral bending in discretely braced top flanges of tub sections resulting from this transverse load. This may be particularly true for cases where the inclination of the web plates to a plane normal to the bottom flange is permitted to exceed 1 to 4, and/or where the unbraced length of the top flanges exceeds 30 ft. Otherwise, this transverse load can typically be ignored. The maximum lateral flange bending moments due to this transverse load can be estimated using Eq. C6.10.3.4-2 in lieu of a more refined analysis, where  $F_t$  is taken as the magnitude of the factored uniformly distributed transverse load. The entire transverse load should be assumed applied to the top flanges (Fan and Helwig, 1999). The cross-frame or strut can be assumed to carry the entire transverse load within the panel under consideration.

bending stress in the noncomposite box flange due to the factored permanent loads and factored construction loads shall not exceed 20.0 ksi. The weight of wet concrete and other temporary or permanent loads placed on a noncomposite box flange may be considered by assuming the box flange acts as a simple beam spanning between webs. Stiffening of the flange may be used where required to control flange deflection and stresses due to loads applied before the concrete deck has hardened or is made composite.

Another potential source of flange lateral bending is due to the forces that develop in Warren-type single-diagonal top lateral bracing systems due to flexure of the tub section. Refer to Article C6.7.5.3 for further discussion regarding this topic.

In cases where a full-length lateral bracing system is not employed within a tub section, as discussed further in Article C6.7.5.3, the minimum width of the top flanges within each field piece should satisfy the guideline given by Eq. C6.10.3.4-1, in conjunction with the flange proportion limits specified in Article 6.11.2.2. In this case,  $L$  in Eq. C6.10.3.4-1 is to be taken as the larger of the distances along the field piece between panels of lateral bracing or between a panel of lateral bracing and the end of the piece. For cases where a full-length lateral bracing system is employed, Eq. C6.10.3.4-1 need not be considered for top flanges of tub sections.

For noncomposite box flanges in compression, local buckling of the flange during critical stages of construction is checked according to Eq. 6.11.3.2-1. Flange lateral bending and lateral torsional buckling are not a consideration for box flanges.

Eq. 6.11.3.2-2 ensures that theoretical web bend-buckling will not occur during construction at sections where noncomposite box flanges are subject to compression. Eq. 6.10.3.2.1-3 serves a similar function at sections where top flanges of tub sections are subject to compression. For box sections with inclined webs,  $D_c$  should be taken as depth of the web in compression measured along the slope in determining the web bend-buckling resistance,  $F_{crw}$ , in either case. Because the flange stress is limited to the web bend-buckling stress, the  $R_b$  factor is always to be taken equal to 1.0 in computing the nominal flexural resistance of the compression flange for constructibility. Options to consider should the flange not satisfy Eq. 6.11.3.2-2 or Eq. 6.10.3.2.1-3, as applicable, for the construction condition are discussed in Article C6.10.3.2.1. For sections with compact or noncompact webs, web bend-buckling is not a consideration, and therefore, need not be checked for these sections.

For noncomposite box flanges in tension, or for continuously braced box flanges in tension or compression, the von Mises yield criterion (Boresi et al., 1978) is used in Eq. 6.11.3.2-3 to consider the effect of the torsional shear.

Longitudinal warping stresses due to cross-section distortion typically need not be considered in checking Eqs. 6.11.3.2-1 and 6.11.3.2-3, but are required to be considered when checking slip of the connections in bolted flange splices for the construction condition as specified in Article 6.13.6.1.4c.

In closed-box sections, noncomposite box flanges on top of the box receive the weight of wet concrete and other loads during construction before the deck hardens or is made composite. Transverse and/or longitudinal stiffening of the box flange may be required to control box-flange deflection and stresses.

### 6.11.3.3—Shear

When checking the shear requirement specified in Article 6.10.3.3, the provisions of Article 6.11.9 shall also apply, as applicable.

### 6.11.4—Service Limit State

Except as specified herein, the provisions of Article 6.10.4 shall apply.

The  $f_t$  term in Eq. 6.10.4.2.2-2 shall be taken equal to zero. Eq. 6.10.4.2.2-3 shall not apply. Except for sections in positive flexure in which the web satisfies the requirement of Article 6.11.2.1.2, all sections shall satisfy Eq. 6.10.4.2.2-4.

Redistribution of the negative moment due to the Service II loads at interior-pier sections in continuous-span flexural members using the procedures specified in Appendix B6 shall not apply.

### C6.11.4

Article 6.10.4.1 refers to the provisions of Article 2.5.2.6, which contain optional live-load deflection criteria and criteria for span-to-depth ratios. In the absence of depth restrictions, the span-to-depth ratios listed for I-sections can be used to establish a reasonable minimum web depth for the design. However, because of the inherent torsional stiffness of a box section, the optimum depth for a box section will typically be slightly less than the optimum depth for an I-section of the same span. Because the size of box flanges can typically be varied less over the bridge length, establishing a sound optimum depth for box sections is especially important. Boxes that are overly shallow may be subject to larger torsional shears.

Under the load combinations specified in Table 3.4.1-1, Eqs. 6.10.4.2.2-1 and 6.10.4.2.2-2 need only be checked for compact sections in positive flexure. For sections in negative flexure and noncompact sections in positive flexure, these equations do not control and need not be checked. However, Eq. 6.10.4.2.2-4 must still be checked for these sections where applicable.

Flange lateral bending is not a consideration for box flanges, and therefore, need not be considered when checking Eq. 6.10.4.2.2-2. Flange lateral bending is not considered in Eq. 6.10.4.2.2-1 because the top flanges are continuously braced at the service limit state. Longitudinal warping stresses due to cross-section distortion need not be considered in checking the equations of Article 6.10.4.2.2, but are required to be considered when checking slip of the connections in bolted flange splices at the service limit state as specified in Article 6.13.6.1.4c. St. Venant torsional shear stresses are also not considered in checking the equations of Article 6.10.4.2.2 for box flanges. The effects of longitudinal warping stresses and torsional shear on the overall permanent deflections at the service limit state are considered to be relatively insignificant.

For box sections with inclined webs,  $D_c$  should be taken as the depth of the web in compression measured along the slope in determining the web bend-buckling resistance,  $F_{crw}$ , for checking Eq. 6.10.4.2.2-4, where applicable.

The applicability of the optional provisions of Appendix B6 to box sections has not been demonstrated. Therefore, these provisions may not be used in the design of box sections.

### 6.11.5—Fatigue and Fracture Limit State

Except as specified herein, the provisions of Article 6.10.5 shall apply.

For fatigue in shear connectors, the provisions of Article 6.11.10 shall also apply, as applicable. The provisions for fatigue in shear connectors specified in Article 6.10.10.3 shall not apply.

When checking the shear requirement specified in Article 6.10.5.3, the provisions of Article 6.11.9 shall also apply, as applicable.

Longitudinal warping stresses and transverse bending stresses due to cross-section distortion shall be considered for:

- Single box sections in straight or horizontally curved bridges,
- Multiple box sections in straight bridges not satisfying the requirements of Article 6.11.2.3,
- Multiple box sections in horizontally curved bridges, or
- Any single or multiple box section with a box flange that is not fully effective according to the provisions of Article 6.11.1.1.

The stress range due to longitudinal warping shall be considered in checking the fatigue resistance of the base metal at all details on the box section according to the provisions specified in Article 6.6.1. The transverse bending stress range shall be considered separately in evaluating the fatigue resistance of the base metal adjacent to flange-to-web fillet welds and adjacent to the termination of fillet welds connecting transverse elements to webs and box flanges. In determining the transverse bending stress range, one cycle of stress shall be defined as 75 percent of the stress range determined by the passage of the factored fatigue load in two different critical transverse positions. In no case shall the stress range calculated in this manner be less than the calculated stress range due to the passage of the factored fatigue load in only one lane. The need for a bottom transverse member within the internal cross-frames to resist the transverse bending stress range in the bottom box flange at the termination of fillet welds connecting cross-frame connection plates to the flange shall be investigated. Transverse cross-frame members next to box flanges shall be attached to the box flange unless longitudinal flange stiffeners are used, in which case the transverse members shall be attached to the longitudinal stiffeners by bolting. The moment of inertia of these transverse cross-frame members shall not be less than the moment of inertia of the largest connection plate for the internal cross-frame under consideration taken about the edge in contact with the web.

### C6.11.5

When a box section is subjected to a torsional load, its cross-section distorts and is restored at diaphragms or cross-frames. This distortion gives rise to secondary bending stresses. A torsional loading in the opposite direction produces a reversal of these distortional secondary bending stresses. In certain cases, as defined herein, these distortional stresses are to be considered when checking fatigue. Situations for which these stresses are of particular concern and for which these stresses may potentially be ignored are discussed in Article C6.11.1.1.

Transverse bending and longitudinal warping stress ranges due to cross-section distortion can be determined using the BEF analogy, as discussed in Article C6.11.1.1. Longitudinal warping stresses are considered additive to the longitudinal major-axis bending stresses.

The largest distortional stress range is usually caused by positioning the live load on one side and then on the opposite side of a box. To cause one cycle of the stress range so computed requires two vehicles to traverse the bridge in separate transverse positions, with one vehicle leading the other. To account for the unlikely event of this occurring over millions of cycles, the provisions permit application of a factor of 0.75 to the computed range of distortional-induced stresses, except when the maximum stress range is caused by loading of only one lane. This 0.75 factor is distinct from the load factor specified for the applicable fatigue load combination in Table 3.4.1-1, i.e., when applicable, both factors may be applied simultaneously. There is no provision to account for the need for two trucks to cause a single cycle of stress in this case. For cases where the nominal fatigue resistance is calculated based on a finite life, the Engineer may wish to consider a reduction in the number of cycles since two cycles are required to cause a single cycle of stress.

The most critical case for transverse bending is likely to be the base metal at the termination of fillet welds connecting transverse elements to webs and box flanges. A stress concentration occurs at the termination of these welds as a result of the transverse bending. The fatigue resistance of this detail when subject to transverse bending is not currently quantified, but is anticipated to be perhaps as low as Category E.

Should this situation be found critical in the web at transverse web stiffeners not serving as connection plates, the transverse bending stress range may be reduced by welding the stiffeners to the flanges. Attaching transverse stiffeners to the flanges reduces the sharp through-thickness bending stresses within the unstiffened portions of the web at the termination of the stiffener-to-web welds, which is usually the most critical region for this check. Cross-frame connection plates already are required to be attached to the flanges according to the provisions of Article 6.6.1.3.1 for this reason.

For single box sections, box flanges in tension shall be considered fracture-critical, unless analysis shows that the section can support the full dead and an appropriate portion of the live load after sustaining a hypothetical complete fracture of the flange and webs at any point.

Unless adequate strength and stability of a damaged structure can be verified by refined analysis, in cross-sections comprised of two box sections, only the bottom flanges in the positive moment regions should be designated as fracture-critical. Where cross-sections contain more than two box girder sections, none of the components of the box sections should be considered fracture-critical.

Should it become necessary to reduce the transverse bending stress range in the box flange adjacent to the cross-frame connection plate welds to the flange, the provision of transverse cross-frame members across the bottom of the box or tub as part of the internal cross-bracing significantly reduces the transverse bending stress range at the welds and ensures that the cross-section shape is retained. Closer spacing of cross-frames also leads to lower transverse bending stresses. Where bottom transverse cross-frame members are provided, they are to be attached to the box flange or to the longitudinal flange stiffeners, as applicable. For closed-box sections, the top transverse cross-frame members should be similarly attached. Where transverse bracing members are welded directly to the box flange, the stress range due to transverse bending should also be considered in checking the fatigue resistance of the base metal adjacent to the termination of these welds. Where transverse bracing members are connected to longitudinal flange stiffeners, the box flange may be considered stiffened when computing the transverse bending stresses. In such cases, the transverse connection plates must still be attached to both flanges as specified in Article 6.6.1.3.1.

Load-induced fatigue is usually not critical for top lateral bracing in tub sections since the concrete deck is much stiffer and resists more of the load than does the bracing. Since the deck resists the majority of the torsional shear in these cases, it is advisable to check the reinforcement in the deck for the additional horizontal shear. Severely skewed supports may cause critical horizontal deck shear.

It is advisable to connect the lateral bracing to the top flanges to eliminate a load path through the web. Although removable deck forms are problematic in tub girders, they are sometimes required by the Owner. In such cases, it may be necessary to lower the lateral bracing by attaching it to the box webs. In these cases, connections to the webs must be made according to the requirements of Article 6.6.1.3.2 to prevent potential problems resulting from fatigue. An adequate load path, with fatigue considered, must be provided between the bracing-to-web connections and the top flanges. Connections of the lateral bracing to the web can be avoided by using metal stay-in-place deck forms.

Fatigue of the base metal at the net section of access holes should be considered. The fatigue resistance at the net section of large access holes is not currently specified; however, base metal at the net section of open bolt holes has been shown to satisfy Category D (Brown et al., 2007). This assumes a stress concentration, or ratio of the elastic tensile stress adjacent to the hole to the average stress on the net area, of 3.0. A less severe fatigue category might be considered if the proper stress concentration at the edges of the access hole is evaluated.

Refer to Article C6.6.2 for further discussion regarding the use of refined analyses to demonstrate that part of a structure is not fracture-critical.

There may be exceptions where box flanges of single-box sections subject to tension need not be considered fracture critical. For example, continuously braced top flanges in regions of negative flexure where there is adequate deck reinforcing to act as a top flange. In such cases, adequate shear connection must also be provided.

## 6.11.6—Strength Limit State

### 6.11.6.1—General

For the purposes of this Article, the applicable Strength load combinations specified in Table 3.4.1-1 shall apply.

### 6.11.6.2—Flexure

#### 6.11.6.2.1—General

If there are holes in the tension flange at the section under consideration, the tension flange shall satisfy the requirement specified in Article 6.10.1.8.

#### C6.11.6.1

At the strength limit state, Article 6.11.6 directs the Engineer to the appropriate Articles for the design of box sections in regions of positive or negative flexure.

#### C6.11.6.2.1

The requirement of Article 6.10.1.8 is intended to prevent net section fracture at a cross-section with holes in the tension flange subject to either positive or negative flexure. Where an access hole is provided in the tension flange, the hole should be deducted in determining the gross section for checking this requirement, as specified in Article 6.8.1.

A continuously braced flange in compression is assumed not to be subject to local or lateral torsional buckling, as applicable. The rationale for excluding these limit state checks is discussed in Article C6.10.3.2.3.

These provisions assume low or zero levels of axial force in the member. At sections that are also subject to a concentrically-applied axial force,  $P_u$ , due to the factored loads in excess of ten percent of the factored axial resistance of the member,  $P_r$ , at the strength limit state, the section should instead be checked according to the provisions of Article 6.8.2.3 or 6.9.2.2, as applicable. According to the equations given in these Articles, when  $P_u$  is ten percent of  $P_r$ , the flexural resistance of the member is reduced by five percent. Below this level, it is reasonable to ignore the effect of the axial force in the design of the member.

#### 6.11.6.2.2—Sections in Positive Flexure

Sections in horizontally curved steel girder bridges shall be considered as noncompact sections and shall satisfy the requirements of Article 6.11.7.2.

Sections in straight bridges that satisfy the following requirements shall qualify as compact sections:

- The specified minimum yield strengths of the flanges and web do not exceed 70.0 ksi,
- The web satisfies the requirement of Article 6.11.2.1.2,
- The section is part of a bridge that satisfies the requirements of Article 6.11.2.3,

#### C6.11.6.2.2

The nominal flexural resistance of sections in positive flexure within straight bridges satisfying the requirements of Article 6.11.2.3 and that also satisfy specific steel grade, web slenderness, effective flange width and ductility requirements is permitted to exceed the moment at first yield according to the provisions of Article 6.10.7. The nominal flexural resistance of these sections, termed compact sections, is therefore more appropriately expressed in terms of moment. For sections in positive flexure in straight bridges not satisfying one or more of these requirements, or for composite sections in positive flexure in horizontally curved bridges, termed noncompact sections, the nominal flexural resistance is not permitted to exceed the moment at

- The box flange is fully effective as specified in Article 6.11.1.1,

and:

- The section satisfies the web slenderness limit:

$$\frac{2D_{cp}}{t_w} \leq 3.76 \sqrt{\frac{E}{F_{yc}}} \quad (6.11.6.2.2-1)$$

where:

$D_{cp}$  = depth of the web in compression at the plastic moment determined as specified in Article D6.3.2 (in.)

Compact sections shall satisfy the requirements of Article 6.11.7.1. Otherwise, the section shall be considered noncompact and shall satisfy the requirements of Article 6.11.7.2.

Compact and noncompact sections shall satisfy the ductility requirement specified in Article 6.10.7.3.

first yield. The nominal flexural resistance in these cases is therefore more appropriately expressed in terms of the elastically computed flange stress.

For reasons discussed in Article C6.10.6.2.2, composite sections in positive flexure in straight bridges with flange yield strengths greater than 70.0 ksi or with webs that do not satisfy Article 6.11.2.1.2 or Eq. 6.11.6.2.2-1 are to be designed at the strength limit state as noncompact sections as specified in Article 6.11.7.2. Furthermore, if the section is not part of a straight bridge that satisfies the restrictions specified in Article 6.11.2.3, or is part of a horizontally curved bridge, or if the box flange is not fully effective as defined in Article 6.11.1.1, the section must be designed as a noncompact section. The ability of such sections to develop a nominal flexural resistance greater than the moment at first yield in the presence of potentially significant St. Venant torsional shear and cross-sectional distortion stresses has not been demonstrated.

Compact sections in positive flexure must satisfy the provisions of Article 6.10.7.3 to ensure a ductile mode of failure. Noncompact sections must also satisfy the ductility requirement specified in Article 6.10.7.3 to ensure a ductile failure. Satisfaction of this requirement ensures an adequate margin of safety against premature crushing of the concrete deck for sections utilizing up to 100-ksi steels and/or for sections utilized in shored construction. This requirement is also a key limit in allowing web buckling to be disregarded in the design of composite sections in positive flexure when the web also satisfies Article 6.11.2.1.2, as discussed in Article C6.10.1.9.1.

#### C6.11.6.2.3

For sections in negative flexure, the provisions of Article 6.11.8 limit the nominal flexural resistance to be less than or equal to the moment at first yield for all types of box girder bridges. As a result, the nominal flexural resistance for these sections is conveniently expressed in terms of the elastically computed flange stress.

The applicability of the optional provisions of Appendices A6 and B6 to box sections has not been demonstrated. Therefore, these provisions may not be used in the design of box sections.

#### 6.11.6.2.3—Sections in Negative Flexure

The provisions of Article 6.11.8 shall apply. The provisions of Appendix A6 shall not apply. Redistribution of the negative moment due to the factored loads at interior-pier sections in continuous-span flexural members using the procedures specified in Appendix B6 shall not apply.

#### 6.11.6.3—Shear

The provisions of Article 6.11.9 shall apply.

#### 6.11.6.4—Shear Connectors

The provisions of Article 6.10.10.4 shall apply. The provisions of Article 6.11.10 shall also apply, as applicable.

## 6.11.7—Flexural Resistance—Sections in Positive Flexure

### 6.11.7.1—Compact Sections

#### 6.11.7.1.1—General

At the strength limit state, the section shall satisfy:

$$M_u \leq \phi_f M_n \quad (6.11.7.1.1-1)$$

where:

$\phi_f$  = resistance factor for flexure specified in Article 6.5.4.2

$M_n$  = nominal flexural resistance of the section determined as specified in Article 6.11.7.1.2 (kip-in.)

$M_u$  = bending moment about the major-axis of the cross-section due to the factored loads at the section under consideration (kip-in.)

#### 6.11.7.1.2—Nominal Flexural Resistance

The nominal flexural resistance of the section shall be taken as specified in Article 6.10.7.1.2, except that for continuous spans, the nominal flexural resistance shall always be subject to the limitation of Eq. 6.10.7.1.2-3.

#### C6.11.7.1.1

For composite sections in positive flexure, lateral bending does not need to be considered in the compression flanges of tub sections at the strength limit state because the flanges are continuously supported by the concrete deck. Flange lateral bending is also not a consideration for box flanges.

#### C6.11.7.1.2

The equations of Article 6.10.7.1.2 are discussed in detail in Article C6.10.7.1.2.

For box sections, Eq. 6.10.7.1.2-3 is to always be used for determining the limiting nominal flexural resistance of compact sections in positive flexure in straight continuous spans. The provisions of Appendix B6, which ensure that interior-pier sections will have sufficient ductility and robustness such that the redistribution of moments caused by partial yielding within the positive flexural regions is inconsequential, are not presently applicable to box sections.

### 6.11.7.2—Noncompact Sections

#### 6.11.7.2.1—General

At the strength limit state, compression flanges shall satisfy:

$$f_{bu} \leq \phi_f F_{nc} \quad (6.11.7.2.1-1)$$

where:

$\phi_f$  = resistance factor for flexure specified in Article 6.5.4.2

$f_{bu}$  = longitudinal flange stress at the section under consideration calculated without consideration of flange lateral bending or longitudinal warping, as applicable (ksi)

#### C6.11.7.2.1

For noncompact sections, the compression flange must satisfy Eq. 6.11.7.2.1-1 and the tension flange must satisfy Eq. 6.11.7.2.1-2 at the strength limit state. For composite sections in positive flexure, lateral bending does not need to be considered in the compression flanges at the strength limit state because the flanges are continuously supported by the concrete deck. Lateral bending is also not a consideration for the tension flange, which is always a box flange in this case.

For noncompact sections, the longitudinal stress in the concrete deck is limited to  $0.6f'_c$  to ensure linear behavior of the concrete, which is assumed in the calculation of the steel flange stresses. This condition is unlikely to govern except in cases involving: (1) shored construction, or

$F_{nc}$  = nominal flexural resistance of the compression flange determined as specified in Article 6.11.7.2.2 (ksi)

The tension flange shall satisfy:

$$f_{bu} \leq \phi_f F_{nt} \quad (6.11.7.2.1-2)$$

where:

$F_{nt}$  = nominal flexural resistance of the tension flange determined as specified in Article 6.11.7.2.2 (ksi)

The maximum longitudinal compressive stress in the concrete deck at the strength limit state, determined as specified in Article 6.10.1.1.1d, shall not exceed  $0.6f'_c$ .

#### 6.11.7.2.2—Nominal Flexural Resistance

The nominal flexural resistance of the compression flanges of tub sections shall be taken as:

$$F_{nc} = R_b R_h F_{yc} \quad (6.11.7.2.2-1)$$

where:

$R_b$  = web load-shedding factor determined as specified in Article 6.10.1.10.2

$R_h$  = hybrid factor determined as specified in Article 6.10.1.10.1

The nominal flexural resistance of the compression flange of closed-box sections shall be taken as:

$$F_{nc} = R_b R_h F_{yc} \Delta \quad (6.11.7.2.2-2)$$

in which:

$$\Delta = \sqrt{1 - 3 \left( \frac{f_v}{F_{yc}} \right)^2} \quad (6.11.7.2.2-3)$$

$f_v$  = St. Venant torsional shear stress in the flange due to the factored loads at the section under consideration (ksi)

$$= \frac{T}{2A_o t_{fc}} \quad (6.11.7.2.2-4)$$

where:

$A_o$  = enclosed area within the box section (in.<sup>2</sup>)

$T$  = internal torque due to the factored loads (kip-in.)

unshored construction where the noncomposite steel dead load stresses are low, combined with (2) geometries causing the neutral axis of the short-term and long-term composite section to be significantly below the bottom of the concrete deck.

#### C6.11.7.2.2

The nominal flexural resistance of noncompact sections in positive flexure is limited to the moment at first yield. Thus, the nominal flexural resistance is expressed simply in terms of the flange stress. For noncompact sections, the elastically computed stress in each flange due to the factored loads, determined in accordance with Article 6.10.1.1.1a, is compared with the yield stress of the flange times the appropriate flange-stress reduction factors.

For box flanges, the effect of the St. Venant torsional shear stress in the flange must also be considered where necessary. The computation of the flange torsional shear stress from Eq. 6.11.7.2.2-4 or 6.11.7.2.2-7, as applicable, due to torques applied separately to the noncomposite and composite sections is discussed in Article C6.11.1.1.

The nominal flexural resistance of the tension flange of closed-box and tub sections shall be taken as:

$$F_{nt} = R_h F_{yt} \Delta \quad (6.11.7.2.2-5)$$

in which:

$$\Delta = \sqrt{1 - 3 \left( \frac{f_v}{F_{yt}} \right)^2} \quad (6.11.7.2.2-6)$$

$f_v$  = St. Venant torsional shear stress in the flange due to the factored loads at the section under consideration (ksi)

$$= \frac{T}{2A_o t_{ft}} \quad (6.11.7.2.2-7)$$

## 6.11.8—Flexural Resistance—Sections in Negative Flexure

### 6.11.8.1—General

#### 6.11.8.1.1—Box Flanges in Compression

At the strength limit state, the following requirement shall be satisfied:

$$f_{bu} \leq \phi_f F_{nc} \quad (6.11.8.1.1-1)$$

where:

$\phi_f$  = resistance factor for flexure specified in Article 6.5.4.2

$f_{bu}$  = longitudinal flange stress due to the factored loads at the section under consideration calculated without consideration of longitudinal warping (ksi)

$F_{nc}$  = nominal flexural resistance of the flange determined as specified in Article 6.11.8.2 (ksi)

#### C6.11.8.1.1

Eq. 6.11.8.1.1-1 ensures that box flanges in compression have sufficient strength with respect to flange local buckling. Flange lateral bending and lateral torsional buckling are not a consideration for box flanges.

In general, bottom box flanges at interior-pier sections are subjected to biaxial stresses due to major-axis bending of the box section and major-axis bending of the internal diaphragm over the bearing sole plate. The flange is also subject to shear stresses due to the internal diaphragm vertical shear, and in cases where it must be considered, the St. Venant torsional shear. Bending of the internal diaphragm over the bearing sole plate can be particularly significant for boxes supported on single bearings. For cases where the shear stresses and/or bending of the internal diaphragm are deemed significant, the following equation may be used to check this combined stress state in the box flange at the strength limit state:

$$\sqrt{f_{bu}^2 - f_{bu} f_{by} + f_{by}^2 + 3(f_d + f_v)^2} \leq \phi_f R_b R_h F_{yc} \quad (C6.11.8.1.1-1)$$

where:

$f_{by}$  = stress in the flange due to the factored loads caused by major-axis bending of the internal diaphragm over the bearing sole plate (ksi)

$f_d$  = shear stress in the flange caused by the internal diaphragm vertical shear due to the factored loads (ksi)

$f_v$  = St. Venant torsional shear stress in the flange due to the factored loads (ksi)

$R_b$  = web load-shedding factor determined as specified in Article 6.10.1.10.2

$R_h$  = hybrid factor determined as specified in Article 6.10.1.10.1

Eq. C6.11.8.1.1-1 represents the general form of the Huber-von Mises-Hencky yield criterion (Ugural and Fenster, 1975).

For a box supported on two bearings,  $f_{by}$  in Eq. C6.11.8.1.1-1 is typically relatively small and can often be neglected.

The box flange may be considered effective with the internal diaphragm at interior-pier sections in making this check. A flange width equal to six times its thickness may be considered effective with the internal diaphragm. The shear stress in the flange,  $f_d$ , caused by the internal diaphragm vertical shear due to the factored loads can then be estimated as:

$$f_d = \frac{VQ}{It_{fc}} \quad (\text{C6.11.8.1.1-2})$$

where:

$V$  = vertical shear in the internal diaphragm due to flexure plus St. Venant torsion (kip)

$Q$  = first moment of one-half the effective box-flange area about the neutral axis of the effective internal diaphragm section (in.<sup>3</sup>)

$I$  = moment of inertia of the effective internal diaphragm section (in.<sup>4</sup>)

Wherever an access hole is provided within the internal diaphragm, the effect of the hole should be considered in computing the section properties of the effective diaphragm section.

#### 6.11.8.1.2—Continuously Braced Flanges in Tension

At the strength limit state, the following requirement shall be satisfied:

$$f_{bu} \leq \phi_f F_{nt} \quad (6.11.8.1.2-1)$$

where:

$F_{nt}$  = nominal flexural resistance of the flange determined as specified in Article 6.11.8.3 (ksi)

#### C6.11.8.1.2

For continuously braced top flanges of tub sections, lateral flange bending need not be considered. St. Venant torsional shears are also typically neglected. The torsional shears may not be neglected, however, in a continuously braced box flange.

### 6.11.8.2—Flexural Resistance of Box Flanges in Compression

#### 6.11.8.2.1—General

The nominal flexural resistance of box flanges in compression without flange longitudinal stiffeners shall be determined as specified in Article 6.11.8.2.2. The nominal flexural resistance of box flanges in compression with flange longitudinal stiffeners shall be determined as specified in Article 6.11.8.2.3.

#### 6.11.8.2.2 Unstiffened Flanges

The nominal flexural resistance of the compression flange shall be taken as:

- If  $\lambda_f \leq R_1 \sqrt{\frac{kE}{F_{yc}}}$ , then:

$$F_{nc} = R_b R_h F_{yc} \Delta \quad (6.11.8.2.2-1)$$

- If  $R_1 \sqrt{\frac{kE}{F_{yc}}} < \lambda_f \leq R_2 \sqrt{\frac{kE}{F_{yc}}}$ , then:

$$F_{nc} = R_b R_h F_{yc} \left[ \Delta - \left( \Delta - \frac{F_{yr}}{R_h F_{yc}} \right) \left\{ 1 - \sin \left[ \frac{\pi}{2} \left( \frac{R_2 - \frac{b_{fc}}{t_{fc}} \sqrt{\frac{F_{yc}}{kE}}}{R_2 - R_1} \right) \right] \right\} \right] \quad (6.11.8.2.2-2)$$

- If  $\lambda_f > R_2 \sqrt{\frac{kE}{F_{yc}}}$ , then:

$$F_{nc} = \frac{0.9 E R_b k}{\left( \frac{b_{fc}}{t_{fc}} \right)^2} - \frac{R_b f_v^2 k}{0.9 E k_s^2} \left( \frac{b_{fc}}{t_{fc}} \right)^2 \quad (6.11.8.2.2-3)$$

in which:

$\lambda_f$  = slenderness ratio for the compression flange

$$= \frac{b_{fc}}{t_{fc}} \quad (6.11.8.2.2-4)$$

$$\Delta = \sqrt{1 - 3 \left( \frac{f_v}{F_{yc}} \right)^2} \quad (6.11.8.2.2-5)$$

$f_v$  = St. Venant torsional shear stress in the flange due to the factored loads at the section under consideration (ksi)

#### C6.11.8.2.2

The nominal flexural resistance of box flanges in compression is defined for three distinct regions based on the slenderness of the flange. For unstiffened flanges, the slenderness is based on the full flange width between webs,  $b_{fc}$ .

For the most slender plates, elastic buckling represented by the classic Euler hyperbola governs the behavior. For flanges under combined normal stress and torsional shear stress, a nonlinear interaction curve is used to derive the resistance of the flange in this region. The interaction curve relates the theoretical elastic Euler buckling equations for an infinitely long plate under a uniform normal stress and under shear stress (Timoshenko and Gere, 1961; Culver, 1972). The elastic buckling resistance of the flange based on this interaction curve is given by Eq. 6.11.8.2.2-3. A general discussion of the problem of reduction of critical local buckling stresses due to the presence of torsional shear may be found in Galambos (1998).

For stocky plates, full yielding of the plate, as defined by the von Mises yield criterion for combined normal and shear stress (Boresi et al., 1978), can be achieved. For such plates, the nominal flexural resistance of the flange is defined by Eq. 6.11.8.2.2-1.

In between these two regions is a transition region that reflects the fact that partial yielding due to residual stresses and initial imperfections does not permit the attainment of the elastic buckling stress. As in previous Specifications, the nominal flexural resistance of the flange in this region is arbitrarily defined in Eq. 6.11.8.2.2-2 by a sine curve. In the original derivation of Eq. 6.11.8.2.2-2, a residual stress level equal to  $0.4 F_{yc}$  was assumed (Culver, 1972).

The specified plate-buckling coefficient for uniform normal stress,  $k$ , and shear-buckling coefficient,  $k_s$ , assume simply-supported boundary conditions at the edges of the flanges (Timoshenko and Gere, 1961).

The limiting flange slenderness defining whether to use Eq. 6.11.8.2.2-1 or 6.11.8.2.2-2 is based on the constant,  $R_1$ , given by Eq. 6.11.8.2.2-8.  $R_1 \sqrt{kE/F_{yc}}$  is defined as 0.6 times the flange slenderness at which the elastic buckling stress given by Eq. 6.11.8.2.2-3 equals  $R_b F_{yc} \Delta$ . The limiting flange slenderness defining whether

$$= \frac{T}{2A_o t_{fc}} \quad (6.11.8.2.2-6)$$

$F_{yr}$  = smaller of the compression-flange stress at the onset of nominal yielding, with consideration of residual stress effects, or the specified minimum yield strength of the web (ksi)

$$= (\Delta - 0.4) F_{yc} \leq F_{yw} \quad (6.11.8.2.2-7)$$

$k$  = plate-buckling coefficient for uniform normal stress  
 $= 4.0$

$k_s$  = plate-buckling coefficient for shear stress  
 $= 5.34$

$R_1$  = constant which when multiplied by  $\sqrt{kE/F_{yc}}$  yields the slenderness ratio equal to 0.6 times the slenderness ratio for which  $F_{nc}$  from Eq. 6.11.8.2.2-3 is equal to  $R_b F_{yc} \Delta$

$$= \frac{0.57}{\sqrt{\frac{1}{2} \left[ \Delta + \sqrt{\Delta^2 + 4 \left( \frac{f_v}{F_{yc}} \right)^2 \left( \frac{k}{k_s} \right)^2} \right]}} \quad (6.11.8.2.2-8)$$

$R_2$  = constant which when multiplied by  $\sqrt{kE/F_{yc}}$  yields the slenderness ratio for which  $F_{nc}$  from Eq. 6.11.8.2.2-3 is equal to  $R_b F_{yr}$

$$= \frac{1.23}{\sqrt{\frac{1}{1.2} \left[ \frac{F_{yr}}{F_{yc}} + \sqrt{\left( \frac{F_{yr}}{F_{yc}} \right)^2 + 4 \left( \frac{f_v}{F_{yc}} \right)^2 \left( \frac{k}{k_s} \right)^2} \right]}} \quad (6.11.8.2.2-9)$$

where:

$b_{fc}$  = compression-flange width between webs (in.)

$A_o$  = enclosed area within the box section (in.<sup>2</sup>)

$R_b$  = web load-shedding factor determined as specified in Article 6.10.1.10.2

$R_h$  = hybrid factor determined as specified in Article 6.10.1.10.1

$T$  = internal torque due to the factored loads (kip-in.)

to use Eq. 6.11.8.2.2-2 or 6.11.8.2.2-3 is based on the constant,  $R_2$ , given by Eq. 6.11.8.2.2-9.  $R_2 \sqrt{kE/F_{yc}}$  is defined as the flange slenderness at which the elastic buckling stress given by Eq. 6.11.8.2.2-3 equals  $R_b F_{yr}$ , where  $F_{yr}$  is given by Eq. 6.11.8.2.2-7.

The computation of the flange torsional shear stress from Eq. 6.11.8.2.2-6 due to torques applied separately to the noncomposite and composite sections is discussed in Article C6.11.1.1.

The term  $R_b$  is a postbuckling strength reduction factor that accounts for the reduction in the section flexural resistance caused by the shedding of compressive stresses from a slender web and the corresponding increase in the flexural stress within the compression flange. The  $R_h$  factor accounts for the reduced contribution of the web to the nominal flexural resistance at first yield in any flange element, due to earlier yielding of the lower strength steel in the web of a hybrid section. The  $R_b$  and  $R_h$  factors are discussed in greater detail in Articles C6.10.1.10.2 and C6.10.1.10.1, respectively. In calculating  $R_b$  and  $R_h$  for a tub section, use one-half of the effective box flange width in conjunction with one top flange and a single web, where the effective box flange width is defined in Article 6.11.1.1. For a closed-box section, use one-half of the effective top and bottom box flange width in conjunction with a single web.

## 6.11.8.2.3—Longitudinally Stiffened Flanges

The nominal flexural resistance of the compression flange shall be taken as equal to the nominal flexural resistance for the compression flange without longitudinal stiffeners, determined as specified in Article 6.11.8.2.2, with the following substitutions:

- $w$  shall be substituted for  $b_{fc}$ ,
- the plate-buckling coefficient for uniform normal stress,  $k$ , shall be taken as:
- If  $n = 1$ , then:

$$k = \left( \frac{8I_s}{wt_{fc}^3} \right)^{\frac{1}{3}} \quad (6.11.8.2.3-1)$$

- If  $n = 2$ , then:

$$k = \left( \frac{0.894I_s}{wt_{fc}^3} \right)^{\frac{1}{3}} \quad (6.11.8.2.3-2)$$

$1.0 \leq k \leq 4.0$  and:

- the plate-buckling coefficient for shear stress,  $k_s$ , shall be taken as:

$$k_s = \frac{5.34 + 2.84 \left( \frac{I_s}{wt_{fc}^3} \right)^{\frac{1}{3}}}{(n+1)^2} \leq 5.34 \quad (6.11.8.2.3-3)$$

where:

$I_s$  = moment of inertia of a single longitudinal flange stiffener about an axis parallel to the flange and taken at the base of the stiffener (in.<sup>4</sup>)

$n$  = number of equally spaced longitudinal flange stiffeners

$w$  = larger of the width of the flange between longitudinal flange stiffeners or the distance from a web to the nearest longitudinal flange stiffener (in.)

Compression-flange longitudinal stiffeners shall satisfy the requirements specified in Article 6.11.11.2.

## C6.11.8.2.3

When a noncomposite unstiffened box flange becomes so slender that nominal flexural resistance of the flange decreases to an impractical level, longitudinal stiffeners can be added to the flange.

The nominal flexural resistance of a longitudinally-stiffened box flange is determined using the same basic equations specified for unstiffened box flanges in Article 6.11.8.2.2. The width,  $w$ , must be substituted for  $b_{fc}$  in the equations. The shear-buckling coefficient,  $k_s$ , for a stiffened plate to be used in the equations is given by Eq. 6.11.8.2.3-3, which comes from Culver (1972). The plate-buckling coefficient for uniform normal stress,  $k$ , to be used in the equations is related to the stiffness of the longitudinal flange stiffeners and is derived from Eq. 6.11.11.2-2.  $k$  can take any value ranging from 1.0 to 4.0. However, a value of  $k$  ranging from 2.0 to 4.0 generally should be assumed. Eq. 6.11.8.2.3-1 applies for one longitudinal flange stiffener; i.e.,  $n = 1$ , and Eq. 6.11.8.2.3-2 applies for two longitudinal flange stiffeners; i.e.,  $n = 2$ . As discussed further in Article C6.11.11.2, as the number of stiffeners is increased beyond one, the required moment of inertia from Eq. 6.11.11.2-2 to achieve the desired  $k$  value begins to increase dramatically and eventually becomes nearly impractical. Therefore, for boxes of typical proportions, it is strongly recommended that the number of longitudinal flange stiffeners not exceed one for maximum economy.

Note that Eq. 6.11.11.2-2 is automatically satisfied by the longitudinal flange stiffener moment of inertia that is assumed in determining the  $k$  value from Eq. 6.11.8.2.3-1 or 6.11.8.2.3-2, as applicable, since Eqs. 6.11.8.2.3-1 and 6.11.8.2.3-2 are derived directly from Eq. 6.11.11.2-2. Another option in lieu of using Eq. 6.11.8.2.3-1 or 6.11.8.2.3-2 is to assume a  $k$  value and then determine the minimum required moment of inertia for each longitudinal flange stiffener from Eq. 6.11.11.2-2 that will provide the assumed value of  $k$ .

If the longitudinal flange stiffeners are very rigid,  $k$  will be at or near a value of 4.0 and plate buckling will be forced to occur between the stiffeners. Less rigid stiffeners will yield a lower value of  $k$  and a corresponding lower value of the flange nominal flexural resistance. Eqs. 6.11.8.2.3-1 and 6.11.8.2.3-2, or alternatively Eq. 6.11.11.2-2, allow the Engineer to match the required stiffener size to the required flange resistance rather than always providing the largest stiffener(s) required to obtain a  $k$  value equal to 4.0.

Longitudinal flange stiffeners are best discontinued at field splice locations, particularly when the span balance is such that the box flange on the other side of the field splice need not be stiffened. To accomplish this successfully, the flange splice plates must be split to allow the stiffener to be taken to the free edge of the flange where the flange

normal stress is zero. The compressive resistance of the unstiffened box flange on the other side of the splice should be checked. Otherwise, if the stiffener must be discontinued in a region subject to a net tensile stress, determined as specified in Article 6.6.1.2.1, the termination of the stiffener-to-flange weld must be checked for fatigue according to the terminus detail. Where it becomes necessary to run the stiffener beyond the field splice, splicing the stiffener across the field splice is recommended.

### 6.11.8.3—Tension-Flange Flexural Resistance

The nominal flexural resistance of the tension flanges of tub sections shall be taken as:

$$F_{nt} = R_h F_{yt} \quad (6.11.8.3-1)$$

where:

$R_h$  = hybrid factor determined as specified in Article 6.10.1.10.1

The nominal flexural resistance of the tension flange of closed-box sections shall be determined from Eq. 6.11.7.2.2-5.

### 6.11.9—Shear Resistance

Except as specified herein, the provisions of Article 6.10.9 shall apply for determining the factored shear resistance of a single web. For the case of inclined webs,  $D$  in Article 6.10.9 shall be taken as the depth of the web plate measured along the slope.

For the case of inclined webs, each web shall be designed for a shear,  $V_{ui}$ , due to the factored loads taken as:

$$V_{ui} = \frac{V_u}{\cos \theta} \quad (6.11.9-1)$$

where:

$V_u$  = vertical shear due to the factored loads on one inclined web (kip)

$\theta$  = the angle of inclination of the web plate to the vertical (degrees)

For all single box sections, horizontally curved sections, and multiple box sections in bridges not satisfying the requirements of Article 6.11.2.3, or with box flanges that are not fully effective according to the provisions of Article 6.11.1.1,  $V_u$  shall be taken as the sum of the flexural and St. Venant torsional shears.

For box flanges,  $b_{fc}$  or  $b_{fj}$ , as applicable, shall be taken as one-half of the effective flange width between webs in checking Eq. 6.10.9.3.2-1, where the effective flange

### C6.11.9

For boxes with inclined webs, the web must be designed for the component of the vertical shear in the plane of the web.

Usually, the box webs are detailed with equal height webs. If the deck is superelevated, the box may be rotated to match the deck slope, which is generally preferred to simplify fabrication by maintaining symmetry of the girder sections. The result is that the inclination of one web is increased over what it would have been if the box were not rotated. The computed shear in that web due to vertically applied loads should be adjusted accordingly.

For the box sections specifically cited in this Article, including sections in horizontally curved bridges, St. Venant torsional shear must be considered in the design of the webs. The total shear in one web is greater than in the other web at the same section since the torsional shear is of opposite sign in the two webs. As a matter of practicality, both webs can be designed for the critical shear.

Although shear and longitudinal stresses in the webs due to warping are not zero, these effects are typically quite small and can be ignored in the design of the webs.

For multiple box sections in straight bridges satisfying the requirements of Article 6.11.2.3 for which a live load distribution factor for moment is employed, one-half the distribution factor for moment should be used in the calculation of the live load vertical shear in each web.

width shall be taken as specified in Article 6.11.1.1, but not to exceed  $18t_f$  where  $t_f$  is the thickness of the box flange.

Web stiffeners shall satisfy the requirements of Article 6.11.11.1.

#### 6.11.10—Shear Connectors

Except as specified herein, shear connectors shall be designed according to the provisions of Article 6.10.10.

Shear connectors shall be provided in negative flexure regions.

For all single box sections, horizontally curved sections, and multiple box sections in bridges not satisfying the requirements of Article 6.11.2.3, or with box flanges that are not fully effective according to the provisions of Article 6.11.1.1, shear connectors shall be designed for the sum of the flexural and St. Venant torsional shears. The longitudinal fatigue shear range per unit length,  $V_{fat}$ , for one top flange of a tub girder shall be computed for the web subjected to additive flexural and torsional shears. The resulting shear connector pitch shall also be used for the other top flange. The radial fatigue shear range due to curvature,  $F_{fat1}$ , given by Eq. 6.10.10.1.2-4 may be ignored in the design of box sections in straight or horizontally curved spans or segments.

For checking the resulting number of shear connectors to satisfy the strength limit state, the cross-sectional area of the steel box section under consideration and the effective area of the concrete deck associated with that box shall be used in determining  $P$  by Eqs. 6.10.10.4.2-2, 6.10.10.4.2-3, 6.10.10.4.2-7, and 6.10.10.4.2-8.

Shear connectors on composite box flanges shall be uniformly distributed across the width of the flange. The maximum transverse spacing,  $s_t$ , between shear connectors on composite box flanges shall satisfy the following requirement:

$$\frac{s_t}{t_f} \sqrt{\frac{F_{yf}}{kE}} \leq R_l \quad (6.11.10-1)$$

where:

$k$  = plate-buckling coefficient for uniform normal stress determined as specified in Article 6.11.8.2

$R_l$  = limiting slenderness ratio for the box flange determined from Eq. 6.11.8.2.2-8

For composite box flanges at the fatigue limit state,  $V_{sr}$  in Eq. 6.10.10.1.2-1 shall be determined as the vector sum of the longitudinal fatigue shear range given by Eq. 6.10.10.1.2-3 and the torsional fatigue shear range in

#### C6.11.10

Shear connectors must be present in regions of negative flexure to resist the torsional shear that exists along the entire span in all types of composite box sections. Also, the prototype and model bridges that were studied in the original development of the live-load distribution provisions for straight box sections had shear connectors throughout the negative flexure region.

Maximum flexural and torsional shears are typically not produced by concurrent loads. However, the interaction between flexure and torsion due to moving loads is too complex to treat practically. Instead, for cases where the torsional shear must be considered, these provisions allow the longitudinal shear range for fatigue to be computed from Eq. 6.10.10.1.2-3 using the sum of the maximum flexural and torsional shears in the web subjected to additive shears. The shear range and the resulting pitch should be computed using one-half the moment of inertia of the composite box section. The top flange over the other web, or the other half of the flange for a closed-box section, should contain an equal number of shear connectors. Because of the inherent conservatism of these requirements, the radial fatigue shear range due to curvature need not be included when computing the horizontal fatigue shear range for box sections in either straight or horizontally curved spans or segments.

Shear connectors on box flanges are best distributed uniformly across the flange width to ensure composite action of the entire flange with the concrete. The shear connectors are to be spaced transversely to satisfy Eq. 6.11.10-1 in order to help prevent local buckling of the flange plate when subject to compression. The torsional shear or shear range resisted by the concrete deck can be determined by multiplying the torsional shear or shear range acting on the top of the composite box section by the ratio of the thickness of the transformed concrete deck to the total thickness of the top flange plus the transformed deck. Adequate transverse reinforcement should be provided in the deck to resist this torsional shear.

the concrete deck. The number of shear connectors required to satisfy the strength limit state shall be determined according to the provisions of Article 6.10.10.4. In addition, the vector sum of the longitudinal and torsional shears due to the factored loads in the concrete deck per connector shall not exceed  $Q_r$ , determined from Eq. 6.10.10.4.1-1.

### 6.11.11—Stiffeners

#### 6.11.11.1—Web Stiffeners

Transverse intermediate web stiffeners shall be designed according to the provisions of Article 6.10.11.1.

Longitudinal web stiffeners shall be designed according to the provisions of Article 6.10.11.3.

Except as specified herein, bearing stiffeners shall be designed according to the provisions of Article 6.10.11.2. Bearing stiffeners should be attached to diaphragms rather than inclined webs. For bearing stiffeners attached to diaphragms, the provisions of Article 6.10.11.2.4b shall apply to the diaphragm rather than to the web. At expansion bearings, bearing stiffeners and diaphragms should be designed for eccentricity due to thermal movement.

#### 6.11.11.2—Longitudinal Compression-Flange Stiffeners

Longitudinal compression-flange stiffeners on box flanges shall be equally spaced across the flange width. The specified minimum yield strength of the stiffeners shall not be less than the specified minimum yield strength of the box flange to which they are attached.

The projecting width,  $b_\ell$ , of a flange longitudinal stiffener element shall satisfy:

$$b_\ell \leq 0.48t_s \sqrt{\frac{E}{F_{yc}}} \quad (6.11.11.2-1)$$

where:

$t_s$  = thickness of the projecting longitudinal stiffener element (in.)

The moment of inertia,  $I_\ell$ , of each stiffener about an axis parallel to the flange and taken at the base of the stiffener shall satisfy:

$$I_\ell \geq \psi w t_{fc}^3 \quad (6.11.11.2-2)$$

where:

$$\begin{aligned} \psi &= 0.125k^3 \text{ for } n = 1 \\ &= 1.120k^3 \text{ for } n = 2 \end{aligned}$$

#### C6.11.11.1

When inclined webs are used, bearing stiffeners should be attached to either an internal or external diaphragm rather than to the webs so that the bearing stiffeners are perpendicular to the sole plate. Thermal movements of the bridge may cause the diaphragm to be eccentric with respect to the bearings. This eccentricity should be recognized in the design of the diaphragm and bearing stiffeners. The effects of the eccentricity are usually most critical when the bearing stiffeners are attached to diaphragms. The effects of the eccentricity can be recognized by designing the bearing stiffener assembly as a beam-column according to the provisions of Articles 6.10.11.2 and 6.9.2.2.

#### C6.11.11.2

Eq. 6.11.11.2-1 is intended to prevent local buckling of the projecting elements of the longitudinal flange stiffener. For structural tees,  $b_\ell$  should be taken as one-half the width of the flange.

Eq. 6.11.11.2-2 for the required longitudinal flange stiffener moment of inertia,  $I_\ell$ , is an approximate expression that within its range of applicability yields values of the elastic critical flange buckling stress close to those obtained by use of the exact but cumbersome equations of elastic stability (Timoshenko and Gere, 1961). The required size of the stiffener increases as the panel becomes smaller since the buckling resistance of the panels increases as the panels become smaller.

The actual longitudinal flange stiffener moment of inertia,  $I_s$ , used in determining the plate-buckling coefficient for uniform normal stress,  $k$ , from either Eq. 6.11.8.2.3-1 or 6.11.8.2.3-2, as applicable, automatically satisfies Eq. 6.11.11.2-2 when that value of  $k$  is used since the equations for  $k$  are derived directly from Eq. 6.11.11.2-2. Alternatively, a  $k$  value can be assumed in lieu of using Eq. 6.11.8.2.3-1 or 6.11.8.2.3-2.  $k$  can take any value ranging from 1.0 to 4.0. However, a value of  $k$  ranging from 2.0 to 4.0 generally should be assumed. The minimum required moment of inertia for each longitudinal flange stiffener that will provide the assumed value of  $k$  can then be determined from Eq. 6.11.11.2-2.

- $k$  = plate-buckling coefficient for uniform normal stress  
 $= 1.0 \leq k \leq 4.0$
- $n$  = number of equally spaced longitudinal flange stiffeners
- $w$  = larger of the width of the flange between longitudinal flange stiffeners or the distance from a web to the nearest longitudinal flange stiffener (in.)

Where required, the number of longitudinal flange stiffeners should preferably not exceed one for maximum economy in boxes of typical proportions. Eq. 6.11.11.2-2 assumes that the box flange plate and the stiffeners are infinitely long and ignores the effect of any transverse bracing or stiffening. Thus, when  $n$  exceeds 1, the required moment of inertia from Eq. 6.11.11.2-2 begins to increase dramatically. When  $n$  exceeds 2, for which the value of  $\psi$  equals  $0.07k^3n^4$ , the required moment of inertia from Eq. 6.11.11.2-2 becomes nearly impractical.

For rare cases where an exceptionally wide box flange is required and  $n$  may need to exceed 2, it is suggested that transverse flange stiffeners be considered to reduce the required size of the longitudinal flange stiffeners to a more practical value. The use of transverse flange stiffeners might also be considered for the case where  $n$  equals 2 if a  $k$  value greater than about 2.5 is needed and it is desired to reduce the required size of the longitudinal stiffeners over that given by Eq. 6.11.11.2-2. The specified minimum yield strength of the transverse flange stiffeners should not be less than the specified minimum yield strength of the box flange. Individual structural tees can be used as transverse flange stiffeners, and/or a bottom strut, provided within the internal transverse bracing of the box and satisfying the requirements of Article 6.11.5, can serve as a transverse flange stiffener if the strut also satisfies the stiffness requirement given by Eq. C6.11.11.2-4. In either case, the transverse flange stiffeners should be attached to the longitudinal flange stiffeners by bolting. The connection to each longitudinal stiffener should be designed to resist the following vertical force:

$$F_s = \frac{\phi_f F_{ys} S_s}{nb_{fc}} \quad (\text{C6.11.11.2-1})$$

where:

$\phi_f$  = resistance factor for flexure specified in Article 6.5.4.2

$F_{ys}$  = specified minimum yield strength of the transverse flange stiffener (ksi)

$S_s$  = section modulus of the transverse flange stiffener (in.<sup>3</sup>)

Individual structural tees serving as transverse flange stiffeners should also be attached to the webs of the box. The connection of transverse flange stiffeners to each web should be designed to resist the following vertical force:

$$F_w = \frac{\phi_f F_{ys} S_s}{2b_{fc}} \quad (\text{C6.11.11.2-2})$$

For the exceptional case where transverse flange stiffeners are deemed necessary, the constant  $\psi$  in Eq. 6.11.11.2-2 is to be taken as 8.0 in determining the required moment of inertia of the longitudinal flange stiffeners.  $n$  in this case should preferably not exceed five. The longitudinal spacing of the transverse flange stiffeners should not exceed three times the full width of the box flange,  $b_{fc}$ , in order for the transverse stiffeners to be considered effective. The plate-buckling coefficient,  $k$ , for uniform normal stress to be used in the equations of Article 6.11.8.2.2 in lieu of  $k$  determined from Eqs. 6.11.8.2.3-1 or 6.11.8.2.3-2 may then be taken as follows:

$$k = \frac{\left[1 + \left(a/b_{fc}\right)^2\right]^2 + 87.3}{(n+1)^2 \left(a/b_{fc}\right)^2 \left[1 + 0.1(n+1)\right]} \leq 4.0 \quad (\text{C6.11.11.2-3})$$

where:

$a$  = longitudinal spacing of the transverse flange stiffeners (in.)

Transverse flange stiffeners spaced at a distance less than or equal to  $4w$  will provide a  $k$  of approximately 4.0 according to Eq. C6.11.11.2-3 when  $n$  does not exceed 5. When the  $k$  value from Eq. C6.11.11.2-3 is used, the moment of inertia,  $I_t$ , of each transverse flange stiffener about an axis through its centroid and parallel to its bottom edge must satisfy:

$$I_t \geq 0.1(n+1)^3 w^3 \frac{f_s A_f}{E a} \quad (\text{C6.11.11.2-4})$$

where:

$A_f$  = area of the box flange including the longitudinal flange stiffeners ( $\text{in.}^2$ )

$f_s$  = largest of the longitudinal flange stresses due to the factored loads in the panels on either side of the transverse flange stiffener under consideration (ksi)

Structural tees are preferred for longitudinal flange stiffeners because a tee provides a high ratio of stiffness to cross-sectional area. Tees also minimize the potential for lateral torsional buckling of the stiffeners. Using less efficient flat bars as stiffeners is an undesirable alternative. Since the longitudinal flange stiffeners are primary load carrying members, the specified minimum yield strength of the stiffeners must not be less than the specified minimum yield strength of the box flange to which they are attached. Tees may not be available in higher grades of steel. In these cases, tees can be fabricated from plates or bars cut from plate.

Longitudinal flange stiffeners should be continuous through internal diaphragms. Consideration should be given to attaching longitudinal flange stiffeners to the internal diaphragms. Tees may be conveniently attached to the diaphragms with a pair of clip angles.

For the cases specified in Article 6.11.5 where transverse bending stresses due to cross-section distortion are to be considered for fatigue, it may be necessary in certain situations to consider providing bottom transverse bracing members as part of the internal cross-frames to control distortion of the box flange and reduce the transverse bending stress ranges in the flange. Where longitudinal flange stiffeners are used, the transverse member is to be attached to the longitudinal stiffeners by bolting. As discussed previously in this Article, bottom transverse bracing members and/or individual transverse flange stiffeners attached to the longitudinal flange stiffeners may also be necessary in the unusual case of an exceptionally wide box flange. For all other cases, additional transverse stiffening of box flanges is not required. It should be emphasized that bottom transverse bracing members and their connections, where provided, need not satisfy the requirements of Eqs. C6.11.11.2-1, C6.11.11.2-2 and C6.11.11.2-4, unless the  $k$  value from Eq. C6.11.11.2-3 is utilized in the design of the box flange.

## 6.12—MISCELLANEOUS FLEXURAL MEMBERS

### 6.12.1—General

#### 6.12.1.1—Scope

The provisions of this Article shall apply to:

- Noncomposite H-shaped members bent about either axis of the cross-section, and noncomposite I-shaped members bent about their weak axis;
- Noncomposite box shaped member, including square and rectangular HSS;
- Noncomposite circular tubes, including round HSS;
- Channels, angles, tees, rectangular bars, and solid rounds;
- Concrete-encased rolled shapes; and
- Composite tubes.

#### C6.12.1.1

This Article covers miscellaneous rolled or built-up noncomposite or composite members subject to flexure, often in combination with axial loads; that is, flexural members not covered by the provisions of Article 6.10 or 6.11. Included are doubly symmetric noncomposite box-shaped members utilized in trusses, frames, and arches, and angles, tees, and channels utilized as cross-frame, diaphragm, and lateral bracing members.

Noncomposite circular tubes or pipes may be designed using the provisions specified herein for round Hollow Structural Sections (HSS) provided that they conform to [ASTM A53](#), Grade B and the appropriate parameters are used in the design. Additional information on connection design for square, rectangular and round HSS may be found in Chapter K of AISC (2005). Resistances for fatigue design for square, rectangular and round HSS may be found in Section 2.20.6 of the ANSI/AWS D1.1 *Structural Welding Code* or in Section 11 of the *AASHTO Standard Specifications for Structural Supports for Highway Signs, Luminaries and Traffic Signals*. Where these members are used in fracture-critical applications, refer to Article 8.2.3 of the *Guide Specifications for the Design of Pedestrian Bridges*.

### 6.12.1.2—Strength Limit State

#### 6.12.1.2.1—Flexure

The factored flexural resistance,  $M_r$ , shall be taken as:

$$M_r = \phi_f M_n \quad (6.12.1.2.1-1)$$

where:

$M_n$  = nominal flexural resistance specified in Articles 6.12.2.2 and 6.12.2.3 for noncomposite and composite members, respectively (kip-in.)

$\phi_f$  = resistance factor for flexure specified in Article 6.5.4.2

#### 6.12.1.2.2—Combined Flexure and Axial Load

The provisions of Article 6.8.2.3 for combined axial tension and flexure or the provisions of Article 6.9.2.2 for combined axial compression and flexure shall apply, as applicable.

#### 6.12.1.2.3—Shear

##### 6.12.1.2.3a—General

The factored shear resistance,  $V_r$ , shall be taken as:

$$V_r = \phi_v V_n \quad (6.12.1.2.3a-1)$$

where:

$V_n$  = nominal shear resistance specified in Articles 6.10.9.2 and 6.12.3 for webs of noncomposite members and composite members, respectively; except for webs of noncomposite box-shaped members, including square and rectangular HSS, for which the provisions of Article 6.11.9 shall apply, and circular tubes, including round HSS, for which the provisions of Article 6.12.1.2.3c shall apply (kip).

$\phi_v$  = resistance factor for shear specified in Article 6.5.4.2

For stems of tees and for elements of noncomposite I- and H-shapes loaded about their weak axis, the shear buckling coefficient,  $k$ , shall be taken as 1.2.

##### 6.12.1.2.3b—Square and Rectangular HSS

For square and rectangular HSS, the web depth,  $D$ , shall be taken as the clear distance between flanges less the inside corner radius on each side and the area of both webs shall be considered effective in resisting the shear.

**6.12.1.2.3c—Circular Tubes**

For circular tubes, including round HSS, the nominal shear resistance,  $V_n$ , shall be taken as:

$$V_n = 0.5F_{cr}A_g \quad (6.12.1.2.3c-1)$$

in which:

$F_{cr}$  = shear buckling resistance (ksi) taken as the larger of either:

$$F_{cr1} = \frac{1.60E}{\sqrt{\frac{L_v}{D}} \left(\frac{D}{t}\right)^{\frac{5}{4}}} \leq 0.58F_y \quad (6.12.1.2.3c-2)$$

or:

$$F_{cr2} = \frac{0.78E}{\left(\frac{D}{t}\right)^{\frac{3}{2}}} \leq 0.58F_y \quad (6.12.1.2.3c-3)$$

where:

$A_g$  = gross area of the section based on the design wall thickness (in.)

$D$  = outside diameter of the tube (in.)

$L_v$  = distance between points of maximum and zero shear (in.)

$t$  = design wall thickness taken equal to 0.93 times the nominal wall thickness for electric-resistance-welded round HSS and taken equal to the nominal wall thickness for all others (in.)

**6.12.2—Nominal Flexural Resistance****6.12.2.1—General**

Except as specified herein, provisions for lateral torsional buckling need not be applied to composite members, noncomposite box-shaped members, noncomposite I- and H-shaped members bent about their weak axis, and circular tubes.

**C6.12.1.2.3c**

The provisions for circular tubes, including round Hollow Structural Sections (HSS), subject to transverse shear are based on the provisions for local buckling of cylinders due to torsion. However, since torsion is generally constant along the member length and transverse shear typically has a gradient, the critical buckling stress for transverse shear is taken as 1.3 times the critical stress for torsion (Brockenbrough and Johnston 1981; Galambos 1998). The torsion equations apply over the full length of the member, but for transverse shear, it is reasonable to use the length between points of maximum and zero shear. The nominal shear resistance is computed assumed that the shear stress at the neutral axis is at  $F_{cr}$ . The resulting stress at the neutral axis is  $V/\pi R t$ , in which the denominator is recognized as half the area of the circular tube.

## 6.12.2.2—Noncomposite Members

### 6.12.2.2.1—I- and H-Shaped Members

The provisions of this Article apply to I- and H-shaped members and members consisting of two channel flanges connected by a web plate.

The provisions of Article 6.10 shall apply to flexure about an axis perpendicular to the web.

The nominal flexural resistance for flexure about the weak axis shall be taken as:

- If  $\lambda_f \leq \lambda_{pf}$ , then:

$$M_n = M_p \quad (6.12.2.2.1-1)$$

- If  $\lambda_{pf} < \lambda_f \leq \lambda_{rf}$ , then:

$$M_n = \left[ 1 - \left( 1 - \frac{S_y}{Z_y} \right) \left( \frac{\lambda_f - \lambda_{pf}}{0.45 \sqrt{\frac{E}{F_{yf}}}} \right) \right] F_{yf} Z_y \quad (6.12.2.2.1-2)$$

in which:

$\lambda_f$  = slenderness ratio for the flange

$$= \frac{b_f}{2t_f} \quad (6.12.2.2.1-3)$$

$\lambda_{pf}$  = limiting slenderness ratio for a compact flange

$$= 0.038 \sqrt{\frac{E}{F_{yf}}} \quad (6.12.2.2.1-4)$$

$\lambda_{rf}$  = limiting slenderness ratio for a noncompact flange

$$= 0.83 \sqrt{\frac{E}{F_{yf}}} \quad (6.12.2.2.1-5)$$

where:

$F_{yf}$  = specified minimum yield strength of the lower-strength flange (ksi)

$M_p$  = plastic moment about the weak axis (kip-in.)

$S_y$  = elastic section modulus about the weak axis (in.<sup>3</sup>)

$Z_y$  = plastic section modulus about the weak axis (in.<sup>3</sup>)

### C6.12.2.2.1

Eqs. 6.12.2.2.1-1 and 6.12.2.2.1-2 are taken from Appendix F of AISC (1999), except that the flange slenderness  $\lambda_{rf}$  corresponding to the transition from inelastic to elastic flange local buckling is consistently set based on the yield moment in weak-axis bending  $F_{yf} S_y$ . AISC (1999) uses  $F_{yf} S_y$  as the moment corresponding to the inelastic-to-elastic flange local buckling transition, but then specifies  $\lambda_{rf}$  based on a smaller moment level. The approach adopted in these provisions is interpreted as a corrected form of the AISC (1999) equations and is conservative relative to the AISC (1999) equations as printed. The yield moment  $F_{yf} S_y$  may be taken conservatively as the moment at the inelastic-to-elastic flange local buckling transition because of the beneficial effects of the stress gradient in the flange associated with weak-axis bending.

For H-shaped members  $M_p = 1.5F_y S$ , where  $S$  is the elastic section modulus about this axis.

### 6.12.2.2.2—Box-Shaped Members

Except as specified herein, for homogeneous doubly symmetric box-shaped members bent about either axis, the nominal flexural resistance shall be taken as:

$$M_n = F_y S \left[ 1 - \frac{0.064 F_y S \ell}{AE} \left( \frac{\sum \left( \frac{b}{t} \right)}{I_y} \right)^{0.5} \right] \quad (6.12.2.2.2-1)$$

where:

$S$  = section modulus about the flexural axis (in.<sup>3</sup>)

$A$  = area enclosed within the centerlines of the plates comprising the box (in.<sup>2</sup>)

$\ell$  = unbraced length (in.)

$I_y$  = moment of inertia about an axis perpendicular to the axis of bending (in.<sup>4</sup>)

$b$  = clear distance between plates (in.)

$t$  = thickness of plates (in.)

For square and rectangular HSS bent about either axis, the nominal flexural resistance shall be taken as the smallest value based on yielding, flange local buckling or web local buckling, as applicable.

For yielding, the nominal flexural resistance for square and rectangular HSS shall be taken as:

$$M_n = M_p = F_y Z \quad (6.12.2.2.2-2)$$

where:

$M_p$  = plastic moment (kip-in.)

$Z$  = plastic section modulus about the axis of bending (in.<sup>3</sup>)

Where the flange slenderness  $\lambda_f$  of square and rectangular HSS exceeds  $\lambda_{pf}$ , flange local buckling shall be checked. For flange local buckling, the nominal flexural resistance shall be taken as:

- If  $\lambda_f \leq \lambda_{rf}$ , then:

$$M_n = M_p - (M_p - F_y S) \left( 3.57 \frac{b_{fc}}{t_{fc}} \sqrt{\frac{F_y}{E}} - 4.0 \right) \leq M_p \quad (6.12.2.2.2-3)$$

- If  $\lambda_f > \lambda_{rf}$ , then:

### C6.12.2.2.2

The lateral-torsional resistance of box shapes is usually quite high and its effect is often ignored. For truss members, frame members, arch ribs, and other situations in which long unbraced lengths are possible, this expediency may not be adequate. Eq. 6.12.2.2.2-1 was derived from the elastic lateral torsional buckling moment,  $M_{CR}$ , given by:

$$M_{CR} = \frac{\pi}{\ell} \sqrt{EI_y GJ} \quad (C6.12.2.2.2-1)$$

in which:

$$G = 0.385E, \text{ and} \quad (C6.12.2.2.2-2)$$

$$J = \frac{4A^2}{\Sigma \frac{b}{t}} \quad (C6.12.2.2.2-3)$$

After substitution of Eqs. C6.12.2.2.2-2 and C6.12.2.2.2-3 into C6.12.2.2.2-1:

$$M_{CR} = \frac{3.90 EA}{\ell} \sqrt{\frac{I_y}{\Sigma \frac{b}{t}}} \quad (C6.12.2.2.2-4)$$

It was assumed that buckling would be in the inelastic range so the CRC column equation was used to estimate the effect of inelastic buckling as:

$$M_I = F_y S \left[ 1 - \frac{F_y S}{4M_{CR}} \right] \quad (C6.12.2.2.2-5)$$

Substitution of Eq. C6.12.2.2.2-4 into C6.12.2.2.2-5 leads to Eq. 6.12.2.2.2-1. The effects of moment gradient are conservatively neglected in Eq. 6.12.2.2.2-1.

For smaller square and rectangular Hollow Structural Sections (HSS), lateral torsional buckling is not considered and larger nominal flexural resistances potentially exceeding  $M_y$  may be obtained. Rectangular HSS bent about the weak or minor axis are not subject to lateral torsional buckling. For lateral torsional buckling about the major axis, the reduction in the lateral torsional buckling resistance for uniform bending, based on an assumed linear reduction between the plastic moment and yield moment, is typically minor in most practical cases. Furthermore, a moment gradient modifier,  $C_b$ , only slightly larger than unity makes this reduction nonexistent. For local buckling of the compression flanges of HSS, Eq. 6.12.2.2.2-4 for members with slender flanges utilizes the same effective width equation utilized for square or rectangular HSS in

$$M_n = F_y S_{eff} \quad (6.12.2.2-4)$$

in which:

$\lambda_f$  = compression-flange slenderness =  $b_{fc}/t_{fc}$

$\lambda_{pf}$  = limiting slenderness for a compact flange

$$= 1.12 \sqrt{\frac{E}{F_y}} \quad (6.12.2.2-5)$$

$\lambda_{rf}$  = limiting slenderness for a noncompact flange

$$= 1.40 \sqrt{\frac{E}{F_y}} \quad (6.12.2.2-6)$$

where:

$b_{fc}$  = clear width of the compression flange between the webs less the inside corner radius on each side (in.)

$S$  = elastic section modulus about the axis of bending (in.<sup>3</sup>)

$S_{eff}$  = effective elastic section modulus about the axis of bending determined using an effective width of the compression flange  $b_e$  (in.<sup>3</sup>), determined as:

$$b_e = 1.92 t_{fc} \sqrt{\frac{E}{F_y} \left[ 1 - \frac{0.38}{(b_{fc}/t_{fc})} \sqrt{\frac{E}{F_y}} \right]} \leq b_{fc} \quad (6.12.2.2-7)$$

$t_{fc}$  = design wall thickness of the compression flange taken equal to 0.93 times the nominal wall thickness for electric-resistance-welded HSS and taken equal to the nominal wall thickness for all others (in.)

Where the flange slenderness  $\lambda_f$  of square and rectangular HSS exceeds  $\lambda_{rf}$ , the following shall also be satisfied at the fatigue and service limit states, and for constructibility:

$$f_c \leq \frac{1.96 E}{\lambda_f^2} \quad (6.12.2.2-8)$$

where:

$f_c$  = compression-flange stress at the section under consideration due to:

axial compression in Article 6.9.4.2.2, except that the stress  $f$  in Eq. 6.9.4.2.2-10 is taken as  $F_y$ . This substitution implies that the stress in the corners of the compression flange is at yield when the ultimate post-buckling resistance of the flange is reached. In such cases, the nominal flexural resistance is determined based on an effective section modulus to the compression flange using the distance from the shifted neutral axis. A conservative estimate of the nominal flexural resistance may be obtained by using the effective width from Eq. 6.12.2.2-7 for both the compression and tension flange in order to maintain symmetry of the cross-section and simplify the calculations. Since post-buckling resistance is assumed at the strength limit state for members with slender flanges, such members must also satisfy Eq. 6.12.2.2-8 to ensure that local buckling of the compression flange does not theoretically occur at the service and fatigue limit states, and for constructability. Similar checks exist in the specification to ensure that shear buckling and web bend buckling do not theoretically occur under these conditions.

- The Service II loads at the service limit state;
- The unfactored permanent load plus the Fatigue I load combination at the fatigue limit state;
- The appropriate factored permanent load for constructibility.

Where the web slenderness,  $D/t_w$ , of square and rectangular HSS exceeds  $\lambda_{pw}$ , web local buckling shall be checked. For web local buckling, the nominal flexural resistance shall be taken as:

$$M_n = M_p - (M_p - F_y S) \left( 0.305 \frac{D}{t_w} \sqrt{\frac{F_y}{E}} - 0.738 \right) \leq M_p \quad (6.12.2.2.2-9)$$

in which:

$$\begin{aligned} \lambda_{pw} &= \text{limiting slenderness for a compact web} \\ &= 2.42 \sqrt{\frac{E}{F_y}} \end{aligned} \quad (6.12.2.2.2-10)$$

where:

$D$  = clear distance between the flanges less the inside corner radius on each side (in.)

$t_w$  = design wall thickness of the web taken equal to 0.93 times the nominal wall thickness for electric-resistance-welded HSS and taken equal to the nominal wall thickness for all others (in.)

#### 6.12.2.3—Circular Tubes

For circular tubes, including round HSS, the nominal flexural resistance shall be taken as the smaller value based on yielding or local buckling, as applicable. The  $D/t$  of circular tubes used as flexural members shall not exceed  $0.45E/F_y$ .

For yielding, the nominal flexural resistance shall be taken as:

$$M_n = M_p = F_y Z \quad (6.12.2.2.3-1)$$

where:

$D$  = outside diameter of tube (in.)

$M_p$  = plastic moment (kip-in.)

$t$  = thickness of tube (in.)

$Z$  = plastic section modulus ( $\text{in.}^3$ )

#### C6.12.2.3

Failure modes and post-buckling behavior of circular tubes, including round Hollow Structural Sections (HSS), can be grouped into the following three categories (Sherman, 1992; Galambos, 1998): 1) for  $D/t$  less than about  $0.05E/F_y$ , a long inelastic plateau occurs in the moment-rotation curve. The cross-section gradually ovalizes, then local wave buckles eventually form after which the flexural resistance slowly decays; 2) for  $0.05E/F_y \leq D/t \leq 0.10E/F_y$ , the plastic moment is nearly achieved but a single local buckle develops and the flexural resistance decays slowly with little or no inelastic plateau; and 3) for  $D/t > 0.10E/F_y$ , multiple buckles form suddenly with little ovalization and the flexural resistance drops rapidly to a more stable level. The specified flexural resistance equations reflect the above regions of behavior for sections with long constant moment regions and little restraint against ovalization at the failure location. The equations are based on five North American studies involving hot-formed seamless pipe, electric-resistance-welded pipe, and fabricated tubing (Sherman, 1992; Galambos, 1998).

For sections where  $D/t$  exceeds  $0.07E/F_y$ , local buckling shall be checked. For local buckling, the nominal flexural resistance shall be taken as:

- If  $\frac{D}{t} \leq \frac{0.31E}{F_y}$ , then:

$$M_n = \left( \frac{0.021E}{\frac{D}{t}} + F_y \right) S \quad (6.12.2.3-2)$$

- If  $\frac{D}{t} > \frac{0.31E}{F_y}$ , then:

$$M_n = F_{cr}S \quad (6.12.2.3-3)$$

in which:

$F_{cr}$  = elastic local buckling stress (ksi)

$$= \frac{0.33E}{\frac{D}{t}} \quad (6.12.2.3-4)$$

where:

$S$  = elastic section modulus ( $\text{in.}^3$ )

#### 6.12.2.4—Tees and Double Angles

For tees and double angles loaded in the plane of symmetry, the nominal flexural resistance shall be taken as the smallest value based on yielding, lateral torsional buckling, or local buckling of the elements, as applicable.

For yielding, the nominal flexural resistance shall be taken as:

$$M_n = M_p = F_y Z_x \quad (6.12.2.4-1)$$

$M_n$  from Eq. 6.12.2.4-1 is limited to  $1.6M_y$  for stems in tension and to  $M_y$  for stems in compression.

where:

$F_y$  = specified minimum yield strength (ksi)

$M_p$  = plastic moment (kip-in.)

$M_y$  = yield moment based on the distance to the tip of the stem (kip-in.)

$Z_x$  = plastic section modulus about the  $x$ -axis ( $\text{in.}^3$ )

#### C6.12.2.4

The provisions for tees and double angles given in this Article are taken from AISC (2005). The plane of symmetry is assumed to be that formed by their weak axis or  $y$ -axis. For flexure of tees and double angles about the  $y$ -axis, which is considered to be a rare case in bridge applications, consult the Commentary to Section F9 of AISC (2005).

The limit on  $M_n$  in Eq. 6.12.2.4-1 of  $1.6M_y$  for cases where the stem is in tension is intended to indirectly control situations where significant yielding of the stem may occur at service load levels. The legs of double angles in continuous contact or with separators may together be assumed treated as the stem in checking the equations of this Article.

Eq. 6.12.2.4-2 is a simplified version of the elastic lateral torsional buckling equation developed in Kitipornchai and Trahair (1980) and discussed further in Ellifritt et al. (1992). The moment gradient modifier  $C_b$  specified for I-sections in Article A6.3.3 is not included in Eq. 6.12.2.4-2 as the application of  $C_b$  to cases where the stem is in compression is unconservative. Also, for reverse curvature bending, the portion with the stem in

For lateral torsional buckling, the nominal flexural resistance shall be taken as:

$$M_n = \frac{\pi\sqrt{EI_y GJ}}{L_b} \left[ B + \sqrt{1+B^2} \right] \leq M_p \quad (6.12.2.2.4-2)$$

in which:

$$B = \pm 2.3 \frac{d}{L_b} \sqrt{\frac{I_y}{J}} \quad (6.12.2.2.4-3)$$

where:

$d$  = total depth of the section (in.)

$G$  = shear modulus of elasticity for steel = 0.385E (ksi)

$I_y$  = moment of inertia about the  $y$ -axis (in.<sup>4</sup>)

$J$  = St. Venant torsional constant (in.<sup>4</sup>)

$L_b$  = unbraced length (in.)

The plus sign for  $B$  in Eq. 6.12.2.2.4-3 shall apply when the stem is in tension and the minus sign shall apply when the stem is in compression. If the tip of the stem is in compression anywhere along the unbraced length, the negative value of  $B$  shall be used.

For sections where the flange is in compression and the flange slenderness  $\lambda_f$  exceeds  $\lambda_{pf}$ , flange local buckling shall be checked. For flange local buckling, the nominal flexural resistance shall be taken as:

$$M_n = M_p - (M_p - 0.7F_y S_{xc}) \left( \frac{\lambda_f - \lambda_{pf}}{\lambda_{rf} - \lambda_{pf}} \right) \leq 1.6M_y \quad (6.12.2.2.4-4)$$

in which:

$\lambda_f$  = flange slenderness =  $b_f/2t_f$

$\lambda_{pf}$  = limiting slenderness for a compact flange

$$= 0.38 \sqrt{\frac{E}{F_y}} \quad (6.12.2.2.4-5)$$

$\lambda_{rf}$  = limiting slenderness for a noncompact flange

$$= 1.0 \sqrt{\frac{E}{F_y}} \quad (6.12.2.2.4-6)$$

compression may govern the lateral torsional buckling resistance even though the corresponding moments may be small in relation to the moments in the other portions of the unbraced length. The lateral torsional buckling resistance for the case where the stem is in compression is substantially smaller than for the case where the stem is in tension. For cases where the stem is in tension, connection details should be designed to minimize end restraint moments that may cause the stem to be in flexural compression at the ends of the member.

For rolled sections, the St. Venant torsional constant  $J$ , including the effect of the web-to-flange fillets, is tabulated in AISC (2005a). For fabricated sections, Eq. A6.3.3-9 may be used with one of the flange terms removed.

For cases where the flange is in compression and  $\lambda_f$  does not exceed  $\lambda_{pf}$ , flange local buckling does not control and need not be checked. Eq. 6.12.2.2.4-4 represents an inelastic flange local buckling resistance equation and corrects an error in the inelastic flange local buckling equation provided in AISC (2005). An elastic flange local buckling resistance equation for cases with  $\lambda_f$  exceeding  $\lambda_{rf}$ , i.e. for slender flanges, is not provided because the limiting slenderness value  $\lambda_{rf}$  beyond which elastic flange local buckling controls is larger than the limiting slenderness value of 12.0 given by Eq. 6.10.2.2-1. The flanges of all rolled tee sections given in AISC (2005) satisfy Eq. 6.10.2.2-1; therefore, this limit need only be checked for fabricated sections. An elastic flange local buckling equation is provided in AISC (2005).

Eq. 6.12.2.2.4-7 for checking local buckling of stems in compression is indirectly derived from Eq. 6.12.2.2.4-2 in the limit of zero unbraced length.

where:

$b_f$  = flange width (in.). For double angles,  $b_f$  shall be taken as the sum of the widths of the outstanding legs.

$S_{xc}$  = elastic section modulus with respect to the compression flange ( $\text{in.}^3$ )

$t_f$  = flange thickness (in.)

For sections where the stem is in compression, local buckling of the stem shall be checked. The local buckling resistance of the stem shall be taken as:

$$M_n = 0.424 \frac{EJ}{d} \leq M_y \quad (6.12.2.2.4-7)$$

Flanges of fabricated sections in compression or tension shall satisfy Eq. 6.10.2.2-1.

#### 6.12.2.2.5—Channels

For channels in flexure about their strong or  $x$ -axis, the nominal flexural resistance shall be taken as the smaller value based on yielding or lateral torsional buckling, as applicable.

For yielding, the nominal flexural resistance shall be taken as:

$$M_n = M_p = F_y Z_x \quad (6.12.2.2.5-1)$$

where:

$F_y$  = specified minimum yield strength (ksi)

$M_p$  = plastic moment (kip-in.)

$Z_x$  = plastic section modulus about the  $x$ -axis ( $\text{in.}^3$ )

Where the unbraced length  $L_b$  exceeds  $L_p$ , lateral torsional buckling shall be checked. For lateral torsional buckling, the nominal flexural resistance shall be taken as:

- If  $L_b \leq L_r$ , then:

$$M_n = C_b \left[ M_p - \left( M_p - 0.7 F_y S_x \right) \left( \frac{L_b - L_p}{L_r - L_p} \right) \right] \leq M_p \quad (6.12.2.2.5-2)$$

#### C6.12.2.2.5

The provisions for channels in flexure about their strong or  $x$ -axis are taken from AISC (2005). For lateral torsional buckling, where  $L_b$  is less than or equal to the limiting length,  $L_p$ , lateral torsional buckling does not control and need not be checked. The lateral torsional buckling Eqs. 6.12.2.2.5-2 and 6.12.2.2.5-3 assume that the channel has compact flanges satisfying Eq. 6.12.2.2.5-10 and a compact web satisfying Eq. 6.12.2.2.5-12; hence, flange and web local buckling need not be checked. All rolled channels given in AISC (2005) have compact flanges and webs for  $F_y \leq 65$  ksi. Thus, Eqs. 6.12.2.2.5-10 and 6.12.2.2.5-12 need not be checked for rolled channels. To utilize Eqs. 6.12.2.2.5-2 and 6.12.2.2.5-3 for fabricated or bent-plate channels, Eqs. 6.12.2.2.5-10 and 6.12.2.2.5-12 must be satisfied. Eqs. 6.12.2.2.5-2 and 6.12.2.2.5-3 also assume that the channel is restrained at the brace points such that twisting of the member does not occur at those points. For fabricated or bent-plate channels, Eq. 6.12.2.2.5-5 taken from Salmon and Johnson (1996) and Eq. A6.3.3-9 may be used for the computation of  $C_w$  and  $J$ , respectively. For rolled channels, values of the warping torsional constant,  $C_w$ , and the St. Venant torsional constant,  $J$ , including the effect of the sloping flanges and web-to-flange fillets, are tabulated in AISC (2005a) and may be used in lieu of the values from these equations.

For channels in flexure about their weak or  $y$ -axis, the limit of  $1.6 F_y S_y$  on the nominal flexural resistance is intended to indirectly prevent substantial yielding of the member at service load levels.

- If  $L_b > L_r$ , then:

$$M_n = F_{cr} S_x \leq M_p \quad (6.12.2.2.5-3)$$

in which:

$F_{cr}$  = elastic lateral torsional buckling stress (ksi)

$$= \frac{C_b \pi^2 E}{\left(\frac{L_b}{r_{ts}}\right)^2} \sqrt{1 + 0.078 \frac{Jc}{S_x h_o} \left(\frac{L_b}{r_{ts}}\right)^2} \quad (6.12.2.2.5-4)$$

$$c = \frac{h_o}{2} \sqrt{\frac{I_y}{C_w}} \quad (6.12.2.2.5-5)$$

$C_w$  = warping torsional constant (in.<sup>6</sup>)

$$= \frac{t_f b^3 h_o^2}{12} \left( \frac{3bt_f + 2h_o t_w}{6bt_f + h_o t_w} \right) \quad (6.12.2.2.5-6)$$

$L_p$  = limiting unbraced length to achieve the nominal flexural resistance  $M_p$  under uniform bending (in.)

$$= 1.76 r_y \sqrt{\frac{E}{F_y}} \quad (6.12.2.2.5-7)$$

$L_r$  = limiting unbraced length to achieve the nominal onset of yielding under uniform bending with consideration of compression-flange residual stress effects (in.)

$$= 1.95 r_{ts} \frac{E}{0.7 F_y} \sqrt{\frac{Jc}{S_x h_o}} \sqrt{1 + \sqrt{1 + 6.76 \left( \frac{0.7 F_y}{E} \frac{S_x h_o}{Jc} \right)^2}} \quad (6.12.2.2.5-8)$$

$$r_{ts}^2 = \frac{\sqrt{I_y C_w}}{S_x} \quad (6.12.2.2.5-9)$$

where:

$C_b$  = moment gradient modifier determined as specified in Article A6.3.3

$L_b$  = unbraced length (in.)

$b$  = distance between the toe of the flange and the centerline of the web (in.)

$h_o$	=	distance between flange centroids (in.)
$I_y$	=	moment of inertia about the y-axis (in. <sup>4</sup> )
$J$	=	St. Venant torsional constant (in. <sup>4</sup> )
$r_{ts}$	=	radius of gyration used in the determination of $L_r$ (in.)
$r_y$	=	radius of gyration about the y-axis (in.)
$S_x$	=	elastic section modulus about the x-axis (in. <sup>3</sup> )
$t_f$	=	thickness of the flange (in.). For rolled channels, use the average thickness.
$t_w$	=	thickness of the web (in.)

For channels in flexure about their weak or y-axis, the nominal flexural resistance shall be determined according to the provisions specified in Article 6.12.2.2.1. The nominal flexural resistance shall not exceed  $1.6F_yS_y$ , where  $S_y$  is the elastic section modulus about the y-axis.

The flange slenderness,  $\lambda_f$ , of fabricated or bent-plate channels shall satisfy:

$$\lambda_f \leq \lambda_{pf} \quad (6.12.2.2.5-10)$$

in which:

$$\begin{aligned} \lambda_f &= \text{flange slenderness of the channel} = b_f/t_f \\ \lambda_{pf} &= \text{limiting slenderness for a compact flange} \\ &= 0.38\sqrt{\frac{E}{F_y}} \quad (6.12.2.2.5-11) \end{aligned}$$

where:

$$\begin{aligned} b_f &= \text{flange width (in.)} \\ t_f &= \text{flange thickness (in.)} \end{aligned}$$

The web slenderness of fabricated or bent-plate channels shall satisfy:

$$\frac{D}{t_w} \leq \lambda_{pw} \quad (6.12.2.2.5-12)$$

in which:

$$\lambda_{pw} = \text{limiting slenderness for a compact web}$$

$$= 3.76 \sqrt{\frac{E}{F_y}} \quad (6.12.2.2.5-13)$$

where:

$D$  = web depth (in.)

$t_w$  = web thickness (in.)

#### 6.12.2.6—Single Angles

Single angles should not be used as pure flexural members. Single angles subject to combined axial compression and flexure may be designed according to the provisions specified in Article 6.9.4.4.

#### C6.12.2.2.6

Single angles are not typically intended to serve as pure flexural members in bridge applications. In most practical applications, single angles are subject to flexure about both principal axes due to the eccentricity of applied axial loads. The condition of flexure due to eccentric axial tension is primarily addressed through the use of the shear lag coefficient,  $U$ , specified in Article 6.8.2.2. The condition of flexure due to eccentric axial compression may be efficiently handled through the use of an effective slenderness ratio,  $(K\ell/r)_{eff}$ , as specified in Article 6.9.4.4, which allows single angles satisfying certain specified conditions to be designed as axially loaded compression members for flexural buckling only. Thus, the calculation of the nominal flexural resistance  $M_n$  of a single-angle member is typically not required for these common cases. In certain unusual cases discussed in Article C6.9.4.4, single angles subject to combined flexure and axial compression must be evaluated as beam-columns according to the provisions specified in Section H2 of AISC (2005) in lieu of using the effective slenderness ratio. In such cases,  $M_n$  of the single angle member may be determined according to the procedures given in Section F10 of AISC (2005).

#### 6.12.2.2.7—Rectangular Bars and Solid Rounds

For rectangular bars and solid rounds in flexure, the nominal flexural resistance shall be taken as the smaller value based on yielding or lateral torsional buckling, as applicable.

For yielding, the nominal flexural resistance shall be taken as:

- For rectangular bars with  $\frac{L_b d}{t^2} \leq \frac{0.08E}{F_y}$  in flexure

about their major geometric axis, rectangular bars in flexure about their minor geometric axis, and solid rounds:

$$M_n = M_p = F_v Z \leq 1.6M_y \quad (6.12.2.2.7-1)$$

where:

#### C6.12.2.2.7

These provisions apply to solid bars of round or rectangular cross-section and are taken from AISC (2005). The nominal flexural resistance of these sections will typically be controlled by yielding, except for rectangular bars with a depth larger than the width, which may be controlled by lateral torsional buckling. Since the shape factor for a rectangular cross-section is 1.5 and for a round cross-section is 1.7, the potential for excessive deflections or permanent deformations under service conditions should be considered.

$d$  = depth of the rectangular bar (in.)

$F_y$  = specified minimum yield strength (ksi)

$L_b$  = unbraced length for lateral displacement or twist,  
as applicable (in.)

$M_p$  = plastic moment (kip-in.)

$M_y$  = yield moment (kip-in.)

$t$  = width of the rectangular bar parallel to the axis of  
bending (in.)

$Z$  = plastic section modulus (in.<sup>3</sup>)

For lateral torsional buckling, the nominal flexural resistance shall be taken as follows for rectangular bars in flexure about their major geometric axis:

- If  $\frac{0.08E}{F_y} < \frac{L_b d}{t^2} \leq \frac{1.9E}{F_y}$ , then:

$$M_n = C_b \left[ 1.52 - 0.274 \left( \frac{L_b d}{t^2} \right) \frac{F_y}{E} \right] M_y \leq M_p \quad (6.12.2.2.7-2)$$

- If  $\frac{L_b d}{t^2} > \frac{1.9E}{F_y}$ , then:

$$M_n = F_{cr} S_x \leq M_p \quad (6.12.2.2.7-3)$$

in which:

$$F_{cr} = \frac{1.9EC_b}{\frac{L_b d}{t^2}} \text{ (ksi)}$$

where:

$C_b$  = moment gradient modifier determined as  
specified in Article A6.3.3

$S_x$  = section modulus about the major geometric axis  
(in.<sup>3</sup>)

For rectangular bars in flexure about their minor geometric axis and for solid rounds, lateral torsional buckling shall not be considered.

### 6.12.2.3—Composite Members

#### 6.12.2.3.1—Concrete-Encased Shapes

For concrete-encased shapes that satisfy the provisions of Article 6.9.5.2.3, the nominal resistance of concrete-encased shapes subjected to flexure without compression shall be taken as the lesser of:

$$M_n = M_{ps}, \text{ or} \quad (6.12.2.3.1-1)$$

$$M_n = M_{yc} \quad (6.12.2.3.1-2)$$

For the purpose of Article 6.9.2.2, the nominal flexural resistance of concrete-encased shapes subjected to compression and flexure shall be taken as:

- If  $\frac{P_u}{\phi_c P_n} \geq 0.3$ , then:

$$M_n = Z F_y + \frac{(d - 2c) A_r F_{yr}}{3} + \left( \frac{d}{2} - \frac{A_w F_y}{1.7 f'_c b} \right) A_w F_y \quad (6.12.2.3.1-3)$$

- If  $0.0 < \left( \frac{P_u}{\phi_c P_n} \right) < 0.3$ , then:

$M_n$  shall be determined by a linear interpolation between the  $M_n$  value given by Eq. 6.12.2.3.1-1 or 6.12.2.3.1-2 at  $P_u = 0$  and the  $M_n$  value given by Eq. 6.12.2.3.1-3 at  $(P_u/\phi_c P_n) \geq 0.3$

where:

$P_u$  = axial compressive force due to the factored loading (kip)

$P_n$  = nominal compressive resistance specified in Article 6.9.5.1 (kip)

$\phi_c$  = resistance factor for axial compression specified in Article 6.5.4.2

$M_{ps}$  = plastic moment of the steel section (kip-in.)

$M_{yc}$  = yield moment of the composite section determined as specified in Article D6.2 (kip-in.)

$Z$  = plastic section modulus of the steel section about the axis of bending (in.<sup>3</sup>)

$A_w$  = web area of the steel section (in.<sup>2</sup>)

$f'_c$  = specified minimum 28-day compressive strength of the concrete (ksi)

#### C6.12.2.3.1

The behavior of the concrete-encased shapes and concrete-filled tubes covered in this Article is discussed extensively in Galambos (1998) and AISC (2005). Such members are most often used as columns or beam columns. The provisions for circular concrete-filled tubes also apply to concrete-filled pipes.

The equation for  $M_n$  when  $(P_u/\phi_c P_n) \geq 0.3$  is an approximate equation for the plastic moment resistance that combines the flexural strengths of the steel shape, the reinforcing bars, and the reinforced concrete. These resistances are defined in the first, second, and third terms of the equation respectively (Galambos, 1998). The equation has been verified by extensive tests (Galambos and Chapuis, 1980).

No test data are available on the loss of bond in composite beam columns. However, consideration of tensile cracking of concrete suggests  $(P_u/\phi_c P_n) = 0.3$  as a conservative limit (AISC, 1999). It is assumed that when  $(P_u/\phi_c P_n)$  is less than 0.3, the nominal flexural resistance is reduced below the plastic moment resistance of the composite section given by Eq. 6.12.2.3.1-3.

When there is no axial load, even with full encasement, it is assumed that the bond is only capable of developing the lesser of the plastic moment resistance of the steel section or the yield moment resistance of the composite section.

$A_r$  = area of the longitudinal reinforcement (in.<sup>2</sup>)

$c$  = distance from the center of the longitudinal reinforcement to the nearest face of the member in the plane of flexure (in.)

$d$  = depth of the member in the plane of flexure (in.)

$b$  = width of the member perpendicular to the plane of flexure (in.)

$F_{yr}$  = specified minimum yield strength of the longitudinal reinforcement (ksi)

#### 6.12.2.3.2—Concrete-Filled Tubes

The nominal flexural resistance of concrete-filled tubes that satisfy the limitations in Articles 6.9.5.2 may be taken as:

- If  $\frac{D}{t} < 2.0 \sqrt{\frac{E}{F_y}}$ , then:

$$M_n = M_{ps} \quad (6.12.2.3.2-1)$$

- If  $2.0 \sqrt{\frac{E}{F_y}} < \frac{D}{t} \leq 8.8 \sqrt{\frac{E}{F_y}}$ , then:

$$M_n = M_{yc} \quad (6.12.2.3.2-2)$$

#### C6.12.2.3.2

Eqs. 6.12.2.3.2-1 and 6.12.2.3.2-2 represent a step function for nominal flexural resistance. No accepted transition equation is available at this writing.

### 6.12.3—Nominal Shear Resistance of Composite Members

#### 6.12.3.1—Concrete-Encased Shapes

The nominal shear resistance may be taken as:

$$V_n = 0.58 F_{yw} D t_w + \frac{F_{yr} A_v (d - c)}{s} \quad (6.12.3.1-1)$$

where:

$F_{yw}$  = specified minimum yield strength of the web of the steel shape (ksi)

$F_{yr}$  = specified minimum yield strength of the transverse reinforcement (ksi)

$D$  = web depth of the steel shape (in.)

$t_w$  = thickness of the web or webs of the steel shape (in.)

$A_v$  = cross-sectional area of transverse reinforcement bars that intercept a diagonal shear crack (in.<sup>2</sup>)

$s$  = longitudinal spacing of transverse reinforcement (in.)

$d$  = depth of the member in the plane of shear (in.)

$c$  = distance from the center of the longitudinal reinforcement to the nearest face of the member in the plane of bending (in.)

### 6.12.3.2—Concrete-Filled Tubes

#### 6.12.3.2.1—Rectangular Tubes

The nominal shear resistance may be taken as:

$$V_n = 1.16 D t_w F_y \quad (6.12.3.2.1-1)$$

where:

$D$  = web depth of the tube (in.)

$t_w$  = wall thickness of the tube (in.)

#### 6.12.3.2.2—Circular Tubes

The nominal shear resistance may be taken as:

$V_n$  = nominal shear resistance of the steel tube alone (kip)

## 6.13—CONNECTIONS AND SPLICES

### 6.13.1—General

Except as specified otherwise, connections and splices for primary members shall be designed at the strength limit state for not less than the larger of:

- The average of the flexural moment-induced stress, shear, or axial force due to the factored loadings at the point of splice or connection and the factored flexural, shear, or axial resistance of the member or element at the same point, or
- 75 percent of the factored flexural, shear, or axial resistance of the member or element.

Where diaphragms, cross-frames, lateral bracing, stringers, or floorbeams for straight or horizontally curved flexural members are included in the structural model used to determine force effects, or alternatively, are designed for explicitly calculated force effects from the results of a separate investigation, end connections for these bracing members shall be designed for the calculated factored member force effects. Otherwise, the end connections for these members shall be designed according to the 75 percent resistance provision contained herein.

### C6.13.1

Where a section changes at a splice, the smaller section is to be used for these requirements. These requirements are retained from AASHTO (2002).

The exception for bracing members for straight or horizontally curved flexural members that are included in the structural model used to determine force effects results from experience with details developed invoking the 75 percent and average load provisions herein. These details tended to become so large as to be unwieldy resulting in large eccentricities and force concentrations. It has been decided that the negatives associated with these connections justifies the exception permitted herein.

Insofar as practicable, connections should be made symmetrical about the axis of the members. Connections, except for lacing bars and handrails, shall contain not less than two bolts. Members, including bracing, should be connected so that their gravity axes will intersect at a point. Eccentric connections should be avoided. Where eccentric connections cannot be avoided, members and connections shall be proportioned for the combined effects of shear and moment due to the eccentricity.

In the case of connections that transfer total member end shear, the gross section shall be taken as the gross section of the connected elements.

The thickness of end connection angles of stringers, floorbeams and girders shall not be less than 0.375 in. End connections for stringers, floorbeams and girders should be made with two angles. Bracket or shelf angles that may be used to furnish support during erection shall not be considered in determining the number of fasteners required to transmit end shear.

Unless otherwise permitted by the contract documents, standard-size bolt holes shall be used in connections in horizontally curved bridges.

End connections of stringers, floorbeams, and girders should be bolted with high-strength bolts. Welded connections may be permitted when bolting is not practical. Where used, welded end connections shall be designed for vertical loads and the bending moment resulting from the restraint against end rotation.

Where timber stringers frame into steel floorbeams, shelf angles with stiffeners shall be provided to support the total reaction. Shelf angles shall not be less than 0.4375 in. thick.

Standard-size bolt holes in connections in horizontally curved bridges ensure that the steel fits together in the field.

## 6.13.2—Bolted Connections

### 6.13.2.1—General

Bolted steel parts may be coated or uncoated and shall fit solidly together after the bolts are tightened. The contract documents shall specify that all joint surfaces, including surfaces adjacent to the bolt head and nut, shall be specified to be free of scale, except tight mill scale, and free of dirt or other foreign material.

High-strength bolted joints shall be designated as either slip-critical or bearing-type connections. For slip-critical connections, the friction value shall be consistent with the specified condition of the faying surfaces as specified in Article 6.13.2.8. All material within the grip of the bolt shall be steel.

#### 6.13.2.1.1—Slip-Critical Connections

Joints subject to stress reversal, heavy impact loads, severe vibration or located where stress and strain due to joint slippage would be detrimental to the serviceability of the structure shall be designated as slip-critical. They include:

#### C6.13.2.1.1

In bolted slip-critical connections subject to shear, the load is transferred between the connected parts by friction up to a certain level of force that is dependent upon the total clamping force on the faying surfaces and the coefficient of friction of the faying surfaces. The

- Joints subject to fatigue loading;
- Joints in shear with bolts installed in oversized holes;
- Joints in shear with bolts installed in short- and long-slotted holes where the force on the joint is in a direction other than perpendicular to the axis of the slot, except where the Engineer intends otherwise and so indicates in the contract documents;
- Joints subject to significant load reversal;
- Joints in which welds and bolts share in transmitting load at a common faying surface;
- Joints in axial tension or combined axial tension and shear;
- Joints in axial compression only, with standard or slotted holes in only one ply of the connection with the direction of the load perpendicular to the direction of the slot, except for connections designed according to the provisions specified in Article 6.13.6.1.3; and
- Joints in which, in the judgment of the Engineer, any slip would be critical to the performance of the joint or the structure and which are so designated in the contract documents.

Slip-critical connections shall be proportioned to prevent slip under Load Combination Service II, as specified in Table 3.4.1-1, and to provide bearing, shear, and tensile resistance at the applicable strength limit state load combinations. The provisions of Article 6.13.2.2 apply.

#### *6.13.2.1.2—Bearing-Type Connections*

Bearing-type connections shall be permitted only for joints subjected to axial compression or joints on bracing members and shall satisfy the factored resistance,  $R_r$ , at the strength limit state.

#### **6.13.2.2—Factored Resistance**

For slip-critical connections, the factored resistance,  $R_r$ , of a bolt at the Service II Load Combination shall be taken as:

$$R_r = R_n \quad (6.13.2.2-1)$$

connectors are not subject to shear, nor is the connected material subject to bearing stress. As loading is increased to a level in excess of the frictional resistance between the faying surfaces, slip occurs, but failure in the sense of rupture does not occur. As a result, slip-critical connections are able to resist even greater loads by shear and bearing against the connected material. The strength of the connection is not related to the slip load. These Specifications require that the slip resistance and the shear and bearing resistance be computed separately. Because the combined effect of frictional resistance with shear or bearing has not been systematically studied and is uncertain, any potential greater resistance due to combined effect is ignored.

For slotted holes, perpendicular to the slot is defined as an angle between approximately 80 to 100 degrees to the axis of the slot.

The intent of this provision is to control permanent deformations under overloads caused by slip in joints that could adversely affect the serviceability of the structure. The provisions are intended to apply to the design live load specified in Article 3.6.1.1. If this criterion were to be applied to a permit load situation, a reduction in the load factor for live load should be considered. Slip-critical connections must also be checked for the strength load combinations in Table 3.4.1-1, assuming that the connection has slipped at these high loads and gone into bearing against the connected material.

#### *C6.13.2.1.2*

In bolted bearing-type connections, the load is resisted by shear in the fastener and bearing upon the connected material, plus some uncertain amount of friction between the faying surfaces. The final failure will be by shear failure of the connectors, by tear out of the connected material, or by unacceptable ovalization of the holes. Final failure load is independent of the clamping force provided by the bolts (Kulak et al., 1987).

#### **C6.13.2.2**

Eq. 6.13.2.2-1 applies to a service limit state for which the resistance factor is 1.0, and, hence, is not shown in the equation.

where:

$R_n$  = nominal resistance as specified in Article 6.13.2.8

The factored resistance,  $R_r$  or  $T_r$ , of a bolted connection at the strength limit state shall be taken as either:

$$R_r = \phi R_n \quad (6.13.2.2-2)$$

$$T_r = \phi T_n \quad (6.13.2.2-3)$$

where:

$R_n$  = nominal resistance of the bolt, connection, or connected material as follows:

- For bolts in shear,  $R_n$  shall be taken as specified in Article 6.13.2.7
- For the connected material in bearing joints,  $R_n$  shall be taken as specified in Article 6.13.2.9
- For connected material in tension or shear,  $R_n$  shall be taken as specified in Article 6.13.5

$T_n$  = nominal resistance of a bolt as follows:

- For bolts in axial tension,  $T_n$  shall be taken as specified in Article 6.13.2.10
- For bolts in combined axial tension and shear,  $T_n$  shall be taken as specified in Article 6.13.2.11

$\phi$  = resistance factor for bolts specified in Article 6.5.4.2, taken as:

- $\phi_s$  for bolts in shear,
- $\phi_t$  for bolts in tension,
- $\phi_{bb}$  for bolts bearing on material,
- $\phi_y$  or  $\phi_u$  for connected material in tension, as appropriate, or
- $\phi_v$  for connected material in shear.

### 6.13.2.3—Bolts, Nuts, and Washers

#### 6.13.2.3.1—Bolts and Nuts

The provisions of Article 6.4.3 shall apply.

#### 6.13.2.3.2—Washers

Washers used in bolted connections shall satisfy the requirements specified in Article 6.4.3. Hardened washers for high-strength bolted connections shall be required where:

Proper location of hardened washers is as important to the performance of the bolts as other elements of a detail. Drawings and details should clearly reflect the number and disposition of washers, especially the washers that are required for slotted-hole applications.

- The outer face of the bolted parts has a slope greater than 1:20, with respect to a plane normal to the bolt axis;
- Tightening is to be performed by the calibrated wrench method, in which case the washer shall be used under the element turned in tightening;
- AASHTO M 253 ([ASTM A490](#)) bolts are to be installed in material having a specified minimum yield strength less than 50.0 ksi, irrespective of the tightening method;
- Needed for oversize or slotted holes according to the provisions specified herein;
- AASHTO M 253 ([ASTM A490](#)) bolts over 1.0 in. in diameter are to be installed in an oversize or short-slotted hole in an outer-ply, in which case a minimum thickness of 0.3125 in. shall be used under both the head and the nut. Multiple hardened washers shall not be used.

Hardened washers shall be installed over oversize and short-slotted holes in an outer ply.

Structural plate washers or a continuous bar with standard holes, not less than 0.3125 in. in thickness, shall be required to completely cover long-slotted holes. Hardened washers for use with high-strength bolts shall be placed over the outer surface of the plate washer or bar.

Load indicator devices shall not be installed over oversize or slotted holes in an outer ply, unless a hardened washer or a structural plate washer is also provided.

#### **6.13.2.4—Holes**

##### *6.13.2.4.1—Type*

###### *6.13.2.4.1a—General*

Unless specified otherwise, standard holes shall be used in high-strength bolted connections.

###### *6.13.2.4.1b—Oversize Holes*

Oversize holes may be used in any or all plies of slip-critical connections. They shall not be used in bearing-type connections.

###### *6.13.2.4.1c—Short-Slotted Holes*

Short-slotted holes may be used in any or all plies of slip-critical or bearing-type connections. The slots may be used without regard to direction of loading in slip-critical connections, but the length shall be normal to the direction of the load in bearing-type connections.

#### 6.13.2.4.1d—Long-Slotted Holes

Long-slotted holes may be used in only one ply of either a slip-critical or bearing-type connection. Long-slotted holes may be used without regard to direction of loading in slip-critical connections but shall be normal to the direction of load in bearing-type connections.

#### 6.13.2.4.2—Size

The dimension of the holes shall not exceed the values given in Table 6.13.2.4.2-1.

**Table 6.13.2.4.2-1—Maximum Hole Sizes**

Bolt Dia.	Standard	Oversize	Short Slot	Long Slot
$d$	Dia.	Dia.	Width × Length	Width × Length
in.	in.	in.	in.	in.
5/8	11/16	13/16	11/16 × 7/8	11/16 × 1-9/16
3/4	13/16	15/16	13/16 × 1	13/16 × 1-7/8
7/8	15/16	1-1/16	15/16 × 1-1/8	15/16 × 2-3/16
1	1-1/16	1-1/4	1-1/16 × 1-5/16	1-1/16 × 2-1/2
$\geq 1-1/8$	$d+1/16$	$d+5/16$	$d+1/16 \times d+3/8$	$d+1/16 \times 2.5d$

#### 6.13.2.5—Size of Bolts

Bolts shall not be less than 0.625 in. in diameter. Bolts 0.625 in. in diameter shall not be used in primary members, except in 2.5-in. legs of angles and in flanges of sections whose dimensions require 0.625-in. fasteners to satisfy other detailing provisions herein. Use of structural shapes that do not allow the use of 0.625-in. fasteners shall be limited to handrails.

Angles whose size is not determined by a calculated demand may use:

- 0.625-in. diameter bolts in 2.0-in. legs,
- 0.75-in. diameter bolts in 2.5-in. legs,
- 0.875-in. diameter bolts in 3.0-in. legs, and
- 1.0-in. diameter bolts in 3.5-in. legs.

The diameter of bolts in angles of primary members shall not exceed one-fourth the width of the leg in which they are placed.

#### 6.13.2.6—Spacing of Bolts

##### 6.13.2.6.1—Minimum Spacing and Clear Distance

The minimum spacing between centers of bolts in standard holes shall be no less than three times the diameter of the bolt. When oversize or slotted holes are used, the minimum clear distance between the edges of adjacent bolt holes in the direction of the force and transverse to the direction of the force shall not be less than twice the diameter of the bolt.

##### C6.13.2.6.1

In uncoated weathering steel structures, pack-out is not expected to occur in joints where bolts satisfy the maximum spacing requirements specified in Article 6.13.2.6.2 (Brockenbrough, 1983).

#### *6.13.2.6.2—Maximum Spacing for Sealing Bolts*

For sealing against the penetration of moisture in joints, the spacing on a single line adjacent to a free edge of an outside plate or shape shall satisfy:

$$s \leq (4.0 + 4.0t) \leq 7.0 \quad (6.13.2.6.2-1)$$

If there is a second line of fasteners uniformly staggered with those in the line adjacent to the free edge, at a gage less than  $1.5 + 4.0t$ , the staggered spacing,  $s$ , in two such lines, considered together, shall satisfy:

$$s \leq 4.0 + 4.0t - \left( \frac{3.0g}{4.0} \right) \leq 7.0 \quad (6.13.2.6.2-2)$$

The staggered spacing need not be less than one-half the requirement for a single line.

where:

$t$  = thickness of the thinner outside plate or shape (in.)

$g$  = gage between bolts (in.)

#### *6.13.2.6.3—Maximum Pitch for Stitch Bolts*

Stitch bolts shall be used in mechanically fastened buildup members where two or more plates or shapes are in contact.

The pitch of stitch bolts in compression members shall not exceed  $12.0t$ . The gage,  $g$ , between adjacent lines of bolts shall not exceed  $24.0t$ . The staggered pitch between two adjacent lines of staggered holes shall satisfy:

$$p \leq 15.0t - \left( \frac{3.0g}{8.0} \right) \leq 12.0t \quad (6.13.2.6.3-1)$$

The pitch for tension members shall not exceed twice that specified herein for compression members. The gage for tension members shall not exceed  $24.0t$ . The maximum pitch of fasteners in mechanically fastened buildup members shall not exceed the lesser of the requirements for sealing or stitch.

#### *6.13.2.6.4—Maximum Pitch for Stitch Bolts at the End of Compression Members*

The pitch of bolts connecting the component parts of a compression member shall not exceed four times the diameter of the fastener for a length equal to 1.5 times the maximum width of the member. Beyond this length, the pitch may be increased gradually over a length equal to 1.5 times the maximum width of the member until the maximum pitch specified in Article 6.13.2.6.3 is reached.

#### *C6.13.2.6.3*

The intent of this provision is to ensure that the parts act as a unit and, in compression members, prevent buckling.

#### 6.13.2.6.5—End Distance

The end distance for all types of holes measured from the center of the bolt shall not be less than the edge distances specified in Table 6.13.2.6.6-1. When oversize or slotted holes are used, the minimum clear end distance shall not be less than the bolt diameter.

The maximum end distance shall be the maximum edge distance as specified in Article 6.13.2.6.6.

#### 6.13.2.6.6—Edge Distances

The minimum edge distance shall be as specified in Table 6.13.2.6.6-1.

The maximum edge distance shall not be more than eight times the thickness of the thinnest outside plate or 5.0 in.

**Table 6.13.2.6.6-1—Minimum Edge Distances**

Bolt Diameter in.	Sheared Edges in.	Rolled Edges of Plates or Shapes, or Gas Cut Edges in.
5/8	1-1/8	7/8
3/4	1-1/4	1
7/8	1-1/2	1-1/8
1	1-3/4	1-1/4
1-1/8	2	1-1/2
1-1/4	2-1/4	1-5/8
1-3/8	2-3/8	1-3/4

#### 6.13.2.7—Shear Resistance

The nominal shear resistance of a high-strength bolt ([ASTM A325](#) or [ASTM A490](#)) or an [ASTM A307](#) bolt (Grade A or B) at the strength limit state in joints whose length between extreme fasteners measured parallel to the line of action of the force is less than 50.0 in. shall be taken as:

- Where threads are excluded from the shear plane:

$$R_n = 0.48A_b F_{ub} N_s \quad (6.13.2.7-1)$$

- Where threads are included in the shear plane:

$$R_n = 0.38A_b F_{ub} N_s \quad (6.13.2.7-2)$$

where:

$A_b$  = area of the bolt corresponding to the nominal diameter (in.<sup>2</sup>)

#### C6.13.2.7

The nominal resistance in shear is based upon the observation that the shear strength of a single high-strength bolt is about 0.60 times the tensile strength of that bolt (Kulak et al., 1987). However, in shear connections with more than two bolts in the line of force, deformation of the connected material causes nonuniform bolt shear force distribution so that the strength of the connection in terms of the average bolt strength decreases as the joint length increases. Rather than provide a function that reflects this decrease in average fastener strength with joint length, a single reduction factor of 0.80 was applied to the 0.60 multiplier. This accommodates bolts in joints up to 50.0 in. in length without seriously affecting the economy of very short joints. The nominal shear resistance of bolts in joints longer than 50.0 in. must be further reduced by an additional 20 percent. Studies have shown that the allowable stress factor of safety against shear failure ranges from 3.3 for compact, i.e., short, joints to approximately 2.0 for joints with an overall length in excess of 50.0 in. It is of interest to note that the longest

$F_{ub}$  = specified minimum tensile strength of the bolt specified in Article 6.4.3 (ksi)

$N_s$  = number of shear planes per bolt

The nominal shear resistance of a bolt in connections greater than 50.0 in. in length shall be taken as 0.80 times the value given by Eq. 6.13.2.7-1 or 6.13.2.7-2.

In determining whether the bolt threads are excluded from the shear planes of the contact surfaces, the thread length of the bolt shall be determined as two thread pitch lengths greater than the specified thread length.

If the threads of a bolt are included in the shear plane in the joint, the shear resistance of the bolt in all shear planes of the joint shall be the value for threads included in the shear plane.

For [ASTM A307](#) bolts, shear design shall be based on Eq. 6.13.2.7-2. When the grip length of an [ASTM A307](#) bolt exceeds 5.0 diameters, the nominal resistance shall be lowered one percent for each 1/16 in. of grip in excess of 5.0 diameters.

and often the most important joints had the lowest factor, indicating that a factor of safety of 2.0 has proven satisfactory in service (Kulak et al., 1987). For flange splices, the 50.0-in. length is to be measured between the extreme bolts on only one side of the connection.

The average value of the nominal resistance for bolts with threads in the shear plane has been determined by a series of tests to be 0.833 ( $0.6F_{ub}$ ), with a standard deviation of 0.03 (Yura et al., 1987). A value of about 0.80 was selected for the specification formula based upon the area corresponding to the nominal body area of the bolt.

The shear strength of bolts is not affected by pretension in the fasteners, provided that the connected material is in contact at the faying surfaces.

The factored resistance equals the nominal shear resistance multiplied by a resistance factor less than that used to determine the factored resistance of a component. This ensures that the maximum strength of the bridge is limited by the strength of the main members rather than by the connections.

The absence of design strength provisions specifically for the case where a bolt in double shear has a nonthreaded shank in one shear plane and a threaded section in the other shear plane is because of the uncertainty of manner of sharing the load between the two shear areas. It also recognizes that knowledge about the bolt placement, which might leave both shear planes in the threaded section, is not ordinarily available to the designer.

The threaded length of an [ASTM A307](#) bolt is not as predictable as that of a high-strength bolt. The requirement to use Eq. 6.13.2.7-2 reflects that uncertainty.

[ASTM A307](#) bolts with a long grip tend to bend, thus reducing their resistance.

### 6.13.2.8—Slip Resistance

The nominal slip resistance of a bolt in a slip-critical connection shall be taken as:

$$R_n = K_h K_s N_s P_t \quad (6.13.2.8-1)$$

where:

$N_s$  = number of slip planes per bolt

$P_t$  = minimum required bolt tension specified in Table 6.13.2.8-1 (kip)

$K_h$  = hole size factor specified in Table 6.13.2.8-2

$K_s$  = surface condition factor specified in Table 6.13.2.8-3

### C6.13.2.8

Extensive data developed through research has been statistically analyzed to provide improved information on slip probability of connections in which the bolts have been preloaded to the requirements of Table 6.13.2.8-1. Two principal variables, bolt pretension and coefficient of friction, i.e., the surface condition factor of the faying surfaces, were found to have the greatest effect on the slip resistance of connections.

Hole size factors less than 1.0 are provided for bolts in oversize and slotted holes because of their effects on the induced tension in bolts using any of the specified installation methods. In the case of bolts in long-slotted holes, even though the slip load is the same for bolts loaded transverse or parallel to the axis of the slot, the values for bolts loaded parallel to the axis have been further reduced, based upon judgment, because of the greater consequences of slip.

**Table 6.13.2.8-1—Minimum Required Bolt Tension**

Bolt Diameter, in.	Required Tension- $P_t$ (kip)	
	M 164 ( <a href="#">A325</a> )	M 253 ( <a href="#">A490</a> )
5/8	19	24
3/4	28	35
7/8	39	49
1	51	64
1-1/8	56	80
1-1/4	71	102
1-3/8	85	121
1-1/2	103	148

**Table 6.13.2.8-2—Values of  $K_h$** 

For standard holes	1.00
For oversize and short-slotted holes	0.85
For long-slotted holes with the slot perpendicular to the direction of the force	0.70
For long-slotted holes with the slot parallel to the direction of the force	0.60

**Table 6.13.2.8-3—Values of  $K_s$** 

For Class A surface conditions	0.33
For Class B surface conditions	0.50
For Class C surface conditions	0.33

The following descriptions of surface condition shall apply to Table 6.13.2.8-3:

- Class A Surface: unpainted clean mill scale, and blast-cleaned surfaces with Class A coatings,
- Class B Surface: unpainted blast-cleaned surfaces and blast-cleaned surfaces with Class B coatings, and
- Class C Surface: hot-dip galvanized surfaces roughened by wire brushing after galvanizing.

The contract documents shall specify that in uncoated joints, paint, including any inadvertent overspray, be excluded from areas closer than one bolt diameter but not less than 1.0 in. from the edge of any hole and all areas within the bolt pattern.

The criteria for slip resistance are for the case of connections subject to a coaxial load. For cases in which the load tends to rotate the connection in the plane of the faying surface, a modified formula accounting for the placement of bolts relative to the center of rotation should be used (Kulak et al., 1987).

The required tension specified for AASHTO M 164 ([ASTM A325](#)) bolts larger than M24 reflects an update from the ISO specification that lists identical material properties for the size range from M16 to M36. This update has not yet been applied to the customary U.S. Specifications.

The minimum bolt tension values given in Table 6.13.2.8-1 are equal to 70 percent of the minimum tensile strength of the bolts. The same percentage of the tensile strength has been traditionally used for the required tension of the bolts.

The effect of ordinary paint coatings on limited portions of the contact area within joints and the effect of overspray over the total contact area have been investigated experimentally (Polyzois and Frank, 1986). The tests demonstrated that the effective area for transfer of shear by friction between contact surfaces was concentrated in an annular ring around and close to the bolts. Paint on the contact surfaces approximately 1.0 in., but not less than the bolt diameter away from the edge of the hole did not reduce the slip resistance. On the other hand, bolt pretension might not be adequate to completely flatten and pull thick material into tight contact around every bolt. Therefore, these Specifications require that all areas between bolts also be free of paint.

The contract documents shall specify that joints having painted faying surfaces be blast-cleaned and coated with a paint that has been qualified by test as a Class A or Class B coating.

Subject to the approval of the Engineer, coatings providing a surface condition factor less than 0.33 may be used, provided that the mean surface condition factor is established by test. The nominal slip resistance shall be determined as the nominal slip resistance for Class A surface conditions, as appropriate for the hole and bolt type, times the surface condition factor determined by test divided by 0.33.

The contract documents shall specify that:

- Coated joints not be assembled before the coatings have cured for the minimum time used in the qualifying test, and
- Faying surfaces specified to be galvanized shall be hot-dip galvanized in accordance with AASHTO M 111M/M 111 ([ASTM A123/A123M](#)). The surfaces shall subsequently be roughened by means of hand-wire brushing. Power-wire brushing shall not be permitted.

If a slip-critical connection is subject to an applied tensile force that reduces the net clamping force, the nominal slip resistance shall be multiplied by the factor specified by Eq. 6.13.2.11-3.

On clean mill scale, this research found that even the smallest amount of overspray of ordinary paint, i.e., a coating not qualified as Class A, within the specified paint-free area, reduced the slip resistance significantly. On blast-cleaned surfaces, the presence of a small amount of overspray was not as detrimental. For simplicity, these Specifications prohibit any overspray from areas required to be free of paint in slip-critical joints, regardless of whether the surface is clean mill scale or blast-cleaned.

The mean value of slip coefficients from many tests on clean mill scale, blast-cleaned steel surfaces and galvanized and roughened surfaces were taken as the basis for the three classes of surfaces. As a result of research by Frank and Yura (1981), a test method to determine the slip coefficient for coatings used in bolted joints was developed (AISC, 1994). The method includes long-term creep test requirements to ensure reliable performance for qualified paint coatings. The method, which requires requalification if an essential variable is changed, is the sole basis for qualification of any coating to be used under these Specifications. Further, normally only two categories of surface conditions for paints to be used in slip-critical joints are recognized: Class A for coatings that do not reduce the slip coefficient below that provided by clean mill scale, and Class B for paints that do not reduce the slip coefficient below that of blast-cleaned steel surfaces.

To cover those cases where a coefficient of friction less than 0.33 might be adequate, the Specification provides that, subject to the approval of the Engineer, and provided that the mean slip coefficient is determined by the specified test procedure, faying surface coatings providing lower slip resistance than Class A coating may be used. It should be noted that both Class A and Class B coatings are required to be applied to blast-cleaned steel.

The research cited in the preceding paragraph also investigated the effect of varying the time from coating the faying surfaces to assembly to ascertain if partially cured paint continued to cure. It was found that all curing ceased at the time the joint was assembled and tightened and that paint coatings that were not fully cured acted as lubricant. Thus, the slip resistance of the joint was severely reduced.

On galvanized faying surfaces, research has shown that the slip factor of galvanized surfaces is significantly improved by treatments, such as hand wire brushing or light "brush-off" grit blasting (Birkemoe and Herrschaft, 1970). In either case, the treatment must be controlled in order to achieve the necessary roughening or scoring. Power wire brushing is unsatisfactory because it tends to polish rather than roughen the surface.

Tests on surfaces that were wire-brushed after galvanizing have indicated an average value of the slip coefficient equal to 0.35 (Kulak et al., 1987). Untreated surfaces with normal zinc have much smaller slip coefficients. Even though the slip coefficient for Class C surfaces is the same as for Class A surfaces, a separate class is retained to avoid potential confusion. The higher value of the slip coefficient equal to 0.40 in previous specifications assumes that the surface has been blast-cleaned after galvanizing, which is not the typical practice. Field experience and test results have indicated that galvanized members may have a tendency to continue to slip under sustained loading (Kulak et al., 1987). Tests of hot-dip galvanized joints subject to sustained loading show a creep-type behavior. Treatments to the galvanized faying surfaces prior to assembly of the joint that caused an increase in the slip resistance under short-duration loads did not significantly improve the slip behavior under sustained loading.

Where hot-dip galvanized coatings are used, and especially if the joint consists of many plies of thickly coated material, relaxation of bolt tension may be significant and may require retensioning of the bolts subsequent to the initial tightening. This loss may be allowed for in design or pretension may be brought back to the prescribed level by a retightening of the bolts after an initial period of "settling-in."

While slip-critical connections with bolts pretensioned to the levels specified in Table 6.13.2.8-1 do not ordinarily slip into bearing when subject to anticipated loads, it is required that they meet the requirements of Article 6.13.2.7 and Article 6.13.2.9 in order to maintain a factor of safety of 2.0, if the bolts slip into bearing as a result of large, unforeseen loads.

### 6.13.2.9—Bearing Resistance at Bolt Holes

The effective bearing area of a bolt shall be taken as its diameter multiplied by the thickness of the connected material on which it bears. The effective thickness of connected material with countersunk holes shall be taken as the thickness of the connected material, minus one-half the depth of the countersink.

For standard holes, oversize holes, short-slotted holes loaded in any direction, and long-slotted holes parallel to the applied bearing force, the nominal resistance of interior and end bolt holes at the strength limit state,  $R_n$ , shall be taken as:

- With bolts spaced at a clear distance between holes not less than  $2.0d$  and with a clear end distance not less than  $2.0d$ :

$$R_n = 2.4dtF_u \quad (6.13.2.9-1)$$

- If either the clear distance between holes is less than  $2.0d$ , or the clear end distance is less than  $2.0d$ :

### C6.13.2.9

Bearing stress produced by a high-strength bolt pressing against the side of the hole in a connected part is important only as an index to behavior of the connected part. Thus, the same bearing resistance applies regardless of bolt shear strength or the presence or absence of threads in the bearing area. The critical value can be derived from the case of a single bolt at the end of a tension member.

Using finger-tight bolts, it has been shown that a connected plate will not fail by tearing through the free edge of the material if the distance  $L$ , measured parallel to the line of applied force from a single bolt to the free edge of the member toward which the force is directed, is not less than the diameter of the bolt multiplied by the ratio of the bearing stress to the tensile strength of the connected part (Kulak et al., 1987).

The criterion for nominal bearing strength is:

$$\frac{L}{d} \geq \frac{r_n}{F_u} \quad (C6.13.2.9-1)$$

$$R_n = 1.2L_c t F_u \quad (6.13.2.9-2)$$

For long-slotted holes perpendicular to the applied bearing force:

- With bolts spaced at a clear distance between holes not less than  $2.0d$  and with a clear end distance not less than  $2.0d$ :

$$R_n = 2.0dtF_u \quad (6.13.2.9-3)$$

- If either the clear distance between holes is less than  $2.0d$ , or the clear end distance is less than  $2.0d$ :

$$R_n = L_c t F_u \quad (6.13.2.9-4)$$

where:

$d$  = nominal diameter of the bolt (in.)

$t$  = thickness of the connected material (in.)

$F_u$  = tensile strength of the connected material specified in Table 6.4.1-1 (ksi)

$L_c$  = clear distance between holes or between the hole and the end of the member in the direction of the applied bearing force (in.)

where:

$r_n$  = nominal bearing pressure (ksi)

$F_u$  = specified minimum tensile strength of the connected part (ksi)

In these Specifications, the nominal bearing resistance of an interior hole is based on the clear distance between the hole and the adjacent hole in the direction of the bearing force. The nominal bearing resistance of an end hole is based on the clear distance between the hole and the end of the member. The nominal bearing resistance of the connected member may be taken as the sum of the resistances of the individual holes. The clear distance is used to simplify the computations for oversize and slotted holes.

Holes may be spaced at clear distances less than the specified values, as long as the lower value specified by Eq. 6.13.2.9-2 or Eq. 6.13.2.9-4, as applicable, is used for the nominal bearing resistance.

### 6.13.2.10—Tensile Resistance

#### 6.13.2.10.1—General

High-strength bolts subjected to axial tension shall be tensioned to the force specified in Table 6.13.2.8-1. The applied tensile force shall be taken as the force due to the external factored loadings, plus any tension resulting from prying action produced by deformation of the connected parts, as specified in Article 6.13.2.10.4.

#### 6.13.2.10.2—Nominal Tensile Resistance

The nominal tensile resistance of a bolt,  $T_n$ , independent of any initial tightening force shall be taken as:

$$T_n = 0.76A_b F_{ub} \quad (6.13.2.10.2-1)$$

where:

$A_b$  = area of bolt corresponding to the nominal diameter (in.<sup>2</sup>)

$F_{ub}$  = specified minimum tensile strength of the bolt specified in Article 6.4.3 (ksi)

#### C6.13.2.10.2

The recommended design strength is approximately equal to the initial tightening force; thus, when loaded to the service load, high-strength bolts will experience little, if any, actual change in stress. For this reason, bolts in connections, in which the applied loads subject the bolts to axial tension, are required to be fully tensioned.

**6.13.2.10.3—Fatigue Resistance**

Where high-strength bolts in axial tension are subject to fatigue, the stress range,  $\Delta f$ , in the bolt, due to the fatigue design live load, plus the dynamic load allowance for fatigue loading specified in Article 3.6.1.4, plus the prying force resulting from cyclic application of the fatigue load, shall satisfy Eq. 6.6.1.2.2-1.

The nominal diameter of the bolt shall be used in calculating the bolt stress range. In no case shall the calculated prying force exceed 30 percent of the externally applied load.

Low carbon ASTM A307 bolts shall not be used in connections subjected to fatigue.

**6.13.2.10.4—Prying Action**

The tensile force due to prying action shall be taken as:

$$Q_u = \left[ \frac{3b}{8a} - \frac{t^3}{20} \right] P_u \quad (6.13.2.10.4-1)$$

where:

$Q_u$  = prying tension per bolt due to the factored loadings taken as 0 when negative (kip)

$P_u$  = direct tension per bolt due to the factored loadings (kip)

$a$  = distance from center of bolt to edge of plate (in.)

$b$  = distance from center of bolt to the toe of fillet of connected part (in.)

$t$  = thickness of thinnest connected part (in.)

**6.13.2.11—Combined Tension and Shear**

The nominal tensile resistance of a bolt subjected to combined shear and axial tension,  $T_n$ , shall be taken as:

- If  $\frac{P_u}{R_n} \leq 0.33$ , then:

$$T_n = 0.76 A_b F_{ub} \quad (6.13.2.11-1)$$

- Otherwise:

$$T_n = 0.76 A_b F_{ub} \sqrt{1 - \left( \frac{P_u}{\phi_s R_n} \right)^2} \quad (6.13.2.11-2)$$

where:

$A_b$  = area of the bolt corresponding to the nominal diameter (in.<sup>2</sup>)

**C6.13.2.10.3**

Properly tightened A325 and A490 bolts are not adversely affected by repeated application of the recommended service load tensile stress, provided that the fitting material is sufficiently stiff that the prying force is a relatively small part of the applied tension. The provisions covering bolt tensile fatigue are based upon study of test reports of bolts that were subjected to repeated tensile load to failure (Kulak et al., 1987).

**C6.13.2.10.4**

Eq. 6.13.2.10.4-1 for estimating the magnitude of the force due to prying is a simplification given in ASCE (1971) of a semiempirical expression (Douty and McGuire, 1965). This simplified formula tends to overestimate the prying force and provides conservative design results (Nair et al., 1974).

**C6.13.2.11**

The nominal tensile resistance of bolts subject to combined axial tension and shear is provided by elliptical interaction curves, which account for the connection length effect on bolts loaded in shear, the ratio of shear strength to tension strength of threaded bolts, and the ratios of root area to nominal body area and tensile stress area to nominal body area (Chesson et al., 1965). Eqs. 6.13.2.11-1 and 6.13.2.11-2 are conservative simplifications of the set of elliptical curves. The equations representing the set of elliptical curves for various cases may be found in AISC (1988). No reduction in the nominal tensile resistance is required when the applied shear force on the bolt due to the factored loads is less than or equal to 33 percent of the nominal shear resistance of the bolt.

$F_{ub}$  = specified minimum tensile strength of the bolt specified in Article 6.4.3 (ksi)

$P_u$  = shear force on the bolt due to the factored loads (kip)

$R_n$  = nominal shear resistance of a bolt specified in Article 6.13.2.7 (kip)

The nominal resistance of a bolt in slip-critical connections under Load Combination Service II, specified in Table 3.4.1-1, subjected to combined shear and axial tension, shall not exceed the nominal slip resistance specified in Article 6.13.2.8 multiplied by:

$$1 - \frac{T_u}{P_t} \quad (6.13.2.11-3)$$

where:

$T_u$  = tensile force due to the factored loads under Load Combination Service II (kip)

$P_t$  = minimum required bolt tension specified in Table 6.13.2.8-1 (kip)

### 6.13.2.12—Shear Resistance of Anchor Bolts

The nominal shear resistance of an [ASTM F1554](#) or an [ASTM A307](#) Grade C anchor bolt at the strength limit state shall be taken as:

- Where threads are included in the shear plane:

$$R_n = 0.48A_bF_{ub}N_s \quad (6.13.2.12-1)$$

where:

$A_b$  = area of the anchor bolt corresponding to the nominal diameter (in.<sup>2</sup>)

$F_{ub}$  = specified minimum tensile strength of the anchor bolt specified in Article 6.4.3 (ksi)

$N_s$  = number of shear planes per anchor bolt

### C6.13.2.12

Conditions typically exist in connections with anchor bolts such that the full resistance of each bolt is probably not entirely utilized when resisting applied shear forces. Oversize holes and other factors tend to cause nonuniformity in anchor bolt stresses and thus, connection inefficiency. Due to these effects, a reduction factor of 0.8 should be applied to the 0.48 multiplier for Eq. 6.13.2.12-1 as appropriate.

See Article C6.13.2.7 for further commentary on strength reduction factors.

For global design of anchorages to concrete, refer to *Building Code Requirements for Structural Concrete* (ACI 318-05), Appendix D.

### 6.13.3—Welded Connections

#### 6.13.3.1—General

Base metal, weld metal, and welding design details shall conform to the requirements of the *AASHTO/AWS D1.5M/D1.5 Bridge Welding Code*. Welding symbols shall conform to those specified in AWS Publication A2.4.

Matching weld metal shall be used in groove and fillet welds, except that the Engineer may specify electrode classifications with strengths less than the base metal when detailing fillet welds, in which case the welding procedure and weld metal shall be selected to ensure sound welds.

#### 6.13.3.2—Factored Resistance

##### 6.13.3.2.1—General

The factored resistance of welded connections,  $R_r$ , at the strength limit state shall be taken as specified in Articles 6.13.3.2.2 through 6.13.3.2.4.

The effective area of the weld shall be taken as specified in Article 6.13.3.3. The factored resistance of the connection material shall be taken as specified in Article 6.13.5.

##### 6.13.3.2.2—Complete Penetration Groove-Welded Connections

###### 6.13.3.2.2a—Tension and Compression

The factored resistance of complete penetration groove-welded connections subjected to tension or compression normal to the effective area or parallel to the axis of the weld shall be taken as the factored resistance of the base metal.

###### 6.13.3.2.2b—Shear

The factored resistance of complete penetration groove-welded connections subjected to shear on the effective area shall be taken as the lesser of the value given by Eq. 6.13.3.2.2b-1 or 60 percent of the factored resistance of the base metal in tension:

$$R_r = 0.6\phi_{e1}F_{exx} \quad (6.13.3.2.2b-1)$$

where:

$F_{exx}$  = classification strength of the weld metal (ksi)

$\phi_{e1}$  = resistance factor for the weld metal specified in Article 6.5.4.2

#### C6.13.3.1

Use of undermatched weld metal is highly encouraged for fillet welds connecting steels with specified minimum yield strength greater than 50 ksi. Research has shown that undermatched welds are much less sensitive to delayed hydrogen cracking and are more likely to produce sound welds on a consistent basis.

##### C6.13.3.2.1

The factored resistance of a welded connection is governed by the resistance of the base metal or the deposited weld metal. The nominal resistance of fillet welds is determined from the effective throat area, whereas the nominal strength of the connected parts is governed by their respective thickness.

The classification strength of the weld metal can conservatively be taken as the classification number, EXX. The letters XX stand for the minimum strength levels of the electrodes in ksi.

##### C6.13.3.2.2a

In groove welds, the maximum forces are usually tension or compression. Tests have shown that groove welds of the same thickness as the connected parts are adequate to develop the factored resistance of the connected parts.

**6.13.3.2.3—Partial Penetration Groove-Welded Connections**

**6.13.3.2.3a—Tension or Compression**

**C6.13.3.2.3a**

The factored resistance of partial penetration groove-welded connections subjected to tension or compression parallel to the axis of the weld or compression normal to the effective area shall be taken as the factored resistance of the base metal.

The factored resistance for partial penetration groove-welded connections subjected to tension normal to the effective area shall be taken as the lesser of either the value given by either Eq. 6.13.3.2.3a-1 or the factored resistance of the base metal:

$$R_r = 0.6\phi_{e1}F_{exx} \quad (6.13.3.2.3a-1)$$

where:

$\phi_{e1}$  = resistance factor for the weld metal specified in Article 6.5.4.2

**6.13.3.2.3b—Shear**

The factored resistance of partial penetration groove-welded connections subjected to shear parallel to the axis of the weld shall be taken as the lesser of either the factored nominal resistance of the connected material specified in Article 6.13.5 or the factored resistance of the weld metal taken as:

$$R_r = 0.6\phi_{e2}F_{exx} \quad (6.13.3.2.3b-1)$$

where:

$\phi_{e2}$  = resistance factor for the weld metal as specified in Article 6.5.4.2

**6.13.3.2.4—Fillet-Welded Connections**

**6.13.3.2.4a—Tension and Compression**

**C6.13.3.2.4a**

The factored resistance for fillet-welded connections subjected to tension or compression parallel to the axis of the weld shall be taken as the factored resistance of the base metal.

Flange-to-web fillet-welded connections may be designed without regard to the tensile or compressive stress in those elements parallel to the axis of the welds.

**6.13.3.2.4b—Shear**

**C6.13.3.2.4b**

The resistance of fillet welds in shear which are made with matched or undermatched weld metal and which have typical weld profiles shall be taken as the product of the effective area specified in Article 6.13.3.3 and the factored resistance of the weld metal taken as:

The factored resistance of fillet welds subjected to shear along the length of the weld is dependent upon the strength of the weld metal and the direction of applied load, which may be parallel or transverse to the weld. In both cases, the weld fails in shear, but the plane of rupture is not the same.

$$R_r = 0.6\phi_{e2}F_{exx} \quad (6.13.3.2.4b-1)$$

Shear yielding is not critical in welds because the material strain hardens without large overall deformations occurring. Therefore, the factored shear resistance is based on the shear strength of the weld metal multiplied by a suitable resistance factor to ensure that the connected part will develop its full strength without premature failure of the weldment.

If fillet welds are subjected to eccentric loads that produce a combination of shear and bending stresses, they must be proportioned on the basis of a direct vector addition of the shear forces on the weld.

It is seldom that weld failure will ever occur at the weld leg in the base metal. The applicable effective area for the base metal is the weld leg which is 30 percent greater than the weld throat. If overstrength weld metal is used or the weld throat has excessive convexity, the capacity can be governed by the weld leg and the shear fracture resistance of the base metal  $0.6 F_u$ .

### 6.13.3.3—Effective Area

The effective area shall be the effective weld length multiplied by the effective throat. The effective throat shall be the shortest distance from the joint root to the weld face.

### 6.13.3.4—Size of Fillet Welds

The size of a fillet weld that may be assumed in the design of a connection shall be such that the forces due to the factored loadings do not exceed the factored resistance of the connection specified in Article 6.13.3.2.

The maximum size of fillet weld that may be used along edges of connected parts shall be taken as:

- For material less than 0.25 in. thick: the thickness of the material, and
- For material 0.25 in. or more in thickness: 0.0625 in. less than the thickness of the material, unless the weld is designated on the contract documents to be built out to obtain full throat thickness.

### C6.13.3.3

Additional requirements can be found in the AASHTO/AWS D1.5M/D1.5 Bridge Welding Code, Article 2.3.

### C6.13.3.4

The minimum size of fillet weld should be taken as specified in Table 6.13.3.4-1. The weld size need not exceed the thickness of the thinner part joined. Smaller fillet welds may be approved by the Engineer based upon applied stress and the use of appropriate preheat.

**Table 6.13.3.4-1—Minimum Size of Fillet Welds**

Base Metal Thickness of Thicker Part Joined ( $T$ ) in.	Minimum Size of Fillet Weld in.
$T \leq 3/4$	1/4
$3/4 < T$	5/16

The requirements for minimum size of fillet welds are based upon the quench effect of thick material on small welds, not on strength considerations. Very rapid cooling of weld metal may result in a loss of ductility. Further, the restraint to weld metal shrinkage provided by thick material may result in weld cracking. A 0.3125-in. fillet weld is the largest that can be deposited in a single pass by manual process, but minimum preheat and interpass temperatures are to be provided.

### 6.13.3.5—Minimum Effective Length of Fillet Welds

The minimum effective length of a fillet weld shall be four times its size and in no case less than 1.5 in.

### 6.13.3.6—Fillet Weld End Returns

Fillet welds that resist a tensile force not parallel to the axis of the weld or that are not proportioned to withstand repeated stress shall not terminate at corners of parts or members. Where such returns can be made in the same plane, they shall be returned continuously, full size, around the corner, for a length equal to twice the weld size. End returns shall be indicated in the contract documents.

Fillet welds deposited on the opposite sides of a common plane of contact between two parts shall be interrupted at a corner common to both welds.

### 6.13.3.7—Seal Welds

Seal welds should be a continuous weld combining the functions of sealing and strength, changing section only as required by strength or the requirements for minimum size fillet weld.

### 6.13.4—Block Shear Rupture Resistance

The web connection of coped beams and all tension connections, including connection plates, splice plates and gusset plates, shall be investigated to ensure that adequate connection material is provided to develop the factored resistance of the connection.

The connection shall be investigated by considering all possible failure planes in the member and connection plates. Such planes shall include those parallel and perpendicular to the applied forces. The planes parallel to the applied force shall be considered to resist only shear stresses. The planes perpendicular to the applied force shall be considered to resist only tension stresses.

The factored resistance of the combination of parallel and perpendicular planes shall be taken as:

### C6.13.3.6

End returns should not be provided around transverse stiffeners.

### C6.13.4

Block shear rupture is one of several possible failure modes for splices, connections, and gusset plates. Investigation of other failure modes and critical sections is still required, e.g., a net section extending across the full plate width, and, therefore, having no parallel planes, may be a more severe requirement for a girder flange or splice plate than the block shear rupture mode. The failure path is defined by the centerlines of the bolt holes. The provisions of Articles 6.13.5, 6.13.6 and 6.14.2.8 should be consulted.

Tests on coped beams have indicated that a tearing failure mode can occur along the perimeter of the bolt holes (Birkemoe and Gilmour, 1978). This block shear failure mode is one in which the resistance is determined by the sum of the nominal shear resistance on a failure

$$R_r = \phi_{bs} R_p (0.58F_u A_{vn} + U_{bs} F_u A_m) \leq \phi_{bs} R_p (0.58F_y A_{vg} + U_{bs} F_u A_m) \quad (6.13.4-1)$$

where:

$R_p$  = reduction factor for holes taken equal to 0.90 for bolt holes punched full size and 1.0 for bolt holes drilled full size or subpunched and reamed to size

$A_{vg}$  = gross area along the plane resisting shear stress (in.<sup>2</sup>)

$A_{vn}$  = net area along the plane resisting shear stress (in.<sup>2</sup>)

$U_{bs}$  = reduction factor for block shear rupture resistance taken equal to 0.50 when the tension stress is non-uniform and 1.0 when the tension stress is uniform

$A_m$  = net area along the plane resisting tension stress (in.<sup>2</sup>)

$F_y$  = specified minimum yield strength of the connected material (ksi)

$F_u$  = specified minimum tensile strength of the connected material specified in Table 6.4.1-1 (ksi)

$\phi_{bs}$  = resistance factor for block shear specified in Article 6.5.4.2

The gross area shall be determined as the length of the plane multiplied by the thickness of the component. The net area shall be the gross area, minus the number of whole or fractional holes in the plane, multiplied by the nominal hole diameter specified in Table 6.13.2.4.2-1 times the thickness of the component.

In determining the net section of cuts carrying tension stress, the effect of staggered holes adjacent to the cuts shall be determined in accordance with Article 6.8.3. For net sections carrying shear stress, the full effective diameter of holes centered within two diameters of the cut shall be deducted. Holes further removed may be disregarded.

## 6.13.5—Connection Elements

### 6.13.5.1—General

This Article shall be applied to the design of connection elements such as splice plates, gusset plates, corner angles, brackets, and lateral connection plates in tension or shear, as applicable.

path(s) and the nominal tensile resistance on a perpendicular segment. The block shear rupture mode is not limited to the coped ends of beams. Tension member connections are also susceptible. The block shear rupture mode should also be checked around the periphery of welded connections.

A conservative model has been adopted to predict the block shear rupture resistance in which the resistance to rupture along the shear plane is added to the resistance to rupture on the tensile plane. Block shear is a rupture or tearing phenomenon and not a yielding phenomenon. However, gross yielding along the shear plane can occur when tearing on the tensile plane commences if  $0.58F_u A_{vn}$  exceeds  $0.58F_y A_{vg}$ . Therefore, Eq. 6.13.4-1 limits the term  $0.58F_u A_{vn}$  to not exceed  $0.58F_y A_{vg}$ . Eq. 6.13.4-1 is consistent with the philosophy for tension members where the gross area is used for yielding and the net area is used for rupture.

In certain cases, e.g., coped beam connections with multiple rows of bolts, the tensile stress on the end plane is non-uniform because the rows of bolts nearest the beam end pick up most of the shear (Ricles and Yura, 1983; Kulak and Grondin, 2001). Therefore, a reduction factor,  $U_{bs}$ , has been included in Eq. 6.13.4-1 to approximate the effect of the non-uniform stress distribution on the tensile plane in such cases. For the majority of connections encountered in steel bridges,  $U_{bs}$  will equal 1.0. The reduction factor,  $R_p$ , conservatively accounts for the reduced rupture resistance in the vicinity of bolt holes that are punched full size (Brown et al. 2007), as discussed further in Article C6.8.2.1.

### 6.13.5.2—Tension

The factored resistance,  $R_r$ , in tension shall be taken as the least of the values given by either Eqs. 6.8.2.1-1 and 6.8.2.1-2 for yielding and fracture, respectively, or the block shear rupture resistance specified in Article 6.13.4.

In determining  $P_{nu}$ , as specified in Eq. 6.8.2.1-2, for lateral connection plates, splice plates, and gusset plates, the reduction factor,  $U$ , specified in Article 6.8.2.2, shall be taken to be equal to 1.0, and the net area of the plate,  $A_n$ , used in Eq. 6.8.2.1-2, shall not be taken as greater than 85 percent of the gross area of the plate.

### C6.13.5.2

Because the length of the lateral connection plate, splice plate, or gusset plate is small compared to the member length, inelastic deformation of the gross section is limited. Hence, the net area of the connecting element is limited to  $0.85A_g$  in recognition of the limited inelastic deformation and to provide a reserve capacity (Kulak et al., 1987).

### 6.13.5.3—Shear

The factored shear resistance,  $R_r$ , of the connection element shall be taken as the smaller value based on shear yielding or shear rupture.

For shear yielding, the factored shear resistance of the connection element shall be taken as:

$$R_r = \phi_v 0.58F_y A_{vg} \quad (6.13.5.3-1)$$

where:

$A_{vg}$  = gross area of the connection element subject to shear ( $\text{in.}^2$ )

$F_y$  = specified minimum yield strength of the connection element (ksi)

$\phi_v$  = resistance factor for shear as specified in Article 6.5.4.2

For shear rupture, the factored shear resistance,  $R_r$ , of the connection element shall be taken as:

$$R_r = \phi_{vu} 0.58R_p F_u A_{vn} \quad (6.13.5.3-2)$$

where:

$A_{vn}$  = net area of the connection element subject to shear ( $\text{in.}^2$ )

$F_u$  = tensile strength of the connection element (ksi)

$R_p$  = reduction factor for holes taken equal to 0.90 for bolt holes punched full size and 1.0 for bolt holes drilled full size or subpunched and reamed to size

$\phi_{vu}$  = resistance factor for shear rupture of connection elements as specified in Article 6.5.4.2

## 6.13.6—Splices

### 6.13.6.1—Bolted Splices

#### 6.13.6.1.1—General

Bolted splices shall be designed at the strength limit state to satisfy the requirements specified in Article 6.13.1. Where a section changes at a splice, the smaller of the two connected sections shall be used in the design.

#### 6.13.6.1.2—Tension Members

Splices for tension members shall satisfy the requirements specified in Article 6.13.5.2. Splices for tension members shall be designed using slip-critical connections as specified in Article 6.13.2.1.1.

#### 6.13.6.1.3—Compression Members

Splices for compression members detailed with milled ends in full contact bearing at the splices and for which the contract documents specify inspection during fabrication and erection, may be proportioned for not less than 50 percent of the lower factored resistance of the sections spliced.

Splices in truss chords, arch members, and columns should be located as near to the panel points as practicable and usually on that side where the smaller force effect occurs. The arrangement of plates, angles, or other splice elements shall be such as to make proper provision for all force effects in the component parts of the members spliced.

#### 6.13.6.1.4—Flexural Members

##### 6.13.6.1.4a—General

In continuous spans, splices should be made at or near points of dead load contraflexure. Web and flange splices in areas of stress reversal shall be investigated for both positive and negative flexure.

In both web and flange splices, there shall not be less than two rows of bolts on each side of the joint. Oversize or slotted holes shall not be used in either the member or the splice plates at bolted splices.

Bolted splices for flexural members shall be designed using slip-critical connections as specified in Article 6.13.2.1.1. The connections shall also be proportioned to prevent slip during the erection of the steel and during the casting of the concrete deck.

The factored flexural resistance of the flanges at the point of splice at the strength limit state shall satisfy the applicable provisions of Article 6.10.6.2.

The flexural stresses due to the factored loads at the strength limit state and for checking slip of the bolted connections at the point of splice shall be determined using the gross section properties.

Bolted flange angle splices shall include two angles, one on each side of the flexural member.

#### C6.13.6.1.3

This is consistent with the provisions of past editions of the Standard Specifications which permitted up to 50 percent of the force in a compression member to be carried through a splice by bearing on milled ends of components.

##### C6.13.6.1.4a

For a flexural member, it is recommended that the smaller section at the point of splice be taken as the side of the splice that has the smaller calculated moment of inertia for the noncomposite steel section.

Bolted splices located in regions of stress reversal near points of dead load contraflexure must be checked for both positive and negative flexure to determine the governing condition.

To ensure proper alignment and stability of the girder during construction, web and flange splices are not to have less than two rows of bolts on each side of the joint. Also, oversize or slotted holes are not permitted in either the member or the splice plates at bolted splices of flexural members for improved geometry control during erection and because a strength reduction may occur when oversize or slotted holes are used in eccentrically loaded bolted web connections.

Also, for improved geometry control, bolted connections for both web and flange splices are to be proportioned to prevent slip under the maximum actions induced during the erection of the steel and during the casting of the concrete deck.

At the following sections with holes in the tension flange:

- Compact composite sections in positive flexure in straight bridges,
- Straight composite I-sections in negative flexure or straight noncomposite I-sections with compact or noncompact webs designed according to the provisions of Appendix A6,

for which the nominal flexural resistance is permitted to exceed the moment at first yield at the strength limit state, it has not yet been fully documented that complete plastification of the cross-section can occur prior to fracture on the net section of the tension flange. Furthermore, the splice design provisions of this Article do not consider the contribution of substantial web yielding to the flexural resistance of the sections listed above. Therefore, the factored flexural resistance of the tension flange at cross-sections with holes at the strength limit state or for constructibility is conservatively limited to be less than or equal to the specified minimum yield stress of the tension flange according to the provisions of Article 6.10.1.8. As a result, this requirement will likely prevent bolted splices from being located in these sections at or near points of maximum applied moment where significant yielding of the web, beyond the localized yielding of the web permitted in hybrid members, is allowed at the strength limit state.

Splices for flexural members have typically been designed in the past by treating the flanges and web of the girder as individual components and then proportioning a calculated design moment for the splice to each component. However, for composite sections, superposition of moments does not apply when at elastic stress levels because the moments are applied to different sections, whereas superposition of stresses is valid. Thus, the use of flexural stresses to compute the actions necessary to design the splice is preferred.

Fatigue of the base metal adjacent to the slip-critical connections in the splice plates may be checked as specified in Table 6.6.1.2.3-1 using the gross section of the splice plates and member. However, the areas of the flange and web splice plates will often equal or exceed the areas of the flange and web to which they are attached. The flanges and web are checked separately for either equivalent or more critical fatigue category details. Therefore, fatigue will generally not govern the design of the splice plates.

### 6.13.6.1.4b—Web Splices

Web splice plates and their connections shall be designed for shear, the moment due to the eccentricity of the shear at the point of splice and the portion of the flexural moment assumed to be resisted by the web at the point of splice. For all single box sections, and for multiple box sections in bridges not satisfying the requirements of Article 6.11.2.3, including horizontally curved bridges, or with box flanges that are not fully effective according to the provisions of Article 6.11.1.1, the shear shall be taken as the sum of the flexural and St. Venant torsional shears in the web subjected to additive shears. For boxes with inclined webs, the web splice shall be designed for the component of the vertical shear in the plane of the web.

As a minimum, at the strength limit state, the design shear,  $V_{uw}$ , shall be taken as follows:

- If  $V_u < 0.5\phi_v V_n$ , then:

$$V_{uw} = 1.5V_u \quad (6.13.6.1.4b-1)$$

- Otherwise:

$$V_{uw} = \frac{(V_u + \phi_v V_n)}{2} \quad (6.13.6.1.4b-2)$$

where:

$\phi_v$  = resistance factor for shear specified in Article 6.5.4.2

$V_u$  = shear due to the factored loading at the point of splice (kip)

$V_n$  = nominal shear resistance determined as specified in Articles 6.10.9.2 and 6.10.9.3 for unstiffened and stiffened webs, respectively (kip)

The design shear at the strength limit state shall not exceed the lesser of the factored shear resistance of the web splice plates specified in Article 6.13.4 or the factored shear resistance of the web splice plates specified in Article 6.13.5.3.

The eccentricity of the design shear shall be taken as the distance from the centerline of the splice to the centroid of the connection on the side of the joint under consideration.

### C6.13.6.1.4b

Eqs. 6.13.6.1.4b-1 and 6.13.6.1.4b-2 provide a more consistent design shear to be used for designing web splice plates and their connections at the strength limit state than that given in past editions of the Standard Specifications and the First Edition of the LRFD Specifications. Eq. 6.13.6.1.4b-1 arbitrarily limits the increase in the shear at the point of splice to 50 percent of the shear due to the factored loading,  $V_u$ , where  $V_u$  is less than 50 percent of the factored shear resistance,  $V_r = \phi_v V_n$ , at the point of splice. The increase in the shear is limited to 50 percent of  $V_u$  because the possibilities for  $V_u$  to change from its calculated value are less than for moment; large unintended shifts in the shear at the splice are unlikely. In addition, the maximum shear is usually not concurrent with the maximum moment at the splice. Thus, the use of a lower value of the design shear in regions where the applied shear is low is deemed reasonable. A lower value of the design shear is also more reasonable for rolled beams, which have significantly higher values of factored shear resistance. For cases where  $V_u$  is greater than 50 percent of  $V_r$ , the design shear is determined from Eq. 6.13.6.1.4b-2 as the average of  $V_u$  and  $V_r$ . For checking slip of the bolted connections, the design shear is simply taken as the shear at the point of splice under Load Combination Service II defined in Table 3.4.1-1. The web with the smallest nominal shear resistance on either side of the splice should be used to determine the design shear.

Web splices are also to be designed for the moment due to the eccentricity of the design shear. The eccentricity is explicitly defined as the distance from the centerline of the splice to the centroid of the connection on the side of the joint under consideration rather than the distance between the centroids of the connections on each side of the joint (Sheikh-Ibrahim and Frank, 1998).

Many different approaches have been used to determine the proportion of the total flexural moment carried by the web at the point of splice, which have not always led to consistent results. For reasons discussed below, it is suggested that the portion of the flexural moment assumed to be resisted by the web be applied at the middepth of the web. As a result, at sections where the neutral axis is not at the middepth of the web, a horizontal force resultant must also be applied at the middepth of the web to establish equilibrium. This horizontal force resultant may be assumed distributed equally to all web bolts. The following equations are suggested to determine a design moment,  $M_{uw}$ , and a design horizontal force resultant,  $H_{uw}$ , to be applied at the middepth of the web for designing the web splice plates and their connections at the strength limit state:

At the strength limit state, the combined flexural and axial stress in the web splice plates shall not exceed the specified minimum yield strength of the splice plates times the resistance factor,  $\phi_f$ , specified in Article 6.5.4.2.

Bolted connections for web splices shall be designed as slip-critical connections for the maximum resultant bolt design force. As a minimum, for checking slip of the web splice bolts, the design shear shall be taken as the shear at the point of splice under Load Combination Service II, as specified in Table 3.4.1-1.

Webs shall be spliced symmetrically by plates on each side. The splice plates shall extend as near as practical for the full depth between flanges.

$$M_{uw} = \frac{t_w D^2}{12} |R_h F_{cf} - R_{cf} f_{ncf}| \quad (\text{C6.13.6.1.4b-1})$$

$$H_{uw} = \frac{t_w D}{2} (R_h F_{cf} + R_{cf} f_{ncf}) \quad (\text{C6.13.6.1.4b-2})$$

where:

$t_w$  = web thickness of the smaller section at the point of splice (in.)

$D$  = web depth of the smaller section at the point of splice (in.)

$R_h$  = hybrid factor specified in Article 6.10.1.10.1. For hybrid sections in which  $F_{cf}$  does not exceed the specified minimum yield strength of the web, the hybrid factor shall be taken as 1.0

$F_{cf}$  = design stress for the controlling flange at the point of splice specified in Article 6.13.6.1.4c; positive for tension, negative for compression (ksi)

$R_{cf}$  = the absolute value of the ratio of  $F_{cf}$  to the maximum flexural stress,  $f_{cf}$ , due to the factored loads at the midthickness of the controlling flange at the point of splice, as defined in Article 6.13.6.1.4c

$f_{ncf}$  = flexural stress due to the factored loads at the midthickness of the noncontrolling flange at the point of splice concurrent with  $f_{cf}$ ; positive for tension, negative for compression (ksi)

In Eqs. C6.13.6.1.4b-1 and C6.13.6.1.4b-2, it is suggested that  $M_{uw}$  and  $H_{uw}$  be computed by conservatively using the stresses at the midthickness of the flanges. By utilizing the stresses at the midthickness of the flanges, the same stress values can be used for the design of both the web and flange splices, which simplifies the calculations. As an alternate, however, the stresses at the inner fibers of the flanges can be used. In either case, the stresses are to be computed considering the application of the moments due to the appropriate factored loadings to the respective cross-sections supporting those loadings. In Eqs. C6.13.6.1.4b-1 and C6.13.6.1.4b-2, the concurrent flexural stress at the midthickness of the noncontrolling flange is factored up in the same proportion as the flexural stress in the controlling flange in order to satisfy the general design requirements of Article 6.13.1. The controlling and noncontrolling flanges are defined in Article C6.13.6.1.4c.

The stresses in Eqs. C6.13.6.1.4b-1 and C6.13.6.1.4b-2 are to be taken as signed quantities. For convenience, absolute value signs are applied to the resulting difference of the stresses in Eq. C6.13.6.1.4b-1. In actuality, the sign of  $M_{uw}$  corresponds to the sign of the flexural moment for the loading condition under consideration.  $H_{uw}$  in Eq. C6.13.6.1.4b-2 is taken as a signed quantity; positive for tension, negative for compression. For sections where the neutral axis is located at the middepth of the web,  $H_{uw}$  will equal zero. For all other sections,  $M_{uw}$  and  $H_{uw}$  applied together will yield a combined stress distribution equivalent to the unsymmetrical stress distribution in the web.

Eqs. C6.13.6.1.4b-1 and C6.13.6.1.4b-2 can also be used to compute values of  $M_{uw}$  and  $H_{uw}$  to be used when checking for slip of the web bolts. However, the following substitutions must first be made in both equations:

- Replace  $F_{cf}$  with the maximum flexural stress,  $f_s$ , due to Load Combination Service II at the midthickness of the flange under consideration for the smaller section at the point of splice,
- Replace  $f_{ncf}$  with the flexural stress,  $f_{os}$ , due to Load Combination Service II at the midthickness of the other flange at the point of splice concurrent with  $f_s$  in the flange under consideration, and
- Set the factors  $R_h$  and  $R_{cf}$  equal to 1.0. It is not necessary to determine a controlling and noncontrolling flange when checking for slip. The same sign convention applies to the stresses.

In areas of stress reversal,  $M_{uw}$  and  $H_{uw}$  must be computed independently for both positive and negative flexure in order to determine the governing condition. For web splices not in an area of stress reversal,  $M_{uw}$  and  $H_{uw}$  need only be computed for the loading condition causing the maximum flexural stress in the controlling flange at the strength limit state or in the flange under consideration for Load Combination Service II.

An alternative approach for compact steel sections whereby all the flexural moment is assumed to be resisted by the flange splices, provided the flanges are capable of resisting the design moment, is presented by Sheikh-Ibrahim and Frank (1998, 2001). This method is only to be applied at the strength limit state; slip of the bolts should still be checked using the conventional approach. Should the flanges not be capable of resisting the full design moment, the web splice is assumed to resist the additional flexural moment in addition to the design shear and the moment due to the eccentricity of the design shear.

For bolt groups subject to eccentric shear, a traditional approach is often used in which the bolt group is subjected to a concentric shear and a centroidal moment. A vector analysis is performed assuming there is no friction, and that the plates and bolts are elastic (AISC, 2001). The use of this traditional elastic approach is preferred over the ultimate strength approach given in AISC (2001), in which an empirical load-deformation relationship of an individual bolt is considered, because it provides a more consistent factor of safety.

To effectively utilize the traditional elastic approach to compute the maximum resultant bolt force, all actions should be applied at the middepth of the web and the polar moment of inertia of the bolt group,  $I_p$ , should be computed about the centroid of the connection. Shifting the polar moment of inertia of the bolt group to the neutral axis of the composite section, which is typically not at the middepth of the web, may cause the bolt forces to be underestimated unless the location of the neutral axis is computed from the summation of the stresses due to the appropriate loadings acting on the respective cross-sections supporting the loadings. Therefore, to simplify the computations and avoid possible errors, it is recommended that all calculated actions in the web be applied at the middepth of the web for the design of the splice. For a uniform vertical pitch of the web bolts, the following formula (AISC, 1963), may then be used to compute  $I_p$  about the centroid of the connection:

$$I_p = \frac{nm}{12} [s^2(n^2 - 1) + g^2(m^2 - 1)] \quad (\text{C6.13.6.1.4b-3})$$

where:

$m$  = number of vertical rows of bolts

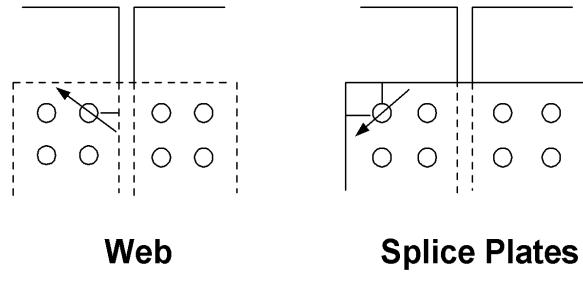

$n$  = number of bolts in one vertical row

$s$  = vertical pitch (in.)

$g$  = horizontal pitch (in.)

When checking the bearing resistance of the web at bolt holes, the resistance of an outermost hole, calculated using the clear edge distance, can conservatively be checked against the maximum resultant force acting on the extreme bolt in the connection. This check is conservative since the resultant force acts in the direction of an inclined distance that is larger than the clear edge distance. Should the bearing resistance be exceeded, it is recommended that the edge distance be increased slightly in lieu of increasing the number of bolts or thickening the web. Other options would be to calculate the bearing resistance based on the inclined distance or to resolve the resultant force in the

direction parallel to the edge distance. In cases where the bearing resistance of the web splice plates controls, the smaller of the clear edge or end distance on the splice plates can be used to compute the bearing resistance of the outermost hole.

**Figure C6.13.6.1.4b-1—Critical Locations for Outermost Holes**

Web splice plates are to be symmetrical on each side of the web and are to extend as near as practical to the full depth of the web between flanges without impinging on bolt assembly clearances. The required bolt assembly clearances are given in AISC (2001).

#### 6.13.6.1.4c—Flange Splices

At the strength limit state, splice plates and their connections on the controlling flange shall be proportioned to provide a minimum resistance taken as the design stress,  $F_{cf}$ , times the smaller effective flange area,  $A_e$ , on either side of the splice, where  $F_{cf}$  is defined as:

$$F_{cf} = \frac{\left( \left| \frac{f_u}{R_h} \right| + \alpha \phi_f F_{yf} \right)}{2} \geq 0.75 \alpha \phi_f F_{yf} \quad (6.13.6.1.4c-1)$$

in which:

$A_e$  = effective area of the flange (in.<sup>2</sup>). For compression flanges,  $A_e$  shall be taken as the gross area of the flange. For tension flanges,  $A_e$  shall be taken as:

$$A_e = \left( \frac{\phi_u F_u}{\phi_y F_{yt}} \right) A_n \leq A_g \quad (6.13.6.1.4c-2)$$

where:

$f_{cf}$  = maximum flexural stress due to the factored loads at the midthickness of the controlling flange at the point of splice (ksi)

$R_h$  = hybrid factor specified in Article 6.10.1.10.1. For hybrid sections in which  $F_{cf}$  does not exceed the specified minimum yield strength of the web, the hybrid factor shall be taken as 1.0

#### C6.13.6.1.4c

Eq. 6.13.6.1.4c-1 defines a design stress to be multiplied by the smaller effective flange area on either side of the splice in order to determine a design force for the splice on the controlling flange at the strength limit state.

The design stress is based on the general design requirements specified in Article 6.13.1. The use of the effective flange area ensures that fracture on the net section of the tension flange will theoretically be prevented at the splice. The smaller value of the effective flange area on either side of the splice is used to determine the flange design force to ensure that the design force does not exceed the factored resistance of the smaller flange.

The controlling flange is defined as either the top or bottom flange for the smaller section at the point of splice, whichever flange has the maximum ratio of the elastic flexural stress at its midthickness due to the factored loads for the loading condition under investigation to its factored flexural resistance. The other flange is termed the noncontrolling flange. In areas of stress reversal, the splice must be checked independently for both positive and negative flexure. For composite sections in positive flexure, the controlling flange is typically the bottom flange. For sections in negative flexure, either flange may qualify as the controlling flange.

The factor  $\alpha$  in Eq. 6.13.6.1.4c-1 is generally taken as 1.0, except that a lower value equal to the ratio of  $F_n$  to  $F_{yf}$  may be used for flanges where  $F_n$  is less than  $F_{yf}$ . Potential cases include bottom flanges of I-sections in compression, or bottom box flanges in compression or tension at the point of splice. In these cases, the calculated  $F_n$  of the flange at the

- $\alpha$  = 1.0, except that a lower value equal to  $(F_n/F_{yf})$  may be used for flanges where  $F_n$  is less than  $F_{yf}$
- $\phi_f$  = resistance factor for flexure specified in Article 6.5.4.2
- $F_n$  = nominal flexural resistance of the flange (ksi)
- $F_{yf}$  = specified minimum yield strength of the flange (ksi)
- $\phi_u$  = resistance factor for fracture of tension members as specified in Article 6.5.4.2
- $\phi_y$  = resistance factor for yielding of tension members as specified in Article 6.5.4.2
- $A_n$  = net area of the tension flange determined as specified in Article 6.8.3 (in.<sup>2</sup>)
- $A_g$  = gross area of the tension flange (in.<sup>2</sup>)
- $F_u$  = specified minimum tensile strength of the tension flange determined as specified in Table 6.4.1-1 (ksi)
- $F_{yt}$  = specified minimum yield strength of the tension flange (ksi)

Splice plates and their connections on the noncontrolling flange at the strength limit state shall be proportioned to provide a minimum resistance taken as the design stress,  $F_{ncf}$ , times the smaller effective flange area,  $A_e$ , on either side of the splice, where  $F_{ncf}$  is defined as:

$$F_{ncf} = R_{cf} \left| \frac{f_{ncf}}{R_h} \right| \geq 0.75\alpha\phi_f F_{yf} \quad (6.13.6.1.4c-3)$$

where:

- $R_{cf}$  = the absolute value of the ratio of  $F_{cf}$  to  $f_{cf}$  for the controlling flange
- $f_{ncf}$  = flexural stress due to the factored loads at the midthickness of the noncontrolling flange at the point of splice concurrent with  $f_{cf}$  (ksi)
- $R_h$  = hybrid factor specified in Article 6.10.1.10.1. For hybrid sections in which  $F_{cf}$  does not exceed the specified minimum yield strength of the web, the hybrid factor shall be taken as 1.0

At the strength limit state, the design force in splice plates subjected to tension shall not exceed the factored resistance in tension specified in Article 6.13.5.2. The design force in splice plates subjected to compression shall not exceed the factored resistance,  $R_r$ , in compression taken as:

splice may be significantly below  $F_{yf}$  making it overly conservative to use  $F_{yf}$  in Eq. 6.13.6.1.4c-1 to determine the flange design force for designing the splice. For I-section flanges in compression, the reduction in  $F_n$  below  $F_{yf}$  is typically not as large as for box flanges. Thus, for simplicity, a conservative value of  $\alpha$  equal to 1.0 may be used for this case even though the specification would permit the use of a lower value.

Eq. 6.13.6.1.4c-3 defines a design stress for the noncontrolling flange at the strength limit state. In Eq. 6.13.6.1.4c-3, the flexural stress at the midthickness of the noncontrolling flange, concurrent with the stress in the controlling flange, is factored up in the same proportion as the flexural stress in the controlling flange in order to satisfy the general design requirements of Article 6.13.1. However, as a minimum, the factored-up stress must be equal to or greater than  $0.75\alpha\phi_f F_{yf}$ .

Eq. 6.13.6.1.4c-5 defines a design stress to be used to compute a flange design force for checking slip of the bolts under Load Combination Service II given in Table 3.4.1-1. Since net section fracture is not a concern when checking for slip under this load combination, the smaller gross flange area on either side of the splice is used to compute the design force. When checking the slip resistance, the use of a Class B surface condition is recommended unless:

- Class A coatings are applied,
- Unpainted clean mill scale is left on the faying surface, or
- The coating has not been properly tested to show conformance with the requirements for Class B coatings.

Since flanges of hybrid girders are allowed to reach  $F_{yf}$ , the applied flexural stress at the midthickness of the flange in Eqs. 6.13.6.1.4c-1, 6.13.6.1.4c-3, and 6.13.6.1.4c-5 is divided by the hybrid factor,  $R_h$ , instead of reducing  $F_{yf}$  by  $R_h$ . In actuality, yielding in the web results in an increase in the applied flange stress. When the flange design stress is less than or equal to the specified minimum yield strength of the web,  $R_h$  is taken equal to 1.0 since there is theoretically no yielding in the web. The load shedding factor,  $R_b$ , is not included in these equations since the presence of the web splice plates precludes the possibility of local web buckling.

Flange splice plates subjected to tension are to be checked for yielding on the gross section, fracture on the net section, and block shear rupture at the strength limit state according to the provisions of Article 6.13.5.2. Block shear rupture will usually not govern the design of splice plates of typical proportion. Flange splice plates subjected to compression at the strength limit state are to be checked only for yielding on the gross section of the plates according to Eq. 6.13.6.1.4c-4. Eq. 6.13.6.1.4c-4 assumes an unbraced length of zero for the splice plates.

$$R_r = \phi_c F_y A_s \quad (6.13.6.1.4c-4)$$

where:

$\phi_c$  = resistance factor for compression as specified in Article 6.5.4.2

$F_y$  = specified minimum yield strength of the splice plate (ksi)

$A_s$  = gross area of the splice plate (in.<sup>2</sup>)

Bolted connections for flange splices shall be designed as slip-critical connections for the flange design force. As a minimum, for checking slip of the flange splice bolts, the design force for the flange under consideration shall be taken as the Service II design stress,  $F_s$ , times the smaller gross flange area on either side of the splice, where  $F_s$  is taken as:

$$F_s = \frac{f_s}{R_h} \quad (6.13.6.1.4c-5)$$

where:

$f_s$  = maximum flexural stress due to Load Combination Service II at the midthickness of the flange under consideration for the smaller section at the point of splice (ksi)

$R_h$  = hybrid factor specified in Article 6.10.1.10.1. For hybrid sections in which  $f_s$  in the flange with the larger stress does not exceed the specified minimum yield strength of the web, the hybrid factor shall be taken as 1.0

Where filler plates are required, the provisions of Article 6.13.6.1.5 shall apply.

For all single box sections, and for multiple box sections in bridges not satisfying the requirements of Article 6.11.2.3, including horizontally curved bridges, or with box flanges that are not fully effective according to the provisions of Article 6.11.1.1, longitudinal warping stresses due to cross-section distortion shall be considered when checking bolted flange splices for slip and for fatigue. Longitudinal warping stresses may be ignored at the strength limit state. St. Venant torsional shear shall also be considered in the design of box-flange bolted splices for these sections at all limit states.

For a flange splice with inner and outer splice plates, the flange design force at the strength limit state may be assumed divided equally to the inner and outer plates and their connections when the areas of the inner and outer plates do not differ by more than ten percent. For this case, the connections would be proportioned assuming double shear. Should the areas of the inner and outer plates differ by more than ten percent, the design force in each splice plate and its connection at the strength limit state should instead be determined by multiplying the flange design force by the ratio of the area of the splice plate under consideration to the total area of the inner and outer splice plates. For this case, the shear resistance of the connection would be checked for the maximum calculated splice-plate force acting on a single shear plane. When checking for slip of the connection for a flange splice with inner and outer splice plates, the slip resistance should always be determined by dividing the flange design force equally to the two slip planes regardless of the ratio of the splice plate areas. Slip of the connection cannot occur unless slip occurs on both planes.

For the box sections cited in this Article, including sections in horizontally curved bridges, longitudinal warping stresses due to cross-section distortion can be significant under construction and service conditions and must therefore be considered when checking the connections of bolted flange splices for slip and for fatigue. The warping stresses in these cases can typically be ignored in checking the top-flange splices once the flange is continuously braced. The warping stresses can also be ignored when checking splices in both the top and bottom flanges at the strength limit state. For these sections, St. Venant torsional shear must also be considered in the design of box-flange bolted splices at all limit states. St. Venant torsional shears are typically neglected in top flanges of tub sections once the flanges are continuously braced. The bolts for box-flange splices may be designed for the effects of the torsional shear using the traditional elastic vector method that is typically applied in the design of web splices. Depending on the limit state under investigation, the shear on the flange bolt group is assumed caused by either the flange force due to the factored loads, or by the appropriate flange design force, as applicable. The moment on the bolt group is taken as the moment resulting from the eccentricity of the St. Venant torsional shear due to the factored loads, assumed applied at the centerline of the splice. At the strength limit state, the torsional shear due to the factored loads need not be multiplied by the factor,  $R_{cf}$ , from Eq. 6.13.6.1.4c-3 when computing the moment for the design of the splice. The box-flange splice plates in these cases should also be designed at the strength limit state for the combined effects of the appropriate flange force and the moment resulting from the eccentricity of the St. Venant torsional shear due to the factored loads.

Where applicable, lateral bending effects in discretely braced top flanges of tub sections and in discretely braced flanges of I-sections shall be considered in the design of the bolted flange splices.

In cases for straight girders where flange lateral bending is deemed significant, and for horizontally curved girders, the effects of the lateral bending must be considered in the design of the bolted splices for discretely braced top flanges of tub sections or discretely braced flanges of I-sections. The traditional elastic vector method may also be used in these cases to account for the effects of flange lateral bending on the design of the splice bolts. The shear on the flange bolt group is assumed caused by the flange force, calculated as described in the preceding paragraph. The flange force is calculated without consideration of the flange lateral bending. The moment on the bolt group is taken as the flange lateral bending moment due to the factored loads. At the strength limit state, the flange lateral bending moment due to the factored loads need not be multiplied by the factor,  $R_{cf}$ , from Eq. 6.13.6.1.4c-3 when computing the moment for the design of the splice. Splice plates subject to flange lateral bending should also be designed at the strength limit state for the combined effects of the appropriate flange force and the flange lateral bending moment due to the factored loads. Lateral flange bending can be ignored in the design of top flange splices once the flange is continuously braced.

#### 6.13.6.1.5—Fillers

When bolts carrying loads pass through fillers 0.25 in. or more in thickness in axially loaded connections, including girder flange splices, either:

- The fillers shall be extended beyond the gusset or splice material, and the filler extension shall be secured by enough additional bolts to distribute the total stress in the member uniformly over the combined section of the member and the filler, or
- As an alternative, the fillers need not be extended and developed provided that the factored resistance of the bolts in shear at the strength limit state, specified in Article 6.13.2.2, is reduced by the following factor:

$$R = \left[ \frac{(1+\gamma)}{(1+2\gamma)} \right] \quad (6.13.6.1.5-1)$$

where:

$$\gamma = A_f/A_p$$

$A_f$  = sum of the area of the fillers on the top and bottom of the connected plate ( $\text{in.}^2$ )

$A_p$  = smaller of either the connected plate area or the sum of the splice plate areas on the top and bottom of the connected plate ( $\text{in.}^2$ )

#### C6.13.6.1.5

Fillers are to be secured by means of additional fasteners so that the fillers are, in effect, an integral part of a shear-connected component at the strength limit state. The integral connection results in well-defined shear planes and no reduction in the factored shear resistance of the bolts.

In lieu of extending and developing the fillers, the reduction factor given by Eq. 6.13.6.1.5-1 may instead be applied to the factored resistance of the bolts in shear. This factor compensates for the reduction in the nominal shear resistance of a bolt caused by bending in the bolt and will typically result in the need to provide additional bolts in the connection. The reduction factor is only to be applied on the side of the connection with the fillers. The factor in Eq. 6.13.6.1.5-1 was developed mathematically (Sheikh-Ibrahim, 2002), and verified by comparison to the results from an experimental program on axially loaded bolted splice connections with undeveloped fillers (Yura, et al., 1982). The factor is more general than a similar factor given in AISC (2005) in that it takes into account the areas of the main connected plate, splice plates and fillers and can be applied to fillers of any thickness. Unlike the empirical AISC factor, the factor given by Eq. 6.13.6.1.5-1 will typically be less than 1.0 for connections utilizing 0.25-in. thick fillers in order to ensure both adequate shear resistance and limited deformation of the connection.

For slip-critical connections, the factored slip resistance of a bolt need not be adjusted for the effect of the fillers. The resistance to slip between filler and either connected part is comparable to that which would exist between the connected parts if fillers were not present.

For slip-critical connections, the factored slip resistance of a bolt, specified in Article 6.13.2.2, shall not be adjusted for the effect of the fillers.

Fillers 0.25 in. or more in thickness shall consist of not more than two plates, unless approved by the Engineer.

For bolted web splices with thickness differences of 0.0625 in. or less, no filler plates are required.

The specified minimum yield strength of fillers 0.25 in. or greater in thickness should not be less than the larger of 70 percent of the specified minimum yield strength of the connected plate and 36.0 ksi.

For fillers 0.25 in. or greater in thickness in axially loaded bolted connections, the specified minimum yield strength of the fillers should theoretically be greater than or equal to the specified minimum yield strength of the connected plate times the factor  $[1/(1+\gamma)]$  in order to provide fully developed fillers that act integrally with the connected plate. However, such a requirement may not be practical or convenient due to material availability issues. As a result, premature yielding of the fillers, bolt bending and increased deformation of the connection may occur in some cases at the strength limit state. To control excessive deformation of the connection, a lower limit on the specified minimum yield strength of the filler plate material is recommended for fillers 0.25 in. or greater in thickness. Connections where the fillers are appropriately extended and developed or where additional bolts are provided according to Eq. 6.13.6.1.5-1 in lieu of extending the fillers, but that do not satisfy the recommended yield strength limit, will still have adequate reserve shear resistance in the connection bolts. However, such connections will have an increased probability of larger deformations at the strength limit state. For fillers less than 0.25 in. in thickness, the effects of yielding of the fillers and deformation of the connection are considered inconsequential. For applications involving the use of weathering steels, a weathering grade product should be specified for the filler plate material.

### **6.13.6.2—Welded Splices**

Welded splice design and details shall conform to the requirements of the latest edition of *AASHTO/AWS D1.5M/D1.5 Bridge Welding Code* and the following provisions specified herein.

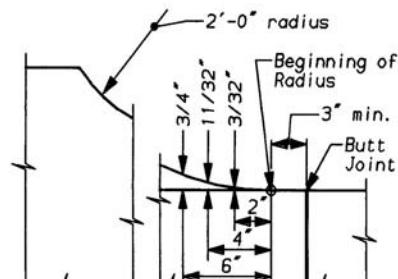

Welded splices shall be designed to resist the design moment, shear, or axial force specified in Article 6.13.1. Tension and compression members may be spliced by means of full penetration butt welds; splice plates should be avoided.

Welded field splices should be arranged to minimize overhead welding.

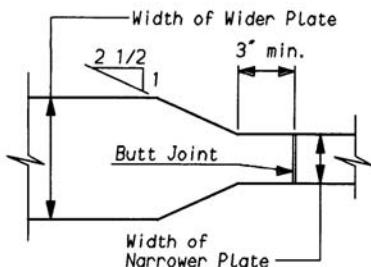

Material of different widths spliced by butt welds shall have symmetric transitions conforming to Figure 6.13.6.2-1. The type of transition selected shall be consistent with the Detail Categories of Table 6.6.1.2.3-1 for the groove-welded splice connection used in the design of the member. The contract documents shall specify that butt weld splices joining material of different thicknesses be ground to a uniform slope between the offset surfaces, including the weld, of not more than one in 2.5.

### **C6.13.6.2**

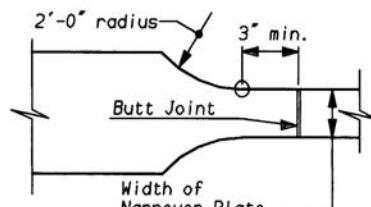

Flange width transition details typically show the transition starting at the butt splice. Figure 6.13.6.2-1 shows a preferred detail where the splice is located a minimum of 3.0 in. from the transition for ease in fitting runoff tabs. Where possible, constant width flanges are preferred in a shipping piece.

(a) Detail of Width Transition

(b) Straight Tapered Transition

(c) 2'-0" Radius Transition

**Figure 6.13.6.2-1—Splice Details****6.13.7—Rigid Frame Connections****6.13.7.1—General**

All rigid frame connections shall be designed to resist the moments, shear, and axial forces due to the factored loading at the strength limit state.

**C6.13.7.1**

The provisions for rigid frame connections are well documented in Chapter 8 of ASCE (1971).

The rigidity is essential to the continuity assumed as the basis for design.

**6.13.7.2—Webs****C6.13.7.2**

The thickness of an unstiffened beam web shall satisfy:

$$t_w \geq \sqrt{3} \left( \frac{M_c}{\phi_v F_y d_b d_c} \right) \quad (6.13.7.2-1)$$

where:

$F_y$  = specified minimum yield strength of the web (ksi)

$M_c$  = column moment due to the factored loadings (kip-in.)

$d_b$  = beam depth (in.)

$d_c$  = column depth (in.)

$\phi_v$  = resistance factor for shear as specified in Article 6.5.4.2

When the thickness of the connection web is less than that given in Eq. 6.13.7.2-1, the web shall be strengthened by diagonal stiffeners or by a reinforcing plate in contact with the web over the connection area.

At knee joints where the flanges of one member are rigidly framed into the flange of another member, stiffeners shall be provided on the web of the second member opposite the compression flange of the first member where:

$$t_w < \frac{A_f}{t_b + 5k} \quad (6.13.7.2-2)$$

and opposite the tension flange of the first member where:

$$t_c < 0.4 \sqrt{A_f} \quad (6.13.7.2-3)$$

where:

$t_w$  = thickness of web to be stiffened (in.)

$k$  = distance from outer face of flange to toe of web fillet of member to be stiffened (in.)

$t_b$  = thickness of flange transmitting concentrated force (in.)

$t_c$  = thickness of flange of member to be stiffened (in.)

$A_f$  = area of flange transmitting concentrated load (in.<sup>2</sup>)

## 6.14—PROVISIONS FOR STRUCTURE TYPES

### 6.14.1—Through-Girder Spans

Where beams or girders comprise the main members of through-spans, such members shall be stiffened against lateral deformation by means of gusset plates or knee braces with solid webs connected to the stiffeners on the main members and the floorbeams. Design of gusset plates shall satisfy the requirements of Article 6.14.2.8.

The provision for checking the beam or connection web ensures adequate strength and stiffness of the steel frame connection.

In bridge structures, diagonal stiffeners of minimum thickness will provide sufficient stiffness. Alternately, web thickness may be increased in the connection region.

The provisions for investigating a member subjected to concentrated forces applied to its flange by the flanges of another member framing into it are intended to prevent crippling of the web and distortions of the flange. It is conservative to provide stiffeners of a thickness equal to that of the flanges of the other member.

### C6.14.1

This requirement may be combined with other plate stiffening requirements.

## 6.14.2—Trusses

### 6.14.2.1—General

Trusses should have inclined end posts. Laterally unsupported hip joints shall be avoided.

Main trusses shall be spaced a sufficient distance apart, center-to-center, to prevent overturning.

Effective depths of the truss shall be assumed as follows:

- The distance between centers of gravity of bolted chords, and
- The distance between centers of pins.

### 6.14.2.2—Truss Members

Members shall be symmetrical about the central plane of the truss.

If the shape of the truss permits, compression chords shall be continuous.

If web members are subject to reversal of stress, their end connections shall not be pinned.

Counters should be avoided.

### C6.14.2.2

Chord and web truss members should usually be made of H-shaped, channel shaped, or box-shaped members. The member or component thereof may be a rolled shape or a fabricated shape using welding or mechanical fasteners. Side plates or components should be solid. Cover plates or web plates may be solid or perforated.

In chords composed of angles in channel-shaped members, the vertical legs of the angles preferably should extend downward.

Counters are sometimes used as web members of light trusses.

Counters should be rigid. If used, adjustable counters should have open turnbuckles, and in the design of these members an allowance of 10.0 ksi shall be made for initial stress. Only one set of diagonals in any panel should be adjustable. Sleeve nuts and loop bars should not be used. The load factor for initial stress should be taken as 1.0.

### 6.14.2.3—Secondary Stresses

The design and details shall be such that secondary stresses will be as small as practicable. Stresses due to the dead load moment of the member shall be considered, as shall those caused by eccentricity of joints or working lines. Secondary stresses due to truss distortion or floorbeam deflection need not be considered in any member whose width measured parallel to the plane of distortion is less than one-tenth of its length.

### 6.14.2.4—Diaphragms

Diaphragms in trusses shall be provided according to the requirements specified in Article 6.7.4.4.

### 6.14.2.5—Camber

The length of the truss members shall be adjusted such that the camber will be equal to or greater than the deflection produced by the dead load.

The gross area of each truss member shall be used in computing deflections of trusses. If perforated plates are used, the effective area of the perforated plate shall be the net volume between centers of perforations divided by the length from center-to-center of perforations.

Design requirements for perforated plates shall satisfy the requirements specified in Articles 6.8.5.2 and 6.9.4.3.2.

#### 6.14.2.6—Working Lines and Gravity Axes

Main members shall be proportioned so that their gravity axes will be as nearly as practicable in the center of the section.

In compression members of unsymmetrical section, such as chord sections formed of side segments and a cover plate, the gravity axis of the section shall coincide as nearly as practicable with the working line, except that eccentricity may be introduced to counteract dead load flexure. In two-angle bottom chord or diagonal members, the working line may be taken as the gage line nearest the back of the angle or at the center of gravity for welded trusses.

#### 6.14.2.7—Portal and Sway Bracing

##### 6.14.2.7.1—General

The need for vertical cross-frames used as sway bracing in trusses shall be investigated. Any consistent structural analysis with or without intermediate sway bracing shall be acceptable as long as equilibrium, compatibility, and stability are satisfied for all applicable limit states.

##### 6.14.2.7.2—Through-Truss Spans

Through-truss spans shall have portal bracing or the strength and stiffness of the truss system shall be shown to be adequate without a braced portal. If portal bracing is used, it should be of the two-plane or box-type, rigidly connected to the end post and the top chord flanges, and be as deep as the clearance will allow. If a single-plane portal is used, it should be located in the central transverse plane of the end posts, with diaphragms between the webs of the posts to provide for a distribution of the portal stresses.

The portal, with or without bracing, shall be designed to take the full reaction of the top chord lateral system, and the end posts shall be designed to transfer this reaction to the truss bearings.

##### 6.14.2.7.3—Deck Truss Spans

Deck truss spans shall have sway bracing in the plane of the end posts, or the strength and stiffeners of the truss system shall be shown to be adequate. Where sway bracing is used, it shall extend the full depth of the trusses below the floor system, and the end sway bracing shall be proportioned to carry the entire upper lateral load to the supports through the end posts of the truss.

##### C6.14.2.7.3

Generally, full depth sway bracing is easily accommodated in deck trusses, and its use is encouraged.

#### **6.14.2.8—Gusset Plates**

The provisions of Articles 6.13.4 and 6.13.5 shall apply, as applicable.

Gusset or connection plates should be used for connecting main members, except where the members are pin-connected. The fasteners connecting each member shall be symmetrical with the axis of the member, so far as practicable, and the full development of the elements of the member should be given consideration.

Re-entrant cuts, except curves made for appearance, should be avoided as far as practicable.

The maximum stress from combined factored flexural and axial loads shall not exceed  $\phi F_y$  based on the gross area.

The maximum shear stress on a section due to the factored loads shall be  $\phi_v F_y / \sqrt{3}$  for uniform shear and  $\phi_v 0.74 F_y / \sqrt{3}$  for flexural shear computed as the factored shear force divided by the shear area.

If the length of the unsupported edge of a gusset plate exceeds  $2.06(E/F_y)^{1/2}$  times its thickness, the edge shall be stiffened. Stiffened and unstiffened gusset edges shall be investigated as idealized column sections.

#### **6.14.2.9—Half Through-Trusses**

The vertical truss members and the floorbeams and their connections in half through-truss spans shall be proportioned to resist a lateral force of not less than 0.30 klf applied at the top chord panel points of each truss, considered as a permanent load for the Strength I Load Combination and factored accordingly.

The top chord shall be considered as a column with elastic lateral supports at the panel points.

#### **C6.14.2.8**

Following the 2007 collapse of the I-35W bridge in Minneapolis, the traditional procedures for designing gusset plates, including the provisions of this Article, have been under extensive review. As of Spring 2008, new design procedures have not been codified. Guidance from FHWA is expected shortly. Designers are advised to obtain the latest approved recommendations from Owners.

#### **6.14.2.10—Factored Resistance**

The factored resistance of tension members shall satisfy the requirements specified in Article 6.8.2.

The factored resistance of compression members shall satisfy the requirements specified in Article 6.9.2.

The nominal bending resistance of the members whose factored resistance is governed by interaction equations, specified in Articles 6.8.2.3 or 6.9.2.2, shall be evaluated as specified in Article 6.12.

#### **6.14.3—Orthotropic Deck Superstructures**

#### **C6.14.2.9**

A discussion of the buckling analysis of columns with elastic lateral supports is contained in Timoshenko and Gere (1961) and in Galambos (1998).

#### **C6.14.3**

Orthotropic deck roadways may be used as upper or lower flanges of trusses, plate girder or box girder bridges, stiffening members of suspension or cable-stayed bridges, tension ties of arch bridges, etc.

Detailed provisions for the design of orthotropic decks are given in Article 9.8.3.

### 6.14.3.1—General

The provisions of this Article shall apply to the design of steel bridges that utilize a stiffened steel plate as a deck.

An orthotropic deck shall be considered an integral part of the bridge superstructure and shall participate in resisting global force effects on the bridge. Connections between the deck and the main structural members shall be designed for interaction effects specified in Article 9.4.1.

The effect of torsional distortions of the cross-sectional shape shall be accounted for in analyzing the girders of orthotropic box girder bridges.

### 6.14.3.2—Effective Width of Deck

The provisions of Article 4.6.2.6.4 shall apply.

### 6.14.3.3—Superposition of Global and Local Effects

#### 6.14.3.3.1—General

In calculating extreme force effects in the deck, global and local effects shall be superimposed. Such combined force effects shall be computed for the same configuration and position of live load.

#### 6.14.3.3.2—Decks in Global Tension

Factored resistance of decks subject to global tension,  $P_u$ , due to the factored loads with simultaneous global shear combined with local flexure shall satisfy:

$$\frac{P_u}{P_r} + \frac{M_{ur}}{M_{rr}} \leq 1.33 \quad (6.14.3.3.2-1)$$

in which:

$$P_u = A_{d,eff} \left( f_g^2 + 3f_{vg}^2 \right)^{0.5} \quad (6.14.3.3.2-2)$$

where:

$f_g$  = axial global stress in deck (ksi)

$f_{vg}$  = simultaneous global shear in deck (ksi)

$A_{d,eff}$  = effective cross-section area of deck, including longitudinal ribs ( $\text{in.}^2$ )

$P_r$  = nominal tensile resistance of the deck, with consideration of effective width of deck (kip)

$M_{ur}$  = local flexural moment of longitudinal rib due to the factored loads (kip-in.)

#### C6.14.3.3.2

Reduction of combined superimposed local and global effects is justified by the small probability of a simultaneous occurrence of the maximum local and global tensile effects and large capacity of orthotropic decks for local overloads.

Global shear effects in orthotropic decks, acting simultaneously with global tensile effects, will increase governing tension in deck. This may be assessed by the Huber-Mises yield criterion used to define the total tensile force effect in Eq. 6.14.3.3.2-2. The effect of simultaneous shear is usually not significant in orthotropic roadways of girder or truss bridges, but it may be important in decks used as tension ties in arch or cable-stayed bridges.

$M_{rr}$  = flexural resistance of longitudinal rib,  
governed by reaching yield in extreme fiber  
(kip-in.)

#### 6.14.3.3.3—Decks in Global Compression

#### C6.14.3.3.3

Unless it can be shown by rigorous analysis that overall buckling of the deck will not occur as a result of global compression combined with local flexural compressive forces in the longitudinal ribs, longitudinal ribs, including effective width of deck plate, shall be designed as individual columns assumed to be simply-supported at transverse beams.

Elastic stability of orthotropic deck ribs under combined loading may be evaluated by formulas in Appendix II of Wolchuk (1963).

#### 6.14.3.4—Transverse Flexure

The factored moment resistances of the transverse beams and deck plate shall be such that:

$$\frac{M_{fb}}{M_{rb}} + \frac{M_{ft}}{M_{rt}} \leq 1.0 \quad (6.14.3.4-1)$$

where:

$M_{fb}$  = applied moment due to the factored loads in transverse beam (kip-in.)

$M_{rb}$  = factored moment resistance of transverse beam (kip-in.)

$M_{ft}$  = applied transverse moment in the deck plate due to the factored loads as a result of the plate carrying wheel loads to adjacent longitudinal ribs (kip-in.)

$M_{rt}$  = factored moment resistance of deck plate in carrying wheel loads to adjacent ribs (kip-in.)

For deck configurations in which the spacing of transverse beams is at least three times the spacing of longitudinal rib webs, the second term in Eq. 6.14.3.4-1 may be omitted.

#### 6.14.3.5—Diaphragms

Diaphragms or cross-frames shall be provided at each support and shall have sufficient stiffness and strength to transmit lateral forces to the bearings and to resist transverse rotation, displacement, and distortion. Intermediate diaphragms or cross-frames shall be provided at locations consistent with the analysis of the girders and shall have sufficient stiffness and strength to resist transverse distortions.

## 6.14.4—Solid Web Arches

### 6.14.4.1—Moment Amplification for Deflection

For moment amplification, provisions specified in Article 4.5.3.2.2c shall be satisfied.

### 6.14.4.2—Web Slenderness

The slenderness of the webs of arch ribs shall satisfy:

$$\frac{D}{t_w} \leq k \sqrt{\frac{E}{f_a}} \quad (6.14.4.2-1)$$

where:

$f_a$  = axial stress due to the factored loads (ksi)

$k$  = plate stability factor specified in Table 6.14.4.2-1

**Table 6.14.4.2-1—Plate Slenderness of Arches**

Condition	$k$	$I_s$
No longitudinal stiffener	1.25	—
One longitudinal stiffener	1.88	$I_s = 0.75Dt_w^3$
Two longitudinal stiffeners	2.51	$I_s = 2.2Dt_w^3$

The moment of inertia of the stiffeners about an axis parallel to the web at the base of the stiffener shall not be less than that specified in Table 6.14.4.2-1.

The width to thickness ratio for the stiffeners shall satisfy:

$$\frac{b}{t_s} \leq 0.408 \sqrt{\frac{E}{f_a + \frac{f_b}{3}}} \leq 12 \quad (6.14.4.2-2)$$

where:

$f_b$  = maximum stress due to the factored loads, including moment amplification (ksi)

### 6.14.4.3—Flange Stability

The width-to-thickness ratio of flanges shall satisfy:

- For the width between webs:

$$\frac{b}{t} \leq 1.06 \sqrt{\frac{E}{f_a + f_b}} \quad (6.14.4.3-1)$$

- For overhang widths:

$$\frac{b}{t} \leq 0.408 \sqrt{\frac{E}{f_a + f_b}} \leq 12 \quad (6.14.4.3-2)$$

## 6.15—PILES

### 6.15.1—General

Piles shall be designed as structural members capable of safely supporting all imposed loads.

For a pile group composed of only vertical piles which is subjected to lateral load, the pile structural analysis shall include explicit consideration of soil-structure interaction effects as specified in Article 10.7.3.9.

### 6.15.2—Structural Resistance

Resistance factors,  $\phi_c$  and  $\phi_f$ , for the strength limit state shall be taken as specified in Article 6.5.4.2. The resistance factors for axial resistance of piles in compression which are subject to damage due to driving shall be applied only to that section of the pile likely to experience damage. Therefore, the specified  $\phi_c$  factors for axial resistance of 0.50 to 0.70 for piles in compression without bending shall be applied only to the axial capacity of the pile. The  $\phi_c$  factors of 0.70 and 0.80 and the  $\phi_f$  factor of 1.00 shall be applied to the combined axial and flexural resistance of the pile in the interaction equation for the compression and flexure terms, respectively.

### C6.15.1

Typically, due to the lack of a detailed soil-structure interaction analysis of pile groups containing both vertical and battered piles, evaluation of combined axial and flexural loading will only be applied to pile groups containing all vertical piles.

### C6.15.2

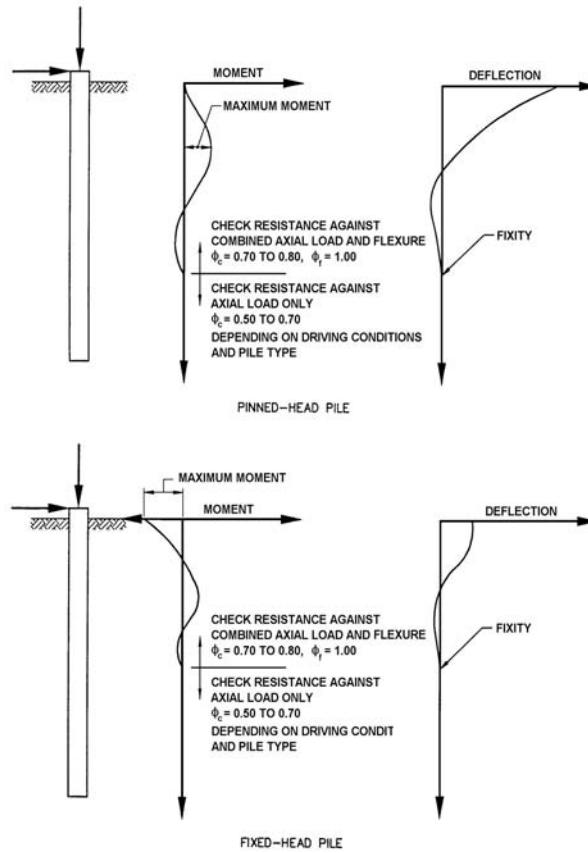

Due to the nature of pile driving, additional factors must be considered in selection of resistance factors that are not normally accounted for in steel members. The factors considered in development of the specified resistance factors include:

- Unintended eccentricity of applied load about pile axis,
- Variations in material properties of pile, and
- Pile damage due to driving.

These factors are discussed by Davisson (1983). While the resistance factors specified herein generally conform to the recommendations given by Davisson (1983), they have been modified to reflect current design philosophy.

The factored compressive resistance,  $P_r$ , includes reduction factors for unintended load eccentricity and material property variations, as well as a reduction for potential damage to piles due to driving, which is most likely to occur near the tip of the pile. The resistance factors for computation of the factored axial pile capacity near the tip of the pile are 0.50 to 0.60 and 0.60 to 0.70 for severe and good driving conditions, respectively. These factors include a base axial compression resistance factor  $\phi_c$  equal to 0.90, modified by reduction multipliers of 0.78 and 0.87 for eccentric loading of H-piles and pipe piles, respectively, and reduction multipliers of 0.75 and 0.875 for difficult and moderately difficult driving conditions.

For steel piles, flexure occurs primarily toward the head of the pile. This upper zone of the pile is less likely to experience damage due to driving. Therefore, relative to combined axial compression and flexure, the resistance factor for axial resistance range of  $\phi_c = 0.70$  to 0.80 accounts for both unintended load eccentricity and pile material property variations, whereas the resistance factor for flexural resistance of  $\phi_f = 1.00$  accounts only for base flexural resistance. This design approach is illustrated on Figure C6.15.2-1 which illustrates the depth to fixity as determined by  $P-\Delta$  analysis.

**Figure C6.15.2-1—Distribution of Moment and Deflection in Vertical Piles Subjected to Lateral Load**

If an unusual situation resulted in significant bending at the pile tip, possible pile damage should be considered in evaluating resistance to combined flexure and axial load.

### 6.15.3—Compressive Resistance

#### 6.15.3.1—Axial Compression

For piles under axial load, the factored resistance of piles in compression,  $P_r$ , shall be taken as specified in Article 6.9.2.1 using the resistance factor,  $\phi_c$ , specified in Article 6.5.4.2.

#### 6.15.3.2—Combined Axial Compression and Flexure

Piles subjected to axial load and flexure shall be designed in accordance with Article 6.9.2.2 using the resistance factors,  $\phi_c$  and  $\phi_f$ , specified in Article 6.5.4.2.

#### 6.15.3.3—Buckling

Instability of piles which extend through water or air shall be accounted for as specified in Article 6.9. Piles which extend through water or air shall be assumed to be fixed at some depth below the ground.

#### C6.15.3.3

An approximate method acceptable to the Engineer may be used in lieu of a  $P-\Delta$  analysis.

Stability shall be determined in accordance with provisions in Article 6.9 for compression members using an equivalent length of the pile equal to the laterally unsupported length, plus an embedded depth to fixity. The depth to fixity shall be determined in accordance with Article 10.7.3.13.4 for battered piles or  $P-\Delta$  analysis for vertical piles.

#### 6.15.4—Maximum Permissible Driving Stresses

Maximum permissible driving stresses for top driven steel piles shall be taken as specified in Article 10.7.8.

## APPENDIX A6—FLEXURAL RESISTANCE OF STRAIGHT COMPOSITE I-SECTIONS IN NEGATIVE FLEXURE AND STRAIGHT NONCOMPOSITE I-SECTIONS WITH COMPACT OR NONCOMPACT WEBS

### A6.1—GENERAL

These provisions shall apply only to sections in straight bridges whose supports are normal or skewed not more than 20 degrees from normal, and with intermediate diaphragms or cross-frames placed in contiguous lines parallel to the supports, that satisfy the following requirements:

- the specified minimum yield strengths of the flanges and web do not exceed 70.0 ksi,
- the web satisfies the noncompact slenderness limit:

$$\frac{2D_c}{t_w} < 5.7 \sqrt{\frac{E}{F_{yc}}} \quad (\text{A6.1-1})$$

and:

- the flanges satisfy the following ratio:

$$\frac{I_{yc}}{I_{yt}} \geq 0.3 \quad (\text{A6.1-2})$$

where:

$D_c$  = depth of the web in compression in the elastic range (in.). For composite sections,  $D_c$  shall be determined as specified in Article D6.3.1.

$I_{yc}$  = moment of inertia of the compression flange of the steel section about the vertical axis in the plane of the web (in.<sup>4</sup>)

$I_{yt}$  = moment of inertia of the tension flange of the steel section about the vertical axis in the plane of the web (in.<sup>4</sup>)

Otherwise, the section shall be proportioned according to the provisions specified in Article 6.10.8.

Sections designed according to these provisions shall qualify as either compact web sections or noncompact web sections determined as specified in Article A6.2.

### CA6.1

The optional provisions of Appendix A6 account for the ability of compact and noncompact web I-sections to develop flexural resistances significantly greater than  $M_y$  when the web slenderness,  $2D_c/t_w$ , is well below the noncompact limit of Eq. A6.1-1, which is a restatement of Eq. 6.10.6.2.3-1, and when sufficient requirements are satisfied with respect to the flange specified minimum yield strengths, the compression-flange slenderness,  $b_f/2t_{fc}$ , and the lateral brace spacing. These provisions also account for the beneficial contribution of the St. Venant torsional constant,  $J$ . This may be useful, particularly under construction situations, for sections with compact or noncompact webs having larger unbraced lengths for which additional lateral torsional buckling resistance may be required. Also, for heavy column shapes with  $D/b_f < 1.7$ , which may be used as beam-columns in steel frames, both the inelastic and elastic buckling resistances are heavily influenced by  $J$ .

The potential benefits of the Appendix A6 provisions tend to be small for I-sections with webs that approach the noncompact web slenderness limit of Eq. A6.1-1. For these cases, the simpler and more streamlined provisions of Article 6.10.8 are recommended. The potential gains in economy by using Appendix A6 increase with decreasing web slenderness. The Engineer should give strong consideration to utilizing Appendix A6 for sections in which the web is compact or nearly compact. In particular, the provisions of Appendix A6 are recommended for sections with compact webs, as defined in Article A6.2.1.

The provisions of Appendix A6 are fully consistent with and are a direct extension of the main procedures in Article 6.10.8 in concept and in implementation. The calculation of potential flexural resistances greater than  $M_y$  is accomplished through the use of the web plastification parameters  $R_{pc}$  and  $R_{pt}$  of Article A6.2, corresponding to flexural compression and tension, respectively. These parameters are applied much like the web bend-buckling and hybrid girder parameters  $R_b$  and  $R_h$  in the main specification provisions.

I-section members with a specified minimum yield strength of the flanges greater than 70.0 ksi are more likely to be limited by Eq. A6.1-1 and are likely to be controlled by design considerations other than the Strength Load Combinations in ordinary bridge construction. In cases where Eq. A6.1-1 is satisfied with  $F_{yc} > 70.0$  ksi, the implications of designing such members in general using a nominal flexural resistance greater than  $M_y$  have not been sufficiently studied to merit the use of Appendix A6.

Eq. A6.1-2 is specified to guard against extremely monosymmetric noncomposite I-sections, in which analytical studies indicate a significant loss in the influence of the St. Venant torsional rigidity  $GJ$  on the lateral-torsional buckling resistance due to cross-section distortion. The influence of web distortion on the lateral torsional buckling resistance is larger for such members. If the flanges are of equal thickness, this limit is equivalent to  $b_{fc} \geq 0.67b_{ft}$ .

#### A6.1.1—Sections with Discretely Braced Compression Flanges

At the strength limit state, the following requirement shall be satisfied:

$$M_u + \frac{1}{3}f_\ell S_{xc} \leq \phi_f M_{nc} \quad (\text{A6.1.1-1})$$

where:

$\phi_f$  = resistance factor for flexure specified in Article 6.5.4.2

$f_\ell$  = flange lateral bending stress determined as specified in Article 6.10.1.6 (ksi)

$M_{nc}$  = nominal flexural resistance based on the compression flange determined as specified in Article A6.3 (kip-in.)

$M_u$  = bending moment about the major-axis of the cross-section determined as specified in Article 6.10.1.6 (kip-in.)

$M_{yc}$  = yield moment with respect to the compression flange determined as specified in Article D6.2 (kip-in.)

$S_{xc}$  = elastic section modulus about the major axis of the section to the compression flange taken as  $M_{yc}/F_{yc}$  (in.<sup>3</sup>)

#### CA6.1.1

Eq. A6.1.1-1 addresses the effect of combined major-axis bending and compression flange lateral bending using an interaction equation approach. This equation expresses the flexural resistance in terms of the section major-axis bending moment,  $M_u$ , and the flange lateral bending stress,  $f_\ell$ , computed from an elastic analysis, applicable within the limits on  $f_\ell$  specified in Article 6.10.1.6 (White and Grubb, 2005).

For adequately braced sections with a compact web and compression flange, Eqs. A6.1.1-1 and A6.1.2-1 are generally a conservative representation of the resistance obtained by procedures that address the effect of flange wind moments given in Article 6.10.3.5.1 of AASHTO (2004). In the theoretical limit that the web area becomes negligible relative to the flange area, these equations closely approximate the results of an elastic-plastic section analysis in which a fraction of the width from the tips of the flanges is deducted to accommodate the flange lateral bending. The conservatism of these equations relative to the theoretical solution increases with increasing  $D_{cp}t_w/b_{fc}t_{fc}$ ,  $f_\ell$ , and/or  $|D_{cp} - D_c|$ . The conservatism at the limit on  $f_\ell$  specified by Eq. 6.10.1.6-1 ranges from about three to ten percent for practical flexural I-sections.

The multiplication of  $f_\ell$  by  $S_{xc}$  in Eq. A6.1.1-1 and by  $S_{xt}$  in Eq. A6.1.2-1 stems from the derivation of these equations, and is explained further in White and Grubb (2005). These equations may be expressed in a stress format by dividing both sides by the corresponding elastic section modulus, in which case, Eq. A6.1.1-1 reduces effectively to Eqs. 6.10.3.2.1-2 and 6.10.8.1.1-1 in the limit that the web approaches its noncompact slenderness limit. Correspondingly, Eq. A6.1.2-1 reduces effectively to Eqs. 6.10.7.2.1-2 and 6.10.8.1.2-1 in this limit.

The elastic section moduli,  $S_{xc}$  in this Article and  $S_{xt}$  in Article A6.1.2, are defined as  $M_{yc}/F_{yc}$  and  $M_{yt}/F_{yt}$ , respectively, where  $M_{yc}$  and  $M_{yt}$  are calculated as specified in Article D6.2. This definition is necessary so that for a composite section with a web proportioned precisely at the noncompact limit given by Eq. A6.1-1, the flexural resistance predicted by Appendix A6 is approximately the same as that predicted by Article 6.10.8. Differences between these predictions are due to the simplifying assumptions of  $J=0$  versus  $J\neq 0$  in determining the elastic lateral torsional buckling resistance and the limiting

unbraced length  $L_r$ , the use of  $k_c = 0.35$  versus the use of  $k_c$  from Eq. A6.3.2-6 in determining the limiting slenderness for a noncompact flange, and the use of a slightly different definition for  $F_{yr}$ . The maximum potential flexural resistance, shown as  $F_{max}$  in Figure C6.10.8.2.1-1, is defined in terms of the flange stresses as  $R_h F_y$  for a section with a web proportioned precisely at the noncompact web limit and designed according to the provisions of Article 6.10.8, where  $R_h$  is the hybrid factor defined in Article 6.10.1.10.1. As discussed in Article 6.10.1.1.1a, for composite sections, the elastically computed flange stress to be compared to this limit is to be taken as the sum of the stresses caused by the loads applied separately to the steel, short-term composite and long-term composite sections. The resulting provisions of Article 6.10.8 are a reasonable strength prediction for slender-web sections in which the web is proportioned precisely at the noncompact limit. By calculating  $S_{xc}$  and  $S_{xt}$  in the stated manner, elastic section moduli are obtained that, when multiplied by the corresponding flexural resistances predicted from Article 6.10.8 for the case of a composite slender-web section proportioned precisely at the noncompact web limit, produce approximately the same flexural resistances as predicted in Appendix A6.

For composite sections with web slenderness values that approach the compact web limit of Eq. A6.2.1-2, the effects of the loadings being applied to the different steel, short-term and long-term sections are nullified by the yielding within the section associated with the development of the stated flexural resistance. Therefore, for compact web sections, these Specifications define the maximum potential flexural resistance, shown as  $M_{max}$  in Figure C6.10.8.2.1-1, as the plastic moment  $M_p$ , which is independent of the effects of the different loadings.

### A6.1.2—Sections with Discretely Braced Tension Flanges

At the strength limit state, the following requirement shall be satisfied:

$$M_u + \frac{1}{3} f_\ell S_{xt} \leq \phi_f M_{nt} \quad (\text{A6.1.2-1})$$

where:

$M_{nt}$  = nominal flexural resistance based on tension yielding determined as specified in Article A6.4 (kip-in.)

$M_{yt}$  = yield moment with respect to the tension flange determined as specified in Article D6.2 (kip-in.)

$S_{xt}$  = elastic section modulus about the major axis of the section to the tension flange taken as  $M_{yt}/F_{yt}$  (in.<sup>3</sup>)

### CA6.1.2

Eq. A6.1.2-1 parallels Eq. A6.1.1-1 for discretely braced compression flanges, but applies to the case of discretely braced flanges in flexural tension due to the major-axis bending moment.

When  $f_\ell$  is equal to zero and  $M_{yc}$  is less than or equal to  $M_{yt}$ , the flexural resistance based on the tension flange does not control and Eq. A6.1.2-1 need not be checked. The web plastification factor for tension flange yielding,  $R_{pb}$ , from Article A6.2 also need not be computed for this case.

### A6.1.3 Sections with Continuously Braced Compression Flanges

At the strength limit state, the following requirement shall be satisfied:

$$M_u \leq \phi_f R_{pc} M_{yc} \quad (\text{A6.1.3-1})$$

where:

$M_{yc}$  = yield moment with respect to the compression flange determined as specified in Article D6.2 (kip-in.)

$R_{pc}$  = web plastification factor for the compression flange determined as specified in Article A6.2.1 or Article A6.2.2, as applicable

### CA6.1.3

Flange lateral bending need not be considered in continuously braced flanges, as discussed further in Article C6.10.1.6.

### A6.1.4 Sections with Continuously Braced Tension Flanges

At the strength limit state, the following requirement shall be satisfied:

$$M_u \leq \phi_f R_{pt} M_{yt} \quad (\text{A6.1.4-1})$$

where:

$M_{yt}$  = yield moment with respect to the tension flange determined as specified in Article D6.2 (kip-in.)

$R_{pt}$  = web plastification factor for the tension flange determined as specified in Article A6.2.1 or Article A6.2.2, as applicable

## A6.2—WEB PLASTIFICATION FACTORS

### A6.2.1—Compact Web Sections

Sections that satisfy the following requirement shall qualify as compact web sections:

$$\frac{2D_{cp}}{t_w} \leq \lambda_{pw(D_{cp})} \quad (\text{A6.2.1-1})$$

in which:

$\lambda_{pw(D_{cp})}$  = limiting slenderness ratio for a compact web corresponding to  $2D_{cp}/t_w$

### CA6.2.1

Eq. A6.2.1-1 ensures that the section is able to develop the full plastic moment capacity  $M_p$  provided that other flange slenderness and lateral torsional bracing requirements are satisfied. This limit is significantly less than the noncompact web limit shown in Table C6.10.1.10.2-2. It is generally satisfied by rolled I-shapes, but typically not by the most efficient built-up sections.

Eq. A6.2.1-2 is a modified web compactness limit relative to prior Specifications that accounts for the higher demands on the web in noncomposite monosymmetric I-sections and in composite I-sections in negative bending with larger shape factors,  $M_p/M_y$  (White and Barth, 1998; Barth et al., 2005). This updated web compactness limit eliminates the need for providing an interaction equation between the web and flange compactness requirements (AASHTO, 1996,

$$= \frac{\sqrt{\frac{E}{F_{yc}}}}{\left(0.54 \frac{M_p}{R_h M_y} - 0.09\right)^2} \leq \lambda_{rw} \left(\frac{D_{cp}}{D_c}\right) \quad (\text{A6.2.1-2})$$

$\lambda_{rw}$  = limiting slenderness ratio for a noncompact web

$$= 5.7 \sqrt{\frac{E}{F_{yc}}} \quad (\text{A6.2.1-3})$$

where:

$D_c$  = depth of the web in compression in the elastic range (in.). For composite sections,  $D_c$  shall be determined as specified in Article D6.3.1.

$D_{cp}$  = depth of the web in compression at the plastic moment determined as specified in Article D6.3.2 (in.)

$M_y$  = yield moment taken as the smaller of  $M_{yc}$  and  $M_{yt}$  determined as specified in Article D6.2 (kip-in.)

$R_h$  = hybrid factor determined as specified in Article 6.10.1.10.1

The web plastification factors shall be taken as:

$$R_{pc} = \frac{M_p}{M_{yc}} \quad (\text{A6.2.1-4})$$

$$R_{pt} = \frac{M_p}{M_{yt}} \quad (\text{A6.2.1-5})$$

where:

$M_p$  = plastic moment determined as specified in Article D6.1 (kip-in.)

$M_{yc}$  = yield moment with respect to the compression flange determined as specified in Article D6.2 (kip-in.)

$M_{yt}$  = yield moment with respect to the tension flange determined as specified in Article D6.2 (kip-in.)

$R_{pc}$  = web plastification factor for the compression flange

$R_{pt}$  = web plastification factor for tension flange yielding

2004). Eq. A6.2.1-2 reduces to the previous web compactness limit given by Equation 6.10.4.1.2-1 in AASHTO (2004) when  $M_p/M_y = 1.12$ , which is representative of the shape factor for doubly-symmetric noncomposite I-sections. The previous web compactness limit is retained in Eq. 6.10.6.2.2-1 for composite sections in positive flexure since research does not exist to quantify the web compactness requirements for these types of sections with any greater precision, and also since most composite sections in positive flexure easily satisfy this requirement.

The compactness restrictions on the web imposed by Eq. A6.2.1-2 are approximately the same as the requirements implicitly required for development of the plastic moment resistance,  $M_p$ , by the  $Q$  formula in AASHTO (2004). Both of these requirements are plotted as a function of  $M_p/M_y$  for  $F_{yc} = 50.0$  ksi in Figure CA6.2.1-1.

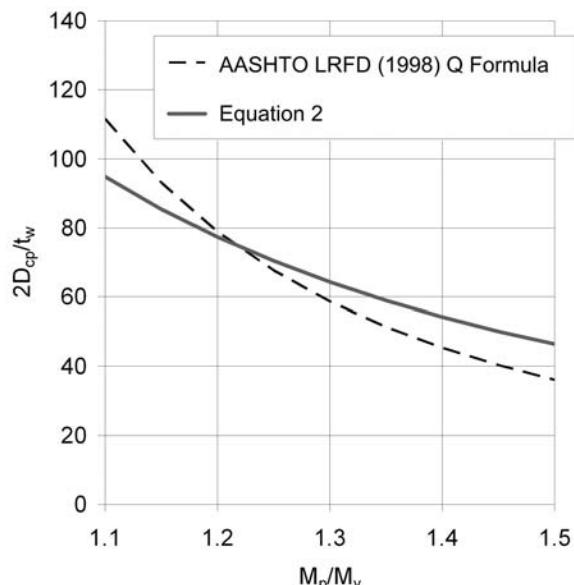

Figure CA6.2.1-1—Web Compactness Limits as a Function of  $M_p/M_y$  from the AASHTO (2004)  $Q$  formula and from Eq. A6.2.1-2 for  $F_{yc} = 50.0$  ksi

For a compact web section, the maximum potential moment resistance, represented by  $M_{max}$  in Figure C6.10.8.2.1-1, is simply equal to  $M_p$ . Eqs. A6.2.1-4 and A6.2.1-5 capture this attribute and eliminate the need to repeat the subsequent flexural resistance equations in a nearly identical fashion for compact and noncompact web sections. For a compact web section, the web plastification factors are equivalent to the cross-section shape factors.

## A6.2.2—Noncompact Web Sections

Sections that do not satisfy the requirement of Eq. A6.2.1-1, but for which the web slenderness satisfies the following requirement:

$$\lambda_w < \lambda_{rw} \quad (\text{A6.2.2-1})$$

shall qualify as noncompact web sections, where:

$\lambda_w$  = slenderness ratio for the web based on the elastic moment

$$= \frac{2D_c}{t_w} \quad (\text{A6.2.2-2})$$

$\lambda_{rw}$  = limiting slenderness ratio for a noncompact web

$$= 5.7 \sqrt{\frac{E}{F_{yc}}} \quad (\text{A6.2.2-3})$$

$D_c$  = depth of the web in compression in the elastic range (in.). For composite sections,  $D_c$  shall be determined as specified in Article D6.3.1.

The web plastification factors shall be taken as:

$$R_{pc} = \left[ 1 - \left( 1 - \frac{R_h M_{yc}}{M_p} \right) \left( \frac{\lambda_w - \lambda_{pw(D_c)}}{\lambda_{rw} - \lambda_{pw(D_c)}} \right) \right] \frac{M_p}{M_{yc}} \leq \frac{M_p}{M_{yc}} \quad (\text{A6.2.2-4})$$

$$R_{pt} = \left[ 1 - \left( 1 - \frac{R_h M_{yt}}{M_p} \right) \left( \frac{\lambda_w - \lambda_{pw(D_c)}}{\lambda_{rw} - \lambda_{pw(D_c)}} \right) \right] \frac{M_p}{M_{yt}} \leq \frac{M_p}{M_{yt}} \quad (\text{A6.2.2-5})$$

where:

$\lambda_{pw(D_c)}$  = limiting slenderness ratio for a compact web corresponding to  $2D_c/t_w$

$$= \lambda_{pw(D_{cp})} \left( \frac{D_c}{D_{cp}} \right) \leq \lambda_{rw} \quad (\text{A6.2.2-6})$$

## CA6.2.2

Eqs. A6.2.2-4 and A6.2.2-5 account for the influence of the web slenderness on the maximum potential flexural resistance,  $M_{max}$  in Figure C6.10.8.2.1-1, for noncompact web sections. As  $2D_c/t_w$  approaches the noncompact web limit  $\lambda_{rw}$ ,  $R_{pc}$  and  $R_{pt}$  approach values equal to  $R_h$  and the maximum potential flexural resistance expressed within the subsequent limit state equations approaches a limiting value of  $R_h M_y$ . As  $2D_{cp}/t_w$  approaches the compact web limit  $\lambda_{pw(D_{cp})}$ , Eqs. A6.2.2-4 and A6.2.2-5 define a smooth

transition in the maximum potential flexural resistance, expressed by the subsequent limit state equations, from  $M_y$  to the plastic moment resistance  $M_p$ . For a compact web section, the web plastification factors  $R_{pc}$  and  $R_{pt}$  are simply the section shape factors corresponding to the compression and tension flanges,  $M_p/M_{yc}$  and  $M_p/M_{yt}$ . The subsequent flexural resistance equations are written using  $R_{pc}$  and  $R_{pt}$  for these types of sections rather than expressing the maximum resistance simply as  $M_p$  to avoid repetition of strength equations that are otherwise identical.

In Eqs. A6.2.2-4 and A6.2.2-5, explicit maximum limits of  $M_p/M_{yc}$  and  $M_p/M_{yt}$  are placed on  $R_{pc}$  and  $R_{pt}$ , respectively. As a result, the larger of the base resistances,  $R_{pc}M_{yc}$  or  $R_{pt}M_{yt}$ , is limited to  $M_p$  for a highly monosymmetric section in which  $M_{yc}$  or  $M_{yt}$  can be greater than  $M_p$ . The limits on  $I_{yc}/I_{yt}$  given in Article 6.10.2.2 will tend to prevent the use of extremely monosymmetric sections that have  $M_{yc}$  or  $M_{yt}$  values greater than  $M_p$ . The upper limits on  $R_{pc}$  and  $R_{pt}$  have been provided to make Eqs. A6.2.2-4 and A6.2.2-5 theoretically correct in these extreme cases, even though the types of monosymmetric sections where these limits control will not likely occur.

Eq. A6.2.2-6 converts the web compactness limit given by Eq. A6.2.1-2, which is defined in terms of  $D_{cp}$ , to a value that can be used consistently in terms of  $D_c$  in Eqs. A6.2.2-4 and A6.2.2-5. In cases where  $D_c/D > 0.5$ ,  $D_{cp}/D$  is typically larger than  $D_c/D$ ; therefore,  $\lambda_{pw(D_c)}$  is

smaller than  $\lambda_{pw(D_{cp})}$ . However, when  $D_c/D < 0.5$ ,  $D_{cp}/D$  is typically smaller than  $D_c/D$  and  $\lambda_{pw(D_c)}$  is larger than  $\lambda_{pw(D_{cp})}$ . In extreme cases where  $D_c/D$  is significantly less than 0.5, the web slenderness associated with the elastic cross-section,  $2D_c/t_w$ , can be larger than  $\lambda_{rw}$  while that associated with the plastic cross-section,  $2D_{cp}/t_w$ , can be smaller than  $\lambda_{pw(D_{cp})}$  without the upper limit of  $\lambda_{rw}(D_{cp}/D_c)$

that is placed on this value. That is, the elastic web is classified as slender while the plastic web is classified as compact. In these cases, the compact web limit is defined as  $\lambda_{pw(D_{cp})} = \lambda_{rw}(D_{cp}/D_c)$ . This is a conservative approximation aimed at protecting against the occurrence of bend-buckling in the web prior to reaching the section plastic resistance.

The ratio  $D_c/D$  is generally greater than 0.5 for noncomposite sections with a smaller flange in compression, such as typical composite I-girders in positive bending before they are made composite.

## A6.3—FLEXURAL RESISTANCE BASED ON THE COMPRESSION FLANGE

### A6.3.1—General

For unbraced lengths in which the member is prismatic, the nominal flexural resistance based on the compression flange,  $M_{nc}$ , shall be taken as the smaller of the local buckling resistance determined as specified in Article A6.3.2, and the lateral torsional buckling resistance determined as specified in Article A6.3.3. Otherwise, Eq. A6.1.1-1 shall be satisfied for both local buckling and lateral torsional buckling using the appropriate value of  $M_{nc}$  determined for each case.

### CA6.3.1

All of the I-section compression-flange flexural resistance equations of these Specifications are based consistently on the logic of identifying the two anchor points shown in Figure C6.10.8.2.1-1 for the case of uniform major-axis bending. Anchor point 1 is located at the length  $L_b = L_p$  for lateral torsional buckling (LTB) or the flange slenderness  $b_{fc}/2t_{fc} = \lambda_{pf}$  for flange local buckling (FLB) corresponding to development of the maximum potential flexural resistance, labeled as  $F_{max}$  or  $M_{max}$  in the figure, as applicable. Anchor point 2 is located at the length  $L_r$  or flange slenderness  $\lambda_{rf}$  for which the inelastic and elastic LTB or FLB resistances are the same.

In Article A6.3, this resistance is taken as  $R_b F_{yr} S_{xc}$ , where  $F_{yr}$  is taken as the smaller of  $0.7F_{yc}$ ,  $F_{yw}$ , or  $R_h F_{yt} S_{xt}/S_{xc}$ , but not smaller than  $0.5F_{yc}$ . The first two of these resistances are the same as in Article 6.10.8. The third resistance expression,  $R_h F_{yt} S_{xt}/S_{xc}$ , which is simply the elastic compression-flange stress at the cross-section moment  $R_h F_{yt} S_{xt} = R_h M_{yt}$ , is specific to Article A6.3 and captures the effects of significant early tension-flange yielding in sections with a small depth of web in compression. In sections that have this characteristic, the early tension-flange yielding invalidates the elastic lateral torsional buckling equation on which the noncompact bracing limit  $L_r$  is based, and also makes the corresponding elastic flange local buckling equation suspect due to potential significant inelastic redistribution of stresses to the compression flange. The limit  $R_h F_{yt} S_{xt}/S_{xc}$  rarely controls for bridge I-girders, but it may control in some instances of pier negative moment sections in composite continuous spans, prior to the section becoming composite, in which the top flange is significantly smaller than the bottom flange. For  $L_b > L_r$  or  $b_{fc}/2t_{fc} > \lambda_{rf}$ , the LTB and FLB resistances are governed by elastic buckling. However, the elastic FLB resistance equations are not specified explicitly in these provisions since the limits of Article 6.10.2.2 preclude elastic FLB for specified minimum yield strengths up to and including  $F_{yc} = 70.0$  ksi, which is the limiting yield strength for the application of the provisions of Appendix A6.

For unbraced lengths subjected to moment gradient, the LTB resistances for the case of uniform major-axis bending are simply scaled by the moment gradient modifier  $C_b$ , with the exception that the LTB resistance is capped at  $F_{max}$  or  $M_{max}$ , as illustrated by the dashed line in Figure C6.10.8.2.1-1. The maximum unbraced length at which the LTB resistance is equal to  $F_{max}$  or  $M_{max}$  under a moment gradient may be determined from Article D6.4.1 or D6.4.2, as applicable. The FLB resistance for moment gradient cases is the same as that for the case of uniform major-axis bending, neglecting the relatively minor influence of moment gradient effects.

### A6.3.2—Local Buckling Resistance

The flexural resistance based on compression flange local buckling shall be taken as:

- If  $\lambda_f \leq \lambda_{pf}$ , then:

$$M_{nc} = R_{pc} M_{yc} \quad (\text{A6.3.2-1})$$

- Otherwise:

$$M_{nc} = \left[ 1 - \left( 1 - \frac{F_{yr} S_{xc}}{R_{pc} M_{yc}} \right) \left( \frac{\lambda_f - \lambda_{pf}}{\lambda_{rf} - \lambda_{pf}} \right) \right] R_{pc} M_{yc} \quad (\text{A6.3.2-2})$$

in which:

$$\begin{aligned} \lambda_f &= \text{slenderness ratio for the compression flange} \\ &= \frac{b_{fc}}{2t_{fc}} \quad (\text{A6.3.2-3}) \end{aligned}$$

$$\begin{aligned} \lambda_{pf} &= \text{limiting slenderness ratio for a compact flange} \\ &= 0.38 \sqrt{\frac{E}{F_{yc}}} \quad (\text{A6.3.2-4}) \end{aligned}$$

$$\begin{aligned} \lambda_{rf} &= \text{limiting slenderness ratio for a noncompact flange} \\ &= 0.95 \sqrt{\frac{E k_c}{F_{yr}}} \quad (\text{A6.3.2-5}) \end{aligned}$$

$k_c$  = flange local buckling coefficient

- For built-up sections:

### CA6.3.2

Eq. A6.3.2-4 defines the slenderness limit for a compact flange, whereas Eq. A6.3.2-5 gives the slenderness limit for a noncompact flange. The nominal flexural resistance of a section with a compact flange is independent of the flange slenderness, whereas the flexural resistance of a section with a noncompact flange is expressed as a linear function of the flange slenderness as illustrated in Figure C6.10.8.2.1-1. The compact flange slenderness limit is the same as specified in AISC (2005), AASHTO (1996, 2004), and Article 6.10.8.2.2. For different grades of steel, this slenderness limit is specified in Table C6.10.8.2.2-1. All current ASTM W shapes except W21×48, W14×99, W14×90, W12×65, W10×12, W8×31, W8×10, W6×15, W6×9 and W6×8.5 have compact flanges at  $F_y < 50.0$  ksi.

Eq. A6.3.2-6 for the flange local buckling coefficient comes from the implementation of Johnson's (1985) research in AISC (2005). The value  $k_c = 0.35$  is a lower bound to values back-calculated by equating the resistances from these provisions, or those of Article 6.10.8.2.2 where this Article is not applicable, to the measured resistances from Johnson's and other tests such as those conducted by Basler et al. (1960). Tests ranging from  $D/t_w = 72$  to 245 were considered. One of the tests from Basler et al. (1960) with  $D/t_w = 185$ , in which the compression flange was damaged in a previous test and then subsequently straightened and cut-back to a narrower width prior to retesting, exhibited a back-calculated  $k_c$  of 0.28. This test was not considered in selecting the lower bound. Other tests by Johnson (1985) that had higher  $D/t_w$  values exhibited back-calculated  $k_c$  values greater than 0.4. A value of  $k_c = 0.43$  is obtained for ideally simply-supported boundary conditions at the web-flange juncture (Timoshenko and Gere, 1961). Smaller values of  $k_c$  correspond to the fact that web local buckling in more slender webs tends to destabilize the compression flange. The value of  $k_c = 0.76$  for rolled shapes is taken from AISC (2005).

$$= \frac{4}{\sqrt{\frac{D}{t_w}}} \quad (\text{A6.3.2-6})$$

$$0.35 \leq k_c \leq 0.76$$

- For rolled shapes:

$$= 0.76$$

where:

$F_{yr}$  = compression-flange stress at the onset of nominal yielding within the cross-section, including residual stress effects, but not including compression-flange lateral bending, taken as the smaller of  $0.7F_{yc}$ ,  $R_h F_{yt}$ ,  $S_{xt}/S_{xc}$  and  $F_{yw}$ , but not less than  $0.5F_{yc}$

$M_{yc}$  = yield moment with respect to the compression flange determined as specified in Article D6.2 (kip-in.)

$M_{yt}$  = yield moment with respect to the tension flange determined as specified in Article D6.2 (kip-in.)

$R_h$  = hybrid factor determined as specified in Article 6.10.1.10.1

$R_{pc}$  = web plastification factor for the compression flange determined as specified in Article A6.2.1 or Article A6.2.2, as applicable

$S_{xc}$  = elastic section modulus about the major axis of the section to the compression flange taken as  $M_{yc}/F_{yc}$  (in.<sup>3</sup>)

$S_{xt}$  = elastic section modulus about the major axis of the section to the tension flange taken as  $M_{yt}/F_{yt}$  (in.<sup>3</sup>)

### A6.3.3—Lateral Torsional Buckling Resistance

### CA6.3.3

For unbraced lengths in which the member is prismatic, the flexural resistance based on lateral torsional buckling shall be taken as:

- If  $L_b \leq L_p$ , then:

$$M_{nc} = R_{pc} M_{yc} \quad (\text{A6.3.3-1})$$

- If  $L_p < L_b \leq L_r$ , then:

Eq. A6.3.3-4 defines the compact unbraced length limit for a member subjected to uniform major-axis bending, whereas Eq. A6.3.3-5 gives the corresponding noncompact unbraced length limit. The nominal flexural resistance of a member braced at or below the compact limit is independent of the unbraced length, whereas the flexural resistance of a member braced at or below the noncompact limit is expressed as a linear function of the unbraced length as illustrated in Figure C6.10.8.2.1-1. The compact bracing limit of Eq. A6.3.3-4 is similar to the

$$M_{nc} = C_b \left[ 1 - \left( 1 - \frac{F_{yr} S_{xc}}{R_{pc} M_{yc}} \right) \left( \frac{L_b - L_p}{L_r - L_p} \right) \right] R_{pc} M_{yc} \leq R_{pc} M_{yc} \quad (\text{A6.3.3-2})$$

- If  $L_b > L_r$ , then:

$$M_{nc} = F_{cr} S_{xc} \leq R_{pc} M_{yc} \quad (\text{A6.3.3-3})$$

in which:

$L_b$  = unbraced length (in.).

$L_p$  = limiting unbraced length to achieve the nominal flexural resistance  $R_{pc} M_{yc}$  under uniform bending (in.)

$$= 1.0 r_t \sqrt{\frac{E}{F_{yc}}} \quad (\text{A6.3.3-4})$$

$L_r$  = limiting unbraced length to achieve the nominal onset of yielding in either flange under uniform bending with consideration of compression-flange residual stress effects (in.)

$$= 1.95 r_t \frac{E}{F_{yr}} \sqrt{\frac{J}{S_{xc} h}} \sqrt{1 + \sqrt{1 + 6.76 \left( \frac{F_{yr}}{E} \frac{S_{xc} h}{J} \right)^2}} \quad (\text{A6.3.3-5})$$

$C_b$  = moment gradient modifier. In lieu of an alternative rational analysis,  $C_b$  may be calculated as follows:

- For unbraced cantilevers and for members where  $M_{mid}/M_2 > 1$  or  $M_2 = 0$

$$C_b = 1.0 \quad (\text{A6.3.3-6})$$

- For all other cases,

$$C_b = 1.75 - 1.05 \left( \frac{M_1}{M_2} \right) + 0.3 \left( \frac{M_1}{M_2} \right)^2 \leq 2.3 \quad (\text{A6.3.3-7})$$

$F_{cr}$  = elastic lateral torsional buckling stress (ksi)

$$= \frac{C_b \pi^2 E}{(L_b/r_t)^2} \sqrt{1 + 0.078 \frac{J}{S_{xc} h} (L_b/r_t)^2} \quad (\text{A6.3.3-8})$$

bracing requirement for use of the general compact-section flexural resistance equations and/or the  $Q$  formula equations in AASHTO (2004). The limit given by Eq. A6.3.3-4 is generally somewhat more restrictive than the limit given by the corresponding  $L_p$  equation in AASHTO (2004) and AISC (2005). The limit given by Eq. A6.3.3-4 is based on linear regression analysis within the region corresponding to the inelastic lateral torsional buckling equation, shown qualitatively in Figure C6.10.8.2.1-1, for a wide range of data from experimental flexural tests involving uniform major-axis bending and in which the physical effective length for lateral torsional buckling is effectively 1.0.

Note that the most economical solution is not necessarily achieved by limiting the unbraced length to  $L_p$  in order to reach the maximum flexural resistance,  $M_{max}$ , particularly if the moment gradient modifier,  $C_b$ , is taken equal to 1.0.

Eq. A6.3.3-8 gives the exact beam-theory based solution for the elastic lateral torsional buckling of a doubly-symmetric I-section (Timoshenko and Gere, 1961) for the case of uniform major-axis bending when  $C_b$  is equal to 1.0 and when  $r_t$  is defined as specified by Eq. C6.10.8.2.3-1. Eq. A6.3.3-10 is a simplification of this  $r_t$  equation obtained by assuming  $D = h = d$ . For sections with thick flanges, Eq. A6.3.3-10 gives an  $r_t$  value that can be as much as three to four percent conservative relative to the exact equation. Use of Eq. C6.10.8.2.3-1 is permitted for software calculations or if the Engineer requires a more precise calculation of the elastic LTB resistance. The format of Eq. A6.3.3-8 and the corresponding  $L_r$  limit of Eq. A6.3.3-5 are particularly convenient for design usage since the terms  $L_b$ ,  $r_t$ ,  $J$ ,  $S_{xc}$  and  $h$  are familiar and are easily calculated or can be readily obtained from design tables. Also, by simply setting  $J$  to zero, Eq. A6.3.3-8 reduces to the elastic lateral torsional buckling resistance used in Article 6.10.8.2.3.

Eq. A6.3.3-8 also gives an accurate approximation of the exact beam-theory based solution for elastic lateral torsional buckling of monosymmetric I-section members (White and Jung, 2003). For the case of  $J > 0$  and uniform bending, and considering I-sections with  $D/b_f > 2$ ,  $b_{fc}/2t_{fc} > 5$  and  $L_b = L_r$ , the error in Eq. A6.3.3-8 relative to the exact beam-theory solution ranges from 12 percent conservative to two percent unconservative (White and Jung, 2003). A comparable  $I_{yc}$ -based equation in AASHTO (2004) gives maximum unconservative errors of approximately 14 percent for the same set of parameters studied. For the unusual case of a noncomposite compact or noncompact web section with  $I_{yc}/I_{yt} > 1.5$  and  $D/b_{fc} < 2$ ,  $D/b_{ft} < 2$  or  $b_{ft}/t_{ft} < 10$ , consideration should be given to using the exact beam-theory equations (White and Jung, 2003) in order to obtain a more accurate solution, or else  $J$  from Eq. A6.3.3-9 may be factored by 0.8 to account for the tendency of Eq. A6.3.3-8 to overestimate the lateral torsional buckling resistance in such cases. For highly monosymmetric I-sections with a smaller compression flange or for composite I-sections in negative flexure, both

$J$  = St. Venant torsional constant (in.<sup>4</sup>)

$$= \frac{Dt_w^3}{3} + \frac{b_{fc}t_{fc}^3}{3} \left( 1 - 0.63 \frac{t_{fc}}{b_{fc}} \right) + \frac{b_{ft}t_{ft}^3}{3} \left( 1 - 0.63 \frac{t_{ft}}{b_{ft}} \right) \quad (\text{A6.3.3-9})$$

$r_t$  = effective radius of gyration for lateral torsional buckling (in.)

$$= \frac{b_{fc}}{\sqrt{12 \left( 1 + \frac{1}{3} \frac{D_c t_w}{b_{fc} t_{fc}} \right)}} \quad (\text{A6.3.3-10})$$

where:

$F_{yr}$  = compression-flange stress at the onset of nominal yielding within the cross-section, including residual stress effects, but not including compression-flange lateral bending, taken as the smaller of  $0.7F_{yc}$ ,  $R_h F_{yt} S_{xt}/S_{xc}$  and  $F_{yw}$ , but not less than  $0.5F_{yc}$

$D_c$  = depth of the web in compression in the elastic range (in.). For composite sections,  $D_c$  shall be determined as specified in Article D6.3.1.

$h$  = depth between the centerline of the flanges (in.)

$M_{mid}$  = major-axis bending moment at the middle of the unbraced length, calculated from the moment envelope value that produces the largest compression at this point in the flange under consideration, or the smallest tension if this point is never in compression (kip-in.).  $M_{mid}$  shall be due to the factored loads and shall be taken as positive when it causes compression and negative when it causes tension in the flange under consideration.

$M_0$  = moment at the brace point opposite to the one corresponding to  $M_2$ , calculated from the moment envelope value that produces the largest compression at this point in the flange under consideration, or the smallest tension if this point is never in compression (kip-in.).  $M_0$  shall be due to the factored loads and shall be taken as positive when it causes compression and negative when it causes tension in the flange under consideration.

Eq. A6.3.3-8 and the prior  $I_{yc}$ -based equation in AASHTO (2004) are somewhat conservative compared to rigorous beam-theory based solutions. This is due to the fact that these equations do not account for the restraint against lateral buckling of the compression flange provided by the larger tension flange or the deck. However, the distortional flexibility of the web significantly reduces this beneficial effect in many practical situations.

Eq. A6.3.3-9 is taken from El Darwish and Johnston (1965) and provides an accurate approximation of the St. Venant torsional constant,  $J$ , neglecting the effect of the web-to-flange fillets. For a compression or tension flange with a ratio,  $b_f/2t_f$ , greater than 7.5, the term in parentheses given in Eq. A6.3.3-9 for that flange may be taken equal to one. Equations from El Darwish and Johnston (1965) that are employed in the calculation of AISC (2005) manual values for  $J$  and include the effect of the web-to-flange fillets are included in Seaburg and Carter (1997).

The Engineer should note the importance of the web term  $D_c t_w$  within Eq. A6.3.3-10. Prior Specifications have often used the radius of gyration of only the compression flange,  $r_{yc} = b_{fc} / \sqrt{12}$ , within design equations for LTB. This approximation can lead to significant unconservative predictions relative to experimental and refined finite-element results. The web term in Eq. A6.3.3-10 accounts for the destabilizing effects of the flexural compression within the web.

The effect of the variation in the moment along the length between brace points is accounted for by using the moment gradient modifier,  $C_b$ . Article C6.10.8.2.3 discusses the  $C_b$  parameter in detail. Article 6.10.8.2.3 addresses unbraced lengths in which the member is nonprismatic. Article A6.3.3 extends the provisions for such unbraced lengths to members with compact and noncompact webs.

Where  $C_b$  is greater than 1.0, indicating the presence of a moment gradient, the lateral torsional buckling resistances may alternatively be calculated by the equivalent procedures specified in Article D6.4.2. Both the equations in this Article and in Article D6.4.2 permit  $M_{max}$  in Figure C6.10.8.2.1-1 to be reached at larger unbraced lengths when  $C_b$  is greater than 1.0. The procedures in Article D6.4.2 allow the Engineer to focus directly on the maximum unbraced length at which the flexural resistance is equal to  $M_{max}$ . The use of these equivalent procedures is strongly recommended when  $C_b$  values greater than 1.0 are utilized in the design.

$M_1$  = moment at the brace point opposite to the one corresponding to  $M_2$ , calculated as the intercept of the most critical assumed linear moment variation passing through  $M_2$  and either  $M_{mid}$  or  $M_0$ , whichever produces the smaller value of  $C_b$  (kip-in.).  $M_1$  may be calculated as follows:

- When the variation in the moment along the entire length between the brace points is concave in shape:

$$M_1 = M_0 \quad (\text{A6.3.3-11})$$

- Otherwise:

$$M_1 = 2M_{mid} - M_2 \geq M_0 \quad (\text{A6.3.3-12})$$

$M_2$  = except as noted below, largest major-axis bending moment at either end of the unbraced length causing compression in the flange under consideration, calculated from the critical moment envelope value (kip-in.).  $M_2$  shall be due to the factored loads and shall be taken as positive. If the moment is zero or causes tension in the flange under consideration at both ends of the unbraced length,  $M_2$  shall be taken as zero.

$M_{yc}$  = yield moment with respect to the compression flange determined as specified in Article D6.2 (kip-in.)

$M_{yt}$  = yield moment with respect to the tension flange determined as specified in Article D6.2 (kip-in.)

$R_h$  = hybrid factor determined as specified in Article 6.10.1.10.1

$R_{pc}$  = web plastification factor for the compression flange determined as specified in Article A6.2.1 or Article A6.2.2, as applicable

$S_{xc}$  = elastic section modulus about the major axis of the section to the compression flange taken as  $M_{yc}/F_{yc}$  (in.<sup>3</sup>)

$S_{xt}$  = elastic section modulus about the major axis of the section to the tension flange taken as  $M_{yt}/F_{yt}$  (in.<sup>3</sup>)

For unbraced lengths where the member consists of noncomposite monosymmetric sections and is subject to reverse curvature bending, the lateral torsional buckling resistance shall be checked for both flanges, unless the top flange is considered to be continuously braced.

For unbraced lengths in which the member is nonprismatic, the flexural resistance based on lateral torsional buckling may be taken as the smallest resistance within the unbraced length under consideration determined from Eq. A6.3.3-1, A6.3.3-2, or A6.3.3-3, as applicable, assuming the unbraced length is prismatic. The flexural resistance  $M_{nc}$  at each section within the unbraced length shall be taken equal to this resistance multiplied by the ratio of  $S_{xc}$  at the section under consideration to  $S_{xc}$  at the section governing the lateral torsional buckling resistance. The moment gradient modifier,  $C_b$ , shall be taken equal to 1.0 in this case and  $L_b$  shall not be modified by an effective length factor.

For unbraced lengths containing a transition to a smaller section at a distance less than or equal to 20 percent of the unbraced length from the brace point with the smaller moment, the flexural resistance based on lateral torsional buckling may be determined assuming the transition to the smaller section does not exist, provided the lateral moment of inertia of the flange or flanges of the smaller section is equal to or larger than one-half the corresponding value in the larger section.

#### A6.4—FLEXURAL RESISTANCE BASED ON TENSION FLANGE YIELDING

The nominal flexural resistance based on tension flange yielding shall be taken as:

$$M_{nt} = R_{pt} M_{yt} \quad (\text{A6.4-1})$$

where:

$M_{yt}$  = yield moment with respect to the tension flange determined as specified in Article D6.2 (kip-in.)

$R_{pt}$  = web plastification factor for tension flange yielding determined as specified in Article A6.2.1 or Article A6.2.2, as applicable

#### CA6.4

Eq. A6.4-1 implements a linear transition in the flexural resistance between  $M_p$  and  $M_{yt}$  as a function of  $2D_c/t_w$  for monosymmetric sections with a larger tension flange and for composite sections in negative flexure where first yielding occurs in the top flange or in the longitudinal reinforcing steel. In the limit that  $2D_c/t_w$  approaches the noncompact web limit given by Eq. A6.2.2-3, Eq. A6.4-1 reduces to the tension flange yielding limit specified in Article 6.10.8.3.

For sections in which  $M_{yt} > M_{yc}$ , Eq. A6.4-1 does not control and need not be checked.

## APPENDIX B6—MOMENT REDISTRIBUTION FROM INTERIOR-PIER I-SECTIONS IN STRAIGHT CONTINUOUS-SPAN BRIDGES

### B6.1—GENERAL

This Article shall apply for the calculation of redistribution moments from the interior-pier sections of continuous span I-section flexural members at the service and/or strength limit states. These provisions shall apply only for I-section members that satisfy the requirements of Article B6.2.

### CB6.1

These optional provisions replace the ten-percent redistribution allowance given in previous Specifications and provide a simple more rational approach for calculating the percentage redistribution from interior-pier sections. This approach utilizes elastic moment envelopes and does not require the direct use of any inelastic analysis methods. The restrictions of Article B6.2 ensure significant ductility and robustness at the interior-pier sections.

In conventional elastic analysis and design, moment and shear envelopes are typically determined by elastic analysis with no redistribution due to the effects of yielding considered. The sections are dimensioned for a resistance equal to or greater than that required by the envelopes. Designs to meet these requirements often involve the addition of cover plates to rolled beams, which introduces details that often have low fatigue resistance, or the introduction of multiple flange transitions in welded beams, which can result in additional fabrication costs. Where appropriate, the use of these provisions to account for the redistribution of moments makes it possible to eliminate such details by using prismatic sections along the entire length of the bridge or between field splices. This practice can improve overall fatigue resistance and provide significant fabrication economies.

Development of these provisions is documented in a number of comprehensive reports (Barker et al., 1997; Schilling et al., 1997; White et al., 1997) and in a summary paper by Barth et al. (2004), which gives extensive references to other supporting research. These provisions account for the fact that the compression flange slenderness,  $b_{fc}/2t_{fc}$ , and the cross-section aspect ratio,  $D/b_{fc}$ , are the predominant factors that influence the moment-rotation behavior at adequately braced interior-pier sections. The provisions apply to sections with compact, noncompact or slender webs.

### B6.2—SCOPE

Moment redistribution shall be applied only in straight continuous span I-section members whose bearing lines are not skewed more than 10 degrees from radial and along which there are no staggered cross-frames. Sections may be either composite or noncomposite in positive or negative flexure.

Cross-sections throughout the unbraced lengths immediately adjacent to interior-pier sections from which moments are redistributed shall have a specified minimum yield strength not exceeding 70.0 ksi. Holes shall not be placed within the tension flange over a distance of two times the web depth on either side of the interior-pier sections from which moments are redistributed. All other sections having tension flange holes shall satisfy the requirements of Article 6.10.1.8 after the moments are redistributed.

### CB6.2

The subject procedures have been developed predominantly in the context of straight non-skewed bridge superstructures without staggered cross-frames. Therefore, their use is restricted to bridges that do not deviate significantly from these idealized conditions.

The development of these provisions focused on nonhybrid and hybrid girders with specified minimum yield strengths up to and including 70.0 ksi. Therefore, use of these provisions with larger yield strengths is not permitted. The influence of tension-flange holes on potential net section fracture at cross-sections experiencing significant inelastic strains is not well known. Therefore, tension flange holes are not allowed over a distance of two times the web depth,  $D$ , on either side of the interior-

Moments shall be redistributed only at interior-pier sections for which the cross-sections throughout the unbraced lengths immediately adjacent to those sections satisfy the requirements of Articles B6.2.1 through B6.2.6. If the refined method of Article B6.6 is used for calculation of the redistribution moments, all interior-pier sections are not required to satisfy these requirements; however, moments shall not be redistributed from sections that do not satisfy these requirements. Such sections instead shall satisfy the provisions of Articles 6.10.4.2, 6.10.8.1 or Article A6.1, as applicable, after redistribution. If the provisions of Articles B6.3 or B6.4 are utilized to calculate interior-pier redistribution moments, the unbraced lengths immediately adjacent to all interior-pier sections shall satisfy the requirements of Articles B6.2.1 through B6.2.6.

### B6.2.1—Web Proportions

The web within the unbraced length under consideration shall be proportioned such that:

$$\frac{D}{t_w} \leq 150 \quad (\text{B6.2.1-1})$$

$$\frac{2D_c}{t_w} \leq 6.8 \sqrt{\frac{E}{F_{yc}}} \quad (\text{B6.2.1-2})$$

and

$$D_{cp} \leq 0.75D \quad (\text{B6.2.1-3})$$

where:

$D_c$  = depth of the web in compression in the elastic range (in.). For composite sections,  $D_c$  shall be determined as specified in Article D6.3.1.

$D_{cp}$  = depth of the web in compression at the plastic moment determined as specified in Article D6.3.2 (in.)

### B6.2.2—Compression Flange Proportions

The compression flange within the unbraced length under consideration shall be proportioned such that:

$$\frac{b_{fc}}{2t_{fc}} \leq 0.38 \sqrt{\frac{E}{F_{yc}}} \quad (\text{B6.2.2-1})$$

pier sections from which moments are redistributed. The distance  $2D$  is an approximate upper bound for the length of the zone of primary inelastic response at these pier sections.

Unless a direct analysis is conducted by the Refined Method outlined in Article B6.6, all the interior-pier sections of a continuous-span member are required to satisfy the requirements of Articles B6.2.1 through B6.2.6 in order to redistribute the pier moments. This is because of the approximations involved in the simplified provisions of Articles B6.3 and B6.4 and the fact that inelastic redistribution moments from one interior support generally produce some nonzero redistribution moments at all of the interior supports.

### CB6.2.1

Eq. B6.2.1-1 simply parallels Eq. 6.10.2.1.1-1 and is intended to eliminate the use of any benefits from longitudinal stiffening of the web at the pier section. The moment-rotation characteristics of sections with longitudinal web stiffeners have not been studied. Eqs. B6.2.1-2 and B6.2.1-3 are limits of the web slenderness and the depth of the web in compression considered in the development of these procedures.

### CB6.2.2

The compression flange is required to satisfy the compactness limit within the unbraced lengths adjacent to the pier section. This limit is restated in Eq. B6.2.2-1. Slightly larger  $b_{fc}/2t_{fc}$  values than this limit have been considered within the supporting research for these provisions. The compactness limit from Articles A6.3.2 and 6.10.8.2 is used for simplicity.

and:

$$b_{fc} \geq \frac{D}{4.25} \quad (\text{B6.2.2-2})$$

### B6.2.3—Section Transitions

The steel I-section member shall be prismatic within the unbraced length under consideration.

### B6.2.4—Compression Flange Bracing

The unbraced length under consideration shall satisfy:

$$L_b \leq \left[ 0.1 - 0.06 \left( \frac{M_1}{M_2} \right) \right] \frac{r_t E}{F_{yc}} \quad (\text{B6.2.4-1})$$

where:

$L_b$  = unbraced length (in.)

$M_1$  = bending moment about the major-axis of the cross-section at the brace point with the lower moment due to the factored loads, taken as either the maximum or minimum moment envelope value, whichever produces the smallest permissible unbraced length (kip-in.)

$M_2$  = bending moment about the major-axis of the cross-section at the brace point with the higher moment due to the factored loads, taken as the critical moment envelope value (kip-in.)

$r_t$  = effective radius of gyration for lateral torsional buckling within the unbraced length under consideration determined from Eq. A6.3.3-10 (in.)

$(M_1/M_2)$  shall be taken as negative when the moments cause reverse curvature.

### B6.2.5—Shear

Webs with or without transverse stiffeners within the unbraced length under consideration shall satisfy the following requirement at the strength limit state:

$$V_u \leq \phi_v V_{cr} \quad (\text{B6.2.5-1})$$

where:

$\phi_v$  = resistance factor for shear specified in Article 6.5.4.2

Eq. B6.2.2-2 represents the largest aspect ratio  $D/b_{fc} = 4.25$  considered in the supporting research. As noted in Articles C6.10.2.2 and CB6.1, increasing values of this ratio have a negative influence on the strength and moment-rotation characteristics of I-section members.

### CB6.2.3

Only members that are prismatic within the unbraced lengths adjacent to interior piers have been considered in the supporting research. Therefore, section transitions are prohibited in these regions.

### CB6.2.4

Eq. B6.2.4-1 gives approximately the same results as the compact-section compression-flange bracing requirements in Article 6.10.4.1.7 of AASHTO (2004), but is written in terms of  $r_t$  rather than  $r_y$ . The use of  $r_y$  in the prior equation leads to an ambiguity in the application of this bracing limit to composite sections in negative flexure. Furthermore, since  $r_t$  focuses strictly on the compression region of the cross-section and does not involve the top flange or the deck for a composite section in negative flexure, it is believed to address the bracing requirements for such a section in a more correct fashion.

Since the negative moment envelope always tends to be concave in shape in the vicinity of interior-pier sections, the consideration of the moment values at the middle of the unbraced length, as required in general for the calculation of  $C_b$  in Articles 6.10.8.2.3 and A6.3.3, is not necessary. Consideration of the moment gradient effects based on the ratio of the end values,  $M_1/M_2$ , is sufficient and conservative.

If  $D_{ctw}/b_{fc}t_{fc}$  in Eq. 6.10.8.2.3-9 or A6.3.3-10 is taken as a representative value of 2.0 and  $F_{yc}$  is taken as 50 ksi, Eq. B6.2.4-1 is satisfied when  $L_b < 13b_{fc}$  for  $M_1/M_2 = 0$  and  $L_b < 9b_{fc}$  for  $M_1/M_2 = 0.5$ .

### CB6.2.5

Use of web shear post-buckling resistance or tension-field action is not permitted within the vicinity of the pier sections designed for redistribution of the negative bending moments.

$V_u$  = shear in the web due to the factored loads (kip)

$V_{cr}$  = shear-buckling resistance determined from Eq. 6.10.9.2-1 for unstiffened webs and from Eq. 6.10.9.3.3-1 for stiffened webs (kip)

### B6.2.6—Bearing Stiffeners

Bearing stiffeners designed by the provisions of Article 6.10.11.2 shall be placed at the interior-pier section under consideration.

## B6.3—SERVICE LIMIT STATE

### B6.3.1—General

Load combination Service II in Table 3.4.1-1 shall apply.

### B6.3.2—Flexure

#### B6.3.2.1—Adjacent to Interior-Pier Sections

With the exception that the requirement of Eq. 6.10.4.2.2-4 shall be satisfied, the provisions of Article 6.10.4.2 shall not be checked within the regions extending in each adjacent span from interior-pier sections satisfying the requirements of Article B6.2 to the nearest flange transition or point of dead-load contraflexure, whichever is closest.

#### CB6.3.2.1

In checking permanent deflections under Load Combination Service II, local yielding is permitted at interior supports satisfying the requirements of Article B6.2. This results in redistribution. The permanent deflections are controlled by imposing the appropriate flange stress limits of Article 6.10.4.2 in each adjacent span at sections outside the nearest flange transition location or point of permanent-load contraflexure, whichever is closest to the interior support under consideration, after redistribution. The appropriate redistribution moments are to be added to the elastic moments due to the Service II loads prior to making these checks. The influence of the strength and ductility at the interior-pier sections is considered within the calculation of the redistribution moments. Therefore, the flange stress limits of Article 6.10.4.2 need not be checked within the regions extending into each adjacent span from the interior-pier section under consideration to the closest point cited above. The provisions of Appendix B6 are not intended to relax the requirement of Eq. 6.10.4.2.2-4. This requirement should be satisfied based on the elastic moments before redistribution.

Additional cambering to account for the small residual deformations associated with redistribution of interior-pier section moments is not recommended. A full-scale bridge designed to permit redistribution of negative moments sustained only very small permanent deflections when tested under the overload condition (Roeder and Eltvik, 1985).

### B6.3.2.2—At All Other Locations

Sections at all other locations shall satisfy the provisions of Article 6.10.4.2, as applicable, after redistribution. For composite sections in positive flexure, the redistribution moments shall be applied to the long-term composite section when computing flexural stresses in the steel section. For computing longitudinal flexural stresses in the concrete deck due to the redistribution moments, the provisions of Article 6.10.1.1.1d shall apply.

The redistribution moments shall be calculated according to the provisions specified in Article B6.3.3 and shall be added to the elastic moments due to the Service II loads.

### B6.3.3—Redistribution Moments

#### B6.3.3.1—At Interior-Pier Sections

At each interior-pier section where the flexural stresses are not checked as permitted in Article B6.3.2.1, the redistribution moment for the Service II loads shall be taken as:

$$M_{rd} = |M_e| - M_{pe} \quad (\text{B6.3.3.1-1})$$

in which:

$$0 \leq M_{rd} \leq 0.2|M_e| \quad (\text{B6.3.3.1-2})$$

where:

$M_{pe}$  = negative-flexure effective plastic moment for the service limit state determined as specified in Article B6.5 (kip-in.)

$M_e$  = critical elastic moment envelope value at the interior-pier section due to the Service II loads (kip-in.)

#### B6.3.3.2—At All Other Locations

The redistribution-moment diagram for the Service II load combination shall be determined by connecting with straight lines the redistribution moments at adjacent interior-pier sections. The lines shall be extended to any points of zero redistribution moment at adjacent supports, including at the abutments.

### CB6.3.2.2

The redistribution moments are in effect permanent moments that remain in the structure. The corresponding locked-in redistribution stresses in composite sections tend to decrease with time as a result of creep in the concrete. However, these redistribution stresses may be continually renewed by subsequent passages of similar loadings. Therefore, the flexural stresses in the steel section due to these moments are to be conservatively calculated based on the long-term composite section.

#### CB6.3.3.1

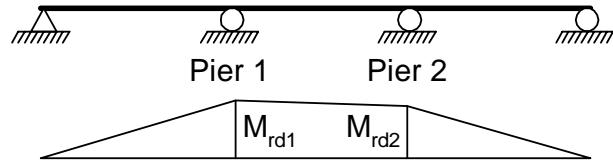

Eqs. B6.3.3.1-1, B6.4.2.1-1 and B6.4.2.1-2 are based on concepts from shakedown analysis of continuous-span girders under repeated application of moving loads (ASCE, 1971; Schilling et al., 1997) using an effective plastic moment that accounts for the interior-pier section moment-rotation characteristics. Shakedown is the appropriate limit state related to moment redistribution in bridges (Galambos, et al. 1993).

At the service limit state, the effective plastic moment in Eq. B6.3.3.1-1 is based on an estimated upper-bound plastic rotation of 0.009 radians at the pier sections, determined by direct inelastic analysis of various trial designs (Schilling, 1986). Flange lateral bending effects are not considered in Eq. B6.3.3.1-1 since due to the restrictions of Article B6.2, the flange lateral bending effects at the interior supports under the Service II Load Combination are taken to be negligible. The refinement of these calculations by consideration of flange lateral bending effects is considered unjustified.

Eq. B6.3.3.1-2 is intended to prevent the use of an interior-pier section that is so small that it could potentially violate the assumed upper-bound inelastic rotation of 0.009 radians under Service II conditions. Note that if the upper limit of Eq. B6.3.3.1-2 is violated, a new interior-pier section must be selected that will ensure that this limit is satisfied.

#### CB6.3.3.2

Figure CB6.3.3.2-1 illustrates a typical redistribution moment diagram for a three-span continuous member for which the redistribution moments are greater than zero at both interior-pier sections. After the live loads are removed, the redistribution moments are held in equilibrium by the support reactions. Therefore, the redistribution moments must vary linearly between the supports.

**Figure CB6.3.3.2-1—Typical Redistribution Moment Diagram**

## B6.4—STRENGTH LIMIT STATE

### B6.4.1—Flexural Resistance

#### B6.4.1.1—Adjacent to Interior-Pier Sections

The flexural resistances of sections within the unbraced lengths immediately adjacent to interior-pier sections satisfying the requirements of Article B6.2 shall not be checked.

#### CB6.4.1.1

Yielding is permitted at interior supports at the strength limit state, and results in redistribution of moments. The influence of the strength and ductility at the interior-pier sections is considered within the calculation of the redistribution moments. Therefore, the flexural resistances of sections within the unbraced lengths immediately adjacent to interior-pier sections from which moments are redistributed need not be checked.

#### B6.4.1.2—At All Other Locations

Sections at all other locations shall satisfy the provisions of Articles 6.10.7, 6.10.8.1 or A6.1, as applicable, after redistribution. For composite sections in positive flexure, the redistribution moments shall be applied to the long-term composite section when computing flexural stresses in the steel section. For computing longitudinal flexural stresses in the concrete deck due to the redistribution moments, the provisions of Article 6.10.1.1d shall apply.

The redistribution moments shall be calculated using the provisions of Article B6.4.2 and shall be added to the elastic moments due to the factored loads at the strength limit state.

#### CB6.4.1.2

Regions outside of unbraced lengths immediately adjacent to interior-pier sections from which moments are redistributed are designed in the same fashion as when the procedures of this Article are not applied, with the exception that the appropriate redistribution moments are to be added to the elastic moments due to the factored loads at the strength limit state prior to making the design checks.

### B6.4.2—Redistribution Moments

#### B6.4.2.1—At Interior-Pier Sections

At each interior-pier section where the flexural resistances are not checked as permitted in Article B6.4.1.1, the redistribution moment at the strength limit state shall be taken as the larger of:

$$M_{rd} = |M_e| + \frac{1}{3} f'_e S_{xc} - \phi_f M_{pe} \quad (\text{B6.4.2.1-1})$$

#### CB6.4.2.1

At the strength limit state, the effective plastic moment in Eqs. B6.4.2.1-1 and B6.4.2.1-2 is based on an estimated upper bound plastic rotation of 0.03 radians at the pier sections, determined by direct inelastic analysis of various trial designs (Schilling, 1986).

Flange lateral bending effects are conservatively included in Eqs. B6.4.2.1-1 and B6.4.2.1-2 to account for the reduction in the flexural resistance of the interior-pier

or:

$$M_{rd} = |M_e| + \frac{1}{3} f_\ell S_{xt} - \phi_f M_{pe} \quad (\text{B6.4.2.1-2})$$

in which:

$$0 \leq M_{rd} \leq 0.2 |M_e| \quad (\text{B6.4.2.1-3})$$

where:

$f_\ell$  = lateral bending stress in the flange under consideration at the interior-pier section (ksi). For continuously braced tension or compression flanges,  $f_\ell$  shall be taken as zero.

$\phi_f$  = resistance factor for flexure specified in Article 6.5.4.2

$M_{pe}$  = negative-flexure effective plastic moment for the strength limit state determined as specified in Article B6.5 (kip-in.)

$M_e$  = critical elastic moment envelope value at the interior-pier section due to the factored loads (kip-in.)

$M_{yc}$  = yield moment with respect to the compression flange determined as specified in Article D6.2 (kip-in.)

$M_{yt}$  = yield moment with respect to the tension flange determined as specified in Article D6.2 (kip-in.)

$S_{xc}$  = elastic section modulus about the major axis of the section to the compression flange taken as  $M_{yc}/F_{yc}$  (in.<sup>3</sup>)

$S_{xt}$  = elastic section modulus about the major axis of the section to the tension flange taken as  $M_{yt}/F_{yt}$  (in.<sup>3</sup>)

#### B6.4.2.2—At All Other Sections

The redistribution-moment diagram for the strength limit state shall be determined using the same procedure specified for the Service II load combination in Article B6.3.3.2.

section at the strength limit state due to these effects. The inclusion of  $f_\ell$  in these equations is intended primarily to address the design for wind loads. Eq. B6.4.2.1-3 is intended to prevent the use of an interior-pier section that is so small that it could potentially violate the assumed upper-bound inelastic rotation of 0.03 radians at the strength limit state. Note that if the upper limit of Eq. B6.4.2.1-3 is violated, a new interior-pier section must be selected that will ensure that this limit is satisfied.

A form of Eqs. B6.4.2.1-1 and B6.4.2.1-2 was proposed in the original research by Barker et al. (1997) that included a resistance factor for shakedown of  $\phi_{sd} = 1.1$ . The resistance factor of  $\phi_{sd} = 1.1$  is justified for this limit state because the shakedown loading is generally less than the maximum plastic resistance and because progressively increasing permanent deflections give ample warning of pending failure. The resistance factor for flexure  $\phi_f$  of Article 6.5.4.2 is selected in these provisions to account for the fact that yielding within regions of positive flexure and the corresponding redistribution of positive bending moments to the interior-pier sections is not considered. Also, as discussed in Article C6.10.7.1.2, additional requirements are specified in continuous spans where significant yielding may occur prior to reaching the section resistances of compact sections in positive flexure.

#### CB6.4.2.2

Figure CB6.3.3.2-1 illustrates a typical redistribution moment diagram.

## B6.5—EFFECTIVE PLASTIC MOMENT

### B6.5.1—Interior-Pier Sections with Enhanced Moment-Rotation Characteristics

For interior-pier sections satisfying the requirements of Article B6.2 and which contain:

- transverse stiffeners spaced at  $D/2$  or less over a minimum distance of  $D/2$  on each side of the interior-pier section

or:

- ultracompact webs that satisfy:

$$\frac{2D_{cp}}{t_w} \leq 2.3\sqrt{\frac{E}{F_{yc}}} \quad (\text{B6.5.1-1})$$

where:

$D_{cp}$  = depth of the web in compression at the plastic moment determined as specified in Article D6.3.2 (in.)

the effective plastic moment shall be taken as:

- For the Service Limit State:

$$M_{pe} = M_n \quad (\text{B6.5.1-2})$$

- For the Strength Limit State:

$$M_{pe} = \begin{cases} 2.78 - 2.3 \frac{b_{fc}}{t_{fc}} \sqrt{\frac{F_{yc}}{E}} \\ -0.35 \frac{D}{b_{fc}} + 0.39 \frac{b_{fc}}{t_{fc}} \sqrt{\frac{F_{yc}}{E}} \frac{D}{b_{fc}} \end{cases} M_n \leq M_n \quad (\text{B6.5.1-3})$$

where:

$M_n$  = nominal flexural resistance of the interior-pier section taken as the smaller of  $F_{nc}S_{xc}$  and  $F_{nt}S_{xt}$ , with  $F_{nc}$  and  $F_{nt}$  determined as specified in Article 6.10.8. For sections with compact or noncompact webs,  $M_n$  may be taken as the smaller of  $M_{nc}$  and  $M_{nt}$  determined as specified in Appendix A6 (kip-in.).

### CB6.5.1

Tests have shown that members with interior-pier sections that satisfy either of the requirements of this Article, in addition to the requirements of Article B6.2, exhibit enhanced moment-rotation characteristics relative to members that satisfy only the requirements of Article B6.2 (White et al., 1997; Barth et al., 2004). These additional requirements involve the use of:

- transverse stiffeners close to the interior-pier section to help restrain the local buckling distortions of the web and compression flange within this region,

or:

- a web that is sufficiently stocky such that its distortions are reduced and the flange local buckling distortions are highly restrained, termed an ultracompact web.

For noncompact web and slender web sections, the influence of the web slenderness on the effective plastic moment is captured through the maximum flexural resistance term  $M_n$  in Eqs. B6.5.1-2 and B6.5.1-3, and in Eqs. B6.5.2-1 and B6.5.2-2.

### B6.5.2—All Other Interior-Pier Sections

For interior-pier sections satisfying the requirements of Article B6.2, but not satisfying the requirements of Article B6.5.1, the effective plastic moment shall be taken as:

- For the Service Limit State:

$$M_{pe} = \begin{cases} 2.90 - 2.3 \frac{b_{fc}}{t_{fc}} \sqrt{\frac{F_{yc}}{E}} \\ -0.35 \frac{D}{b_{fc}} + 0.39 \frac{b_{fc}}{t_{fc}} \sqrt{\frac{F_{yc}}{E}} \frac{D}{b_{fc}} \end{cases} M_n \leq M_n \quad (\text{B6.5.2-1})$$

- For the Strength Limit State:

$$M_{pe} = \begin{cases} 2.63 - 2.3 \frac{b_{fc}}{t_{fc}} \sqrt{\frac{F_{yc}}{E}} \\ -0.35 \frac{D}{b_{fc}} + 0.39 \frac{b_{fc}}{t_{fc}} \sqrt{\frac{F_{yc}}{E}} \frac{D}{b_{fc}} \end{cases} M_n \leq M_n \quad (\text{B6.5.2-2})$$

### B6.6—REFINED METHOD

#### B6.6.1—General

Continuous span I-section flexural members satisfying the requirements of Article B6.2 also may be proportioned based on a direct analysis. In this approach, the redistribution moments shall be determined by satisfying rotational continuity and specified inelastic moment-rotation relationships at selected interior-pier sections. Direct analysis may be employed at the service and/or strength limit states. The elastic moment envelope due to the factored loads shall be used in this analysis.

For the direct analysis, the redistribution moments shall be determined using the elastic stiffness properties of the short-term composite section assuming the concrete deck to be effective over the entire span length. For composite sections in positive flexure, the redistribution moments shall be applied to the long-term composite section when computing elastic flexural stresses in the steel section. For computing elastic longitudinal flexural stresses in the concrete deck due to the redistribution moments, the provisions of Article 6.10.1.1.1d shall apply.

Sections adjacent to interior piers from which moments are redistributed shall satisfy the requirements of Article B6.3.2.1 at the service limit state and Article B6.4.1.1 at the strength limit state. All other sections shall satisfy all applicable provisions of Articles 6.10.4.2, 6.10.7, 6.10.8.1, or A6.1 after a solution is found.

#### CB6.5.2

Eqs. B6.5.2-1 and B6.5.2-2 are based on a lower-bound estimate of the moment-rotation characteristics of interior-pier sections that satisfy the limits of Article B6.2

(Barth et al., 2004). Cases with unbraced lengths smaller than the limit given by Eq. B6.2.4-1, significant torsional restraint from a composite deck, and/or compression-flange slenderness values significantly smaller than the compact flange limit often exhibit significantly enhanced moment-rotation characteristics and corresponding larger effective plastic moments than the values obtained from these equations.

The web slenderness,  $2D_c/t_w$  or  $2D_{cp}/t_w$ , does not appear directly in Eqs. B6.5.2-1 and B6.5.2-2. For noncompact and slender web sections, the influence of the web slenderness on the effective plastic moment is captured through the maximum flexural resistance term  $M_n$ .

#### CB6.6.1

The Engineer is also provided the option to use a refined method in which a direct shakedown analysis is conducted at the service and/or strength limit states. This analysis requires the simultaneous satisfaction of continuity and moment-rotation relationships at all interior-pier sections from which moments are redistributed. If software that handles this type of calculation along with the determination of the elastic moment envelopes does not exist, significant manual work is required in conducting the analysis calculations. The Engineer can gain some additional benefit when using direct analysis in that the restriction that all interior-pier sections within the member satisfy the requirements of Article B6.2.1 is relaxed. Also, the directly calculated inelastic rotations at the interior pier sections will tend to be smaller than the upper-bound values that the equations in Articles B6.3 through B6.5 are based upon.

The redistribution moments are to be computed using the stiffness properties of the short-term composite section because the redistribution moments are formed by short-term loads.

Although direct analysis methods can be formulated that account for the redistribution of moments from regions of positive flexure, there is typically no significant

In applying direct analysis at the strength limit state, the ordinates of the nominal moment-rotation curves shall be multiplied by the resistance factor for flexure specified in Article 6.5.4.2. In applying direct analysis at the Service II limit state, the nominal moment-rotation curves shall be used.

economic benefit associated with redistribution of positive bending moments. This is because, in most practical cases, the interior-pier sections have the highest elastic stresses. Also, the development of some inelastic rotations at the pier sections simply allows a continuous-span member to respond in a fashion involving only slightly less rotational restraint from the adjacent spans than if these sections remain elastic.

With the exception of the additional requirements of Article 6.10.7.1.2 for composite sections subjected to positive flexure within continuous spans in which the adjacent interior-pier sections do not satisfy Article B6.2, these Specifications generally neglect the influence of partial yielding prior to and associated with the development of member maximum flexural resistances. Therefore, the influence of partial yielding within regions of positive flexure on the redistribution of moments to the interior piers and on the calculated inelastic pier rotations is also to be neglected within the direct analysis approach. The unconservative attributes associated with neglecting positive-moment yielding prior to reaching the maximum flexural resistance within regions of positive flexure are offset by:

- The use of  $\phi_f = 1.0$  rather than a shakedown resistance factor of  $\phi_{sd} = 1.1$  as originally formulated by Barker et al. (1997) and discussed in Article CB6.4.2.1,

and:

- The lower-bound nature of the moment-rotation relationships utilized for the interior-pier sections.

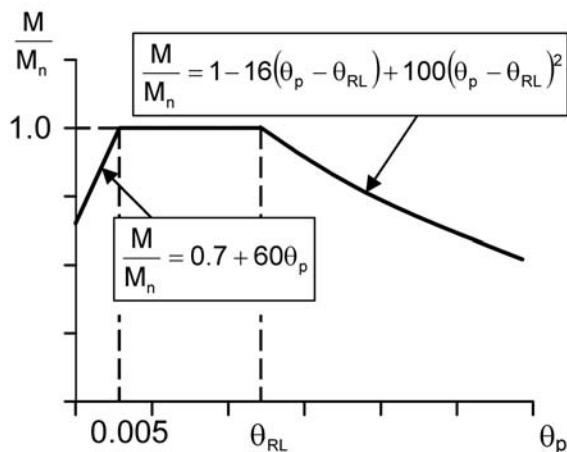

Moment-rotation relationships have been proposed that account for yielding in positive flexure, such as in Barker et al. (1997). However, these relationships account in only a very simplistic fashion for the distributed yielding effects that tend to occur over a significant length due to the small moment gradients that typically exist within regions of positive flexure. Significantly greater accuracy can be achieved in the analysis for these effects by the use of distributed plasticity analysis models rather than plastic-hinge type models. However, these types of analysis models are not readily accessible to the Engineer at the present time.

### B6.6.2—Nominal Moment-Rotation Curves

At interior-pier sections that satisfy the requirements of Article B6.2, the nominal moment-rotation curve given in Figure B6.6.2-1 may be used.

### CB6.6.2

The moment-rotation relationships in this Article are developed in White et al. (1997) and Barth et al. (2004). The moment-rotation relationships for interior-pier sections with enhanced moment-rotation characteristics that satisfy the additional limits of Article B6.5.1 are given by Eq. B6.6.2-1, which is obtained by replacing the coefficient 0.128 in Eq. B6.6.2-2 by 0.137 (Barth et al., 2004). It is expected that exceeding the limits of Article B6.2 may result in substantial degradation of the interior-pier moment-rotation characteristics. Therefore, the restrictions of Article B6.2 may not be relaxed by use of alternative moment-rotation relationships.

**Figure B6.6.2-1—Nominal Moment-Rotation Curve for Interior-Pier Sections Satisfying Article B6.2**

in which:

$\theta_{RL}$  = plastic rotation at which the interior-pier section moment nominally begins to decrease with increasing  $\theta_p$  (radians)

$$= 0.137 - 0.143 \frac{b_{fc}}{t_{fc}} \sqrt{\frac{F_{yc}}{E}} - 0.0216 \frac{D}{b_{fc}} + 0.0241 \frac{D}{b_{fc}} \frac{b_{fc}}{t_{fc}} \sqrt{\frac{F_{yc}}{E}} \quad (\text{B6.6.2-1})$$

for sections that satisfy the additional requirements specified in Article B6.5.1, and:

$$= 0.128 - 0.143 \frac{b_{fc}}{t_{fc}} \sqrt{\frac{F_{yc}}{E}} - 0.0216 \frac{D}{b_{fc}} + 0.0241 \frac{D}{b_{fc}} \frac{b_{fc}}{t_{fc}} \sqrt{\frac{F_{yc}}{E}} \quad (\text{B6.6.2-2})$$

for all other sections.

where:

$\theta_p$  = plastic rotation at the interior-pier section (rad.)

$M$  = bending moment about the major-axis of the cross-section due to the factored loads (kip-in.)

$M_n$  = nominal flexural resistance of the interior-pier section taken as the smaller of  $F_{nc}S_{xc}$  and  $F_{nt}S_{xt}$ , with  $F_{nc}$  and  $F_{nt}$  determined as specified in Article 6.10.8 (kip-in.). For sections with compact or noncompact webs,  $M_n$  may be taken as the smaller of  $M_{nc}$  and  $M_{nt}$  determined as specified in Appendix A6. For load combinations that induce significant flange lateral bending stresses, the influence of flange lateral bending shall be considered by deducting the larger of

$$\frac{1}{3} f_\ell S_{xc} \text{ or } \frac{1}{3} f_\ell S_{xt} \text{ from the above values.}$$

$f_t$  = lateral bending stress in the flange under consideration at the interior-pier section (ksi). For continuously braced tension or compression flanges,  $f_t$  shall be taken as zero.

Other nominal moment-rotation relationships may be employed for interior-pier sections that satisfy the requirements of Article B6.2 provided that the relationships are developed considering all potential factors that influence the moment-rotation characteristics within the restrictions of those requirements.

Interior-pier sections not satisfying the requirements of Article B6.2 shall be assumed to remain elastic in the analysis, and shall satisfy the provisions of Articles 6.10.4.2, 6.10.8.1, or Article A6.1, as applicable, after a solution is found.

## APPENDIX C6—BASIC STEPS FOR STEEL BRIDGE SUPERSTRUCTURES

### C6.1—GENERAL

This outline is intended to be a generic overview of the design process. It should not be regarded as fully complete, nor should it be used as a substitute for a working knowledge of the provisions of this section.

### C6.2—GENERAL CONSIDERATIONS

- A. Design Philosophy (1.3.1)
- B. Limit States (1.3.2)
- C. Design and Location Features (2.3) (2.5)

### C6.3—SUPERSTRUCTURE DESIGN

- A. Develop General Section
  - 1. Roadway Width (Highway Specified)
  - 2. Span Arrangements (2.3.2) (2.5.4) (2.5.5) (2.6)
  - 3. Select Bridge Type—assumed to be I- or Box Girder
- B. Develop Typical Section
  - 1. I-Girder
    - a. Composite (6.10.1.1) or Noncomposite (6.10.1.2)
    - b. Hybrid or Nonhybrid (6.10.1.3)
    - c. Variable Web Depth (6.10.1.4)
    - d. Cross-section Proportion Limits (6.10.2)
  - 2. Box Girder
    - a. Multiple Boxes or Single Box (6.11.1.1) (6.11.2.3)
    - b. Hybrid or Nonhybrid (6.10.1.3)
    - c. Variable Web Depth (6.10.1.4)
    - d. Cross-section Proportion Limits (6.11.2)

## APPENDIX D6—FUNDAMENTAL CALCULATIONS FOR FLEXURAL MEMBERS

### D6.1—PLASTIC MOMENT

The plastic moment,  $M_p$ , shall be calculated as the moment of the plastic forces about the plastic neutral axis. Plastic forces in steel portions of a cross-section shall be calculated using the yield strengths of the flanges, the web, and reinforcing steel, as appropriate. Plastic forces in concrete portions of the cross-section that are in compression may be based on a rectangular stress block with the magnitude of the compressive stress equal to  $0.85f'_c$ . Concrete in tension shall be neglected.

The position of the plastic neutral axis shall be determined by the equilibrium condition that there is no net axial force.

The plastic moment of a composite section in positive flexure can be determined by:

- Calculating the element forces and using them to determine whether the plastic neutral axis is in the web, top flange or concrete deck;
- Calculating the location of the plastic neutral axis within the element determined in the first step; and
- Calculating  $M_p$ . Equations for the various potential locations of the plastic neutral axis (PNA) are given in Table D6.1-1.

The forces in the longitudinal reinforcement may be conservatively neglected. To do this, set  $P_{rb}$  and  $P_{rt}$  equal to zero in the equations in Table D6.1-1.

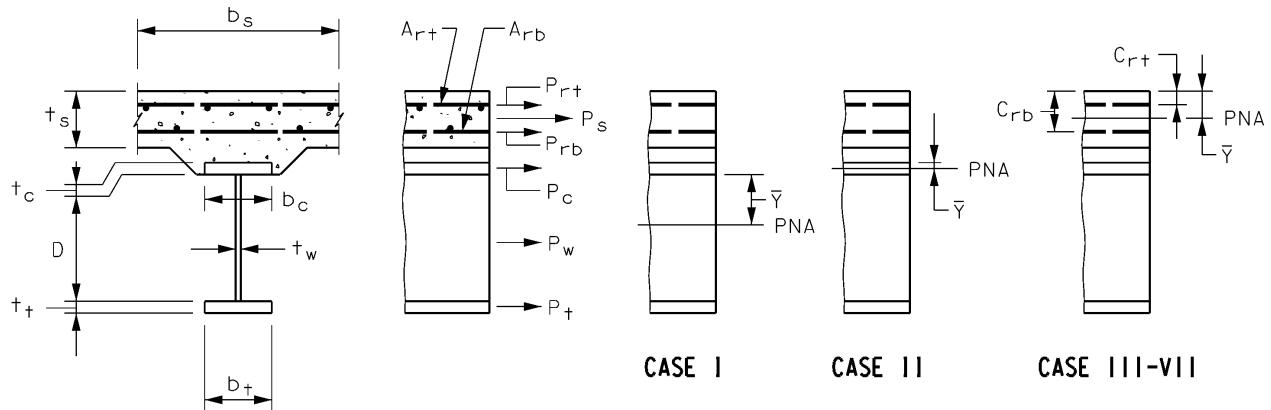

The plastic moment of a composite section in negative flexure can be calculated by an analogous procedure. Equations for the two cases most likely to occur in practice are given in Table D6.1-2.

The plastic moment of a noncomposite section may be calculated by eliminating the terms pertaining to the concrete deck and longitudinal reinforcement from the equations in Tables D6.1-1 and D6.1-2 for composite sections.

In the equations for  $M_p$  given in Tables D6.1-1 and D6.1-2,  $d$  is the distance from an element force to the plastic neutral axis. Element forces act at (a) mid-thickness for the flanges and the concrete deck, (b) mid-depth of the web, and (c) center of reinforcement. All element forces, dimensions, and distances should be taken as positive. The condition should be checked in the order listed in Tables D6.1-1 and D6.1-2.

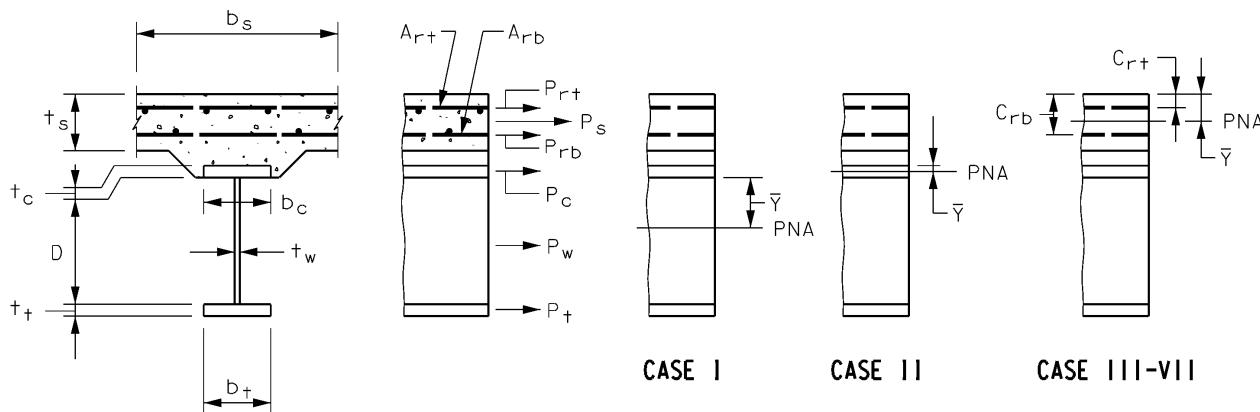

Table D6.1-1—Calculation of  $\bar{Y}$  and  $M_p$  for Sections in Positive Flexure

Case	PNA	Condition	$\bar{Y}$ and $M_p$
I	In Web	$P_t + P_w \geq P_c + P_s + P_{rb} + P_{rt}$	$\bar{Y} = \left( \frac{D}{2} \right) \left[ \frac{P_t - P_c - P_s - P_{rt} - P_{rb}}{P_w} + 1 \right]$ $M_p = \frac{P_w}{2D} \left[ \bar{Y}^2 + (D - \bar{Y})^2 \right] + [P_s d_s + P_{rt} d_{rt} + P_{rb} d_{rb} + P_c d_c + P_t d_t]$
II	In Top Flange	$P_t + P_w + P_c \geq P_s + P_{rb} + P_{rt}$	$\bar{Y} = \left( \frac{t_c}{2} \right) \left[ \frac{P_w + P_t - P_s - P_{rt} - P_{rb}}{P_c} + 1 \right]$ $M_p = \frac{P_c}{2t_c} \left[ \bar{Y}^2 + (t_c - \bar{Y})^2 \right] + [P_s d_s + P_{rt} d_{rt} + P_{rb} d_{rb} + P_w d_w + P_t d_t]$
III	Concrete Deck, Below $P_{rb}$	$P_t + P_w + P_c \geq \left( \frac{c_{rb}}{t_s} \right) P_s + P_{rb} + P_{rt}$	$\bar{Y} = (t_s) \left[ \frac{P_c + P_w + P_t - P_{rt} - P_{rb}}{P_s} \right]$ $M_p = \left( \frac{\bar{Y}^2 P_s}{2t_s} \right) + [P_{rt} d_{rt} + P_{rb} d_{rb} + P_c d_c + P_w d_w + P_t d_t]$
IV	Concrete Deck, at $P_{rb}$	$P_t + P_w + P_c + P_{rb} \geq \left( \frac{c_{rb}}{t_s} \right) P_s + P_{rt}$	$\bar{Y} = c_{rb}$ $M_p = \left( \frac{\bar{Y}^2 P_s}{2t_s} \right) + [P_{rt} d_{rt} + P_c d_c + P_w d_w + P_t d_t]$
V	Concrete Deck, Above $P_{rb}$ Below $P_{rt}$	$P_t + P_w + P_c + P_{rb} \geq \left( \frac{c_{rt}}{t_s} \right) P_s + P_{rt}$	$\bar{Y} = (t_s) \left[ \frac{P_{rb} + P_c + P_w + P_t - P_{rt}}{P_s} \right]$ $M_p = \left( \frac{\bar{Y}^2 P_s}{2t_s} \right) + [P_{rt} d_{rt} + P_{rb} d_{rb} + P_c d_c + P_w d_w + P_t d_t]$
VI	Concrete Deck, at $P_{rt}$	$P_t + P_w + P_c + P_{rb} + P_{rt} \geq \left( \frac{c_{rt}}{t_s} \right) P_s$	$\bar{Y} = c_{rt}$ $M_p = \left( \frac{\bar{Y}^2 P_s}{2t_s} \right) + [P_{rb} d_{rb} + P_c d_c + P_w d_w + P_t d_t]$
VII	Concrete Deck, Above $P_{rt}$	$P_t + P_w + P_c + P_{rb} + P_{rt} < \left( \frac{c_{rt}}{t_s} \right) P_s$	$\bar{Y} = (t_s) \left[ \frac{P_{rb} + P_c + P_w + P_t + P_{rt}}{P_s} \right]$ $M_p = \left( \frac{\bar{Y}^2 P_s}{2t_s} \right) + [P_{rt} d_{rt} + P_{rb} d_{rb} + P_c d_c + P_w d_w + P_t d_t]$

**Table D6.1-2—Calculation of  $\bar{Y}$  and  $M_p$  for Sections in Negative Flexure**

Case	PNA	Condition	$\bar{Y}$ and $M_p$
I	In Web	$P_c + P_w \geq P_t + P_{rb} + P_{rt}$	$\bar{Y} = \left( \frac{D}{2} \right) \left[ \frac{P_c - P_t - P_{rt} - P_{rb}}{P_w} + 1 \right]$ $M_p = \frac{P_w}{2D} \left[ \bar{Y}^2 + (D - \bar{Y})^2 \right] + [P_{rt}d_{rt} + P_{rb}d_{rb} + P_t d_t + P_c d_c]$
II	In Top Flange	$P_c + P_w + P_t \geq P_{rb} + P_{rt}$	$\bar{Y} = \left( \frac{t_t}{2} \right) \left[ \frac{P_w + P_c - P_{rt} - P_{rb}}{P_t} + 1 \right]$ $M_p = \frac{P_t}{2t_t} \left[ \bar{Y}^2 + (t_t - \bar{Y})^2 \right] + [P_{rt}d_{rt} + P_{rb}d_{rb} + P_w d_w + P_c d_c]$

in which:

$$P_{rt} = F_{yrt} A_{rt}$$

$$P_s = 0.85 f_c' b_s t_s$$

$$P_{rb} = F_{yrb} A_{rb}$$

$$P_c = F_{yc} b_c t_c$$

$$P_w = F_{yw} D t_w$$

$$P_t = F_{yt} b_t t_t$$

## D6.2—YIELD MOMENT

### D6.2.1—Noncomposite Sections

The yield moment,  $M_y$ , of a noncomposite section shall be taken as the smaller of the moment required to cause nominal first yielding in the compression flange,  $M_{yc}$ , and the moment required to cause nominal first yielding in the tension flange,  $M_{yt}$ , at the strength limit state. Flange lateral bending in all types of sections and web yielding in hybrid sections shall be disregarded in this calculation.

### D6.2.2—Composite Sections in Positive Flexure

The yield moment of a composite section in positive flexure shall be taken as the sum of the moments applied separately to the steel and the short-term and long-term composite sections to cause nominal first yielding in either steel flange at the strength limit state. Flange lateral bending in all types of sections and web yielding in hybrid sections shall be disregarded in this calculation.

The yield moment of a composite section in positive flexure may be determined as follows:

- Calculate the moment  $M_{D1}$  caused by the factored permanent load applied before the concrete deck has hardened or is made composite. Apply this moment to the steel section.
- Calculate the moment  $M_{D2}$  caused by the remainder of the factored permanent load. Apply this moment to the long-term composite section.
- Calculate the additional moment  $M_{AD}$  that must be applied to the short-term composite section to cause nominal yielding in either steel flange.
- The yield moment is the sum of the total permanent load moment and the additional moment.

Symbolically, the procedure is:

- 1) Solve for  $M_{AD}$  from the equation:

$$F_{yf} = \frac{M_{D1}}{S_{NC}} + \frac{M_{D2}}{S_{LT}} + \frac{M_{AD}}{S_{ST}} \quad (\text{D6.2.2-1})$$

- 2) Then calculate:

$$M_y = M_{D1} + M_{D2} + M_{AD} \quad (\text{D6.2.2-2})$$

where:

$S_{NC}$  = noncomposite section modulus (in.<sup>3</sup>)

$S_{ST}$  = short-term composite section modulus (in.<sup>3</sup>)

$S_{LT}$  = long-term composite section modulus (in.<sup>3</sup>)

$M_{D1}$ ,  $M_{D2}$   
&  $M_{AD}$  = moments due to the factored loads applied to  
the appropriate sections (kip-in.)

$M_y$  shall be taken as the lesser value calculated for the compression flange,  $M_{yc}$ , or the tension flange,  $M_{yt}$ .

### D6.2.3 Composite Sections in Negative Flexure

For composite sections in negative flexure, the procedure specified in Article D6.2.2 is followed, except that the composite section for both short-term and long-term moments shall consist of the steel section and the longitudinal reinforcement within the effective width of the concrete deck. Thus,  $S_{ST}$  and  $S_{LT}$  are the same value. Also,  $M_{yt}$  shall be taken with respect to either the tension flange or the longitudinal reinforcement, whichever yields first.

### D6.2.4 Sections with Cover Plates

For sections containing flange cover plates,  $M_{yc}$  or  $M_{yt}$  shall be taken as the smallest value of moment associated with nominal first yielding based on the stress in either the flange under consideration or in any of the cover plates attached to that flange, whichever yields first. Flange lateral bending in all types of sections and web yielding in hybrid sections shall be disregarded in this calculation.

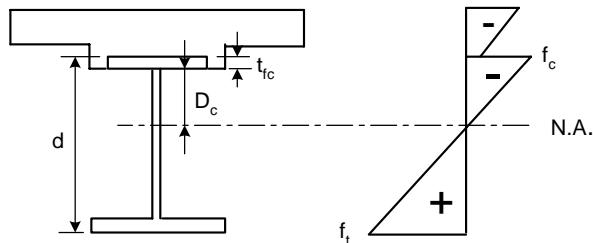

## D6.3—DEPTH OF THE WEB IN COMPRESSION

### D6.3.1—In the Elastic Range ( $D_c$ )

For composite sections in positive flexure, the depth of the web in compression in the elastic range,  $D_c$ , shall be the depth over which the algebraic sum of the stresses in the steel, long-term composite and short-term composite sections from the dead and live loads, plus impact, is compressive.

In lieu of computing  $D_c$  at sections in positive flexure from stress diagrams, the following equation may be used:

$$D_c = \left( \frac{-f_c}{|f_c| + f_t} \right) d - t_{fc} \geq 0 \quad (\text{D6.3.1-1})$$

**Figure D6.3.1-1—Computation of  $D_c$  at Sections in Positive Flexure**

### CD6.3.1

At sections in positive flexure,  $D_c$  of the composite section will increase with increasing span length because of the increasing dead-to-live load ratio. Therefore, in general it is important to recognize the effect of the dead-load stress on the location of the neutral axis of the composite section in regions of positive flexure.

According to these Specifications, for composite sections in positive flexure, Eq. D6.3.1-1 only need be employed for checking web bend-buckling at the service limit state and for computing the  $R_b$  factor at the strength limit state for sections in which web longitudinal stiffeners are required based on Article 6.10.2.1.1. Eq. D6.3.1-1 is never needed for composite sections in positive flexure when the web satisfies the requirement of Article 6.10.2.1.1 such that longitudinal stiffeners are not required. Articles C6.10.1.9.2, C6.10.1.10.2, and C6.10.4.2.2 discuss the rationale for these calculations, which introduce a dependency of the flexural resistance on the applied load whenever  $R_b < 1$ , and therefore, potentially complicate subsequent rating calculations for these section types. Article C6.10.1.9.1 explains why the calculation of  $D_c$  is not required for composite sections in positive flexure when the web satisfies Article 6.10.2.1.1.

where:

$d$  = depth of the steel section (in.)

$f_c$  = sum of the compression-flange stresses caused by the different loads, i.e.,  $DC1$ , the permanent load acting on the noncomposite section;  $DC2$ , the permanent load acting on the long-term composite section;  $DW$ , the wearing surface load; and  $LL+IM$ ; acting on their respective sections (ksi).  $f_c$  shall be taken as negative when the stress is in compression. Flange lateral bending shall be disregarded in this calculation.

$f_t$  = the sum of the tension-flange stresses caused by the different loads (ksi). Flange lateral bending shall be disregarded in this calculation.

For composite sections in negative flexure,  $D_c$  shall be computed for the section consisting of the steel girder plus the longitudinal reinforcement with the exception of the following. For composite sections in negative flexure at the service limit state where the concrete deck is considered effective in tension for computing flexural stresses on the composite section due to Load Combination Service II,  $D_c$  shall be computed from Eq. D6.3.1-1.

#### D6.3.2—At Plastic Moment ( $D_{cp}$ )

For composite sections in positive flexure, the depth of the web in compression at the plastic moment,  $D_{cp}$ , shall be taken as follows for cases from Table D6.1-1 where the plastic neutral axis is in the web:

$$D_{cp} = \frac{D}{2} \left( \frac{F_{yt} A_t - F_{yc} A_c - 0.85 f'_c A_s - F_{yrs} A_{rs}}{F_{yw} A_w} + 1 \right) \quad (\text{D6.3.2-1})$$

where:

$A_c$  = area of the compression flange (in.<sup>2</sup>)

$A_{rs}$  = total area of the longitudinal reinforcement within the effective concrete deck width (in.<sup>2</sup>)

$A_s$  = area of the concrete deck (in.<sup>2</sup>)

$A_t$  = area of the tension flange (in.<sup>2</sup>)

$A_w$  = area of the web (in.<sup>2</sup>)

$D_{cp}$  = depth of the web in compression at the plastic moment (in.)

$F_{yrs}$  = specified minimum yield strength of the longitudinal reinforcement (ksi)

For composite sections in negative flexure, the concrete deck is typically not considered to be effective in tension. Therefore, the distance between the neutral axis locations for the steel and composite sections is small in this case and the location of the neutral axis for the composite section is largely unaffected by the dead-load stress. Therefore, for the majority of situations, these Specifications specify the use of  $D_c$  computed simply for the section consisting of the steel girder plus the longitudinal reinforcement, without considering the algebraic sum of the stresses acting on the noncomposite and composite sections. This eliminates potential difficulties in subsequent load rating since the resulting  $D_c$  is independent of the applied loading, and therefore the flexural resistance in negative bending, which depends on  $D_c$ , does not depend on the applied load. The single exception is that if the concrete deck is assumed effective in tension in regions of negative flexure at the service limit state, as permitted for composite sections satisfying the requirements specified in Article 6.10.4.2.1, Eq. D6.3.1-1 must be used to compute  $D_c$ . For this case, in Figure D6.3.1-1, the stresses  $f_c$  and  $f_t$  should be switched, the signs shown in the stress diagram should be reversed,  $t_{fc}$  should be the thickness of the bottom flange, and  $D_c$  should instead extend from the neutral axis down to the top of the bottom flange.

For all other composite sections in positive flexure,  $D_{cp}$  shall be taken equal to zero.

For composite sections in negative flexure,  $D_{cp}$  shall be taken as follows for cases from Table D6.1-2 where the plastic neutral axis is in the web:

$$D_{cp} = \frac{D}{2A_w F_{yw}} [F_{yt} A_t + F_{yw} A_w + F_{yrs} A_{rs} - F_{yc} A_c] \quad (\text{D6.3.2-2})$$

For all other composite sections in negative flexure,  $D_{cp}$  shall be taken equal to  $D$ .

For noncomposite sections where:

$$F_{yw} A_w \geq |F_{yc} A_c - F_{yt} A_t| \quad (\text{D6.3.2-3})$$

$D_{cp}$  shall be taken as:

$$D_{cp} = \frac{D}{2A_w F_{yw}} [F_{yt} A_t + F_{yw} A_w - F_{yc} A_c] \quad (\text{D6.3.2-4})$$

For all other noncomposite sections,  $D_{cp}$  shall be taken equal to  $D$ .

## D6.4—LATERAL TORSIONAL BUCKLING EQUATIONS FOR $C_B > 1.0$ , WITH EMPHASIS ON UNBRACED LENGTH REQUIREMENTS FOR DEVELOPMENT OF THE MAXIMUM FLEXURAL RESISTANCE

### D6.4.1—By the Provisions of Article 6.10.8.2.3

For unbraced lengths in which the member is prismatic, the lateral torsional buckling resistance of the compression flange shall be taken as:

- If  $L_b \leq L_p$ , then:

$$F_{nc} = R_b R_h F_{yc} \quad (\text{D6.4.1-1})$$

- If  $L_p < L_b \leq L_r$ , then:

$$\circ \quad \text{If } L_b \leq L_p + \left(1 - \frac{1}{C_b}\right) \left(1 - \frac{F_{yr}}{R_h F_{yc}}\right) (L_r - L_p), \text{ then:}$$

### CD6.4.1

For values of the moment gradient modifier  $C_b$  greater than 1.0, the maximum LTB resistance  $F_{max}$  shown in Figure C6.10.8.2.1-1 may be reached at larger unbraced lengths. The provisions in this Article are equivalent to those in Articles 6.10.8.2.3, but allow the Engineer to focus on the conditions for which the LTB resistance is equal to  $F_{max} = R_b R_h F_{yc}$  when the effects of moment gradient are included in determining the limits on  $L_b$ .

The largest unbraced length for which the LTB resistance of Article 6.10.8.2.3 is equal to the flange local buckling or FLB resistance of Article 6.10.8.2.2 may be determined by substituting  $F_{nc(FLB)}/R_b$  for  $R_h F_{yc}$  in checking the  $L_b$  requirement for the use of Eq. D6.4.1-2 or D6.4.1-4 as applicable, where  $F_{nc(FLB)}$  is the FLB resistance obtained from Article 6.10.8.2.2.

$$F_{nc} = R_b R_h F_{yc} \quad (\text{D6.4.1-2})$$

- Otherwise:

$$F_{nc} = C_b \left[ 1 - \left( 1 - \frac{F_{yr}}{R_h F_{yc}} \right) \left( \frac{L_b - L_p}{L_r - L_p} \right) \right] R_b R_h F_{yc} \leq R_b R_h F_{yc} \quad (\text{D6.4.1-3})$$

- If  $L_b > L_r$ , then:

- If  $L_b \leq \pi r_i \sqrt{\frac{C_b E}{R_h F_{yc}}}$ , then:

$$F_{nc} = R_b R_h F_{yc} \quad (\text{D6.4.1-4})$$

- Otherwise:

$$F_{nc} = F_{cr} \leq R_b R_h F_{yc} \quad (\text{D6.4.1-5})$$

All terms in the above equations shall be taken as defined in Article 6.10.8.2.3.

#### D6.4.2—By the Provisions of Article A6.3.3

For unbraced lengths in which the member is prismatic, the flexural resistance based on lateral torsional buckling shall be taken as:

- If  $L_b \leq L_p$ , then:

$$M_{nc} = R_{pc} M_{yc} \quad (\text{D6.4.2-1})$$

- If  $L_p < L_b \leq L_r$ , then:

- If  $L_b \leq L_p + \left( \frac{1 - \frac{1}{C_b}}{1 - \frac{F_{yr} S_{xc}}{R_{pc} M_{yc}}} \right) (L_r - L_p)$ , then:

$$M_{nc} = R_{pc} M_{yc} \quad (\text{D6.4.2-2})$$

- Otherwise:

$$M_{nc} = C_b \left[ 1 - \left( 1 - \frac{F_{yr} S_{xc}}{R_{pc} M_{yc}} \right) \left( \frac{L_b - L_p}{L_r - L_p} \right) \right] R_{pc} M_{yc} \leq R_{pc} M_{yc} \quad (\text{D6.4.2-3})$$

- If  $L_b > L_r$ , then:

- If :

If  $D_c t_w / b_{fc} t_{fc}$  in Eq. 6.10.8.2.3-9 is taken as a representative value of 2.0,  $F_{yc}$  is taken as 50 ksi, and  $F_{yw} > 0.7F_{yc}$ , the LTB resistance of Article 6.10.8.2.3 is equal to  $F_{max}$  for  $L_b < 22b_{fc}$  when  $C_b > 1.75$  and  $L_b < 17b_{fc}$  for  $C_b > 1.3$ . The Engineer should note that, even with relatively small values of  $C_b$ , the unbraced length requirements to achieve a flexural resistance of  $F_{max}$  are significantly larger than those associated with uniform major-axis bending and  $C_b = 1$ . Article C6.10.8.2.3 discusses the appropriate calculation of  $C_b > 1$  for bridge design.

#### CD6.4.2

For values of the moment gradient modifier  $C_b$  greater than 1.0, the maximum LTB resistance  $M_{max}$  shown in Figure C6.10.8.2.1-1 may be reached at larger unbraced lengths. The provisions in this Article are equivalent to those in Article A6.3.3, but allow the Engineer to focus on the conditions for which the LTB resistance is equal to  $M_{max} = R_{pc} M_{yc}$  when the effects of moment gradient are included in determining the limits on  $L_b$ .

The largest unbraced length for which the LTB resistance of Article A6.3.3 is equal to the flange local buckling or FLB resistance of Article A6.3.2 may be determined by substituting  $M_{nc(FLB)}$  for  $R_{pc} M_{yc}$  in checking the  $L_b$  requirement for the use of Eq. D6.4.2-2 or D6.4.2-4 as applicable, where  $M_{nc(FLB)}$  is the FLB resistance obtained from Article A6.3.2.

Article A6.3.3 typically requires similar to somewhat smaller values than Article 6.10.8.2.3 for the limits on  $L_b$  required to reach the member resistance of  $M_{max} > R_h M_{yc}$ , depending on the magnitude of  $R_{pc}$ . If  $D_c t_w / b_{fc} t_{fc}$  in Eq. A6.3.3-10 is taken as a representative value of 2.0,  $F_{yc}$  is taken as 50 ksi, and  $F_{yw} > 0.7F_{yc}$ , then for  $R_{pc} = 1.12$ , the LTB resistance of this Article is typically equal to  $M_{max}$  when  $L_b < 22b_{fc}$  for  $C_b > 1.75$  and when  $L_b < 15b_{fc}$  for  $C_b > 1.30$ . For  $R_{pc} = 1.30$  and using the above assumptions,  $M_{max}$  is achieved by the LTB equations when  $L_b < 20b_{fc}$  for  $C_b > 1.75$  and when  $L_b < 13b_{fc}$  for  $C_b > 1.30$ . The Engineer should note that, even with relatively small values of  $C_b$ ,

$$L_b \leq 1.95 r_t \frac{C_b S_{xc} E}{R_{pc} M_{yc}} \sqrt{\frac{J}{S_{xc} h}} \sqrt{1 + \sqrt{1 + 6.76 \left( \frac{R_{pc} M_{yc}}{C_b S_{xc} E} \frac{S_{xc} h}{J} \right)^2}}$$

then:

$$M_{nc} = R_{pc} M_{yc} \quad (\text{D6.4.2-4})$$

- Otherwise:

$$M_{nc} = F_{cr} S_{xc} \leq R_{pc} M_{yc} \quad (\text{D6.4.2-5})$$

All terms in the above equations shall be taken as defined in Article A6.3.3.

## D6.5—CONCENTRATED LOADS APPLIED TO WEBS WITHOUT BEARING STIFFENERS

### D6.5.1—General

At bearing locations and at other locations subjected to concentrated loads, where the loads are not transmitted through a deck or deck system, webs without bearing stiffeners shall be investigated for the limit states of web local yielding and web crippling according to the provisions of Articles D6.5.2 and D6.5.3.

the unbraced length requirements to achieve a flexural resistance of  $M_{max}$  are significantly larger than those associated with uniform major-axis bending and  $C_b = 1$ . Article C6.10.8.2.3 discusses the appropriate calculation of  $C_b > 1$  for bridge design.

### CD6.5.1

The equations of this Article are essentially identical to the equations given in AISC (2005). The limit state of sidesway web buckling given in AISC (2005) is not included because it governs only for members subjected to concentrated loads directly applied to the steel section, and for members for which the compression flange is braced at the load point, the tension flange is unbraced at this point, and the ratio of  $D/t_w$  to  $L_b/b_{fl}$  is less than or equal to 1.7. These conditions typically do not occur in bridge construction.

Built-up sections and rolled shapes without bearing stiffeners at the indicated locations should either be modified to comply with these requirements, or else bearing stiffeners designed according to the provisions of Article 6.10.11.2 should be placed on the web at the location under consideration.

For unusual situations in which diametrically opposed concentrated loads are directly applied to the web of the steel section at the level of each of the flanges, such as if a concentrated force were applied directly over a reaction point at an unstiffened location along the length of a girder, the AISC (2005) provisions pertaining to additional stiffener requirements for concentrated forces should be considered.

### D6.5.2—Web Local Yielding

Webs subject to compressive or tensile concentrated loads shall satisfy:

$$R_u \leq \phi_b R_n \quad (\text{D6.5.2-1})$$

in which:

$R_n$  = nominal resistance to the concentrated loading (kip)

### CD6.5.2

This limit state is intended to prevent localized yielding of the web resulting from either high compressive or tensile stress due to a concentrated load or bearing reaction.

A concentrated load acting on a rolled shape or a built-up section is assumed critical at the toe of the fillet located a distance  $k$  from the outer face of the flange resisting the concentrated load or bearing reaction, as applicable. For a rolled shape,  $k$  is published in the

- For interior-pier reactions and for concentrated loads applied at a distance from the end of the member that is greater than  $d$ :

$$R_n = (5k + N) F_{yw} t_w \quad (\text{D6.5.2-2})$$

- Otherwise:

$$R_n = (2.5k + N) F_{yw} t_w \quad (\text{D6.5.2-3})$$

where:

$\phi_b$  = resistance factor for bearing specified in Article 6.5.4.2

$d$  = depth of the steel section (in.)

$k$  = distance from the outer face of the flange resisting the concentrated load or bearing reaction to the web toe of the fillet (in.)

$N$  = length of bearing (in.).  $N$  shall be greater than or equal to  $k$  at end bearing locations.

$R_u$  = factored concentrated load or bearing reaction (kip)

### D6.5.3—Web Crippling

Webs subject to compressive concentrated loads shall satisfy:

$$R_u \leq \phi_w R_n \quad (\text{D6.5.3-1})$$

in which:

$R_n$  = nominal resistance to the concentrated loading (kip)

- For interior-pier reactions and for concentrated loads applied at a distance from the end of the member that is greater than or equal to  $d/2$ :

$$R_n = 0.8t_w^2 \left[ 1 + 3\left(\frac{N}{d}\right)\left(\frac{t_w}{t_f}\right)^{1.5} \right] \sqrt{\frac{EF_{yw}t_f}{t_w}} \quad (\text{D6.5.3-2})$$

- Otherwise:

- If  $N/d \leq 0.2$ , then:

$$R_n = 0.4t_w^2 \left[ 1 + 3\left(\frac{N}{d}\right)\left(\frac{t_w}{t_f}\right)^{1.5} \right] \sqrt{\frac{EF_{yw}t_f}{t_w}} \quad (\text{D6.5.3-3})$$

available tables giving dimensions for the shapes. For a built-up section,  $k$  may be taken as the distance from the outer face of the flange to the web toe of the web-to-flange fillet weld.

In Eq. D6.5.2-2 for interior loads or interior-pier reactions, the load is assumed to distribute along the web at a slope of 2.5 to 1 and over a distance of  $(5k + N)$ . An interior concentrated load is defined as a load applied at a distance from the end of the member that is greater than the depth of the steel section  $d$ . In Eq. D6.5.2-3 for end loads or end reactions, the load is assumed to distribute along the web at the same slope over a distance of  $(2.5k + N)$ . These criteria are largely based on the work of Johnston and Kubo (1941) and Graham et al. (1959).

### CD6.5.3

This limit state is intended to prevent local instability or crippling of the web resulting from a high compressive stress due to a concentrated load or bearing reaction.

Eqs. D6.5.3-2 and D6.5.3-3 are based on research by Roberts (1981). Eq. D6.5.3-4 for  $N/d > 0.2$  was developed after additional testing by Elgaaly and Salkar (1991) to better represent the effect of longer bearing lengths at the ends of members.

- If  $N/d > 0.2$ , then:

$$R_n = 0.4t_w^2 \left[ 1 + \left( \frac{4N}{d} - 0.2 \right) \left( \frac{t_w}{t_f} \right)^{1.5} \right] \sqrt{\frac{EF_{yw}t_f}{t_w}} \quad (\text{D6.5.3-4})$$

where:

$\phi_w$  = resistance factor for web crippling specified in Article 6.5.4.2

$t_f$  = thickness of the flange resisting the concentrated load or bearing reaction (in.)

## SECTION 7

# ALUMINUM STRUCTURES

### 7.1—SCOPE

This Section covers the design of aluminum members, splices, and connections for highway bridges, including beam and girder structures, frames, trusses, and arches. Bridges with concrete slabs supported on aluminum floor systems and with orthotropic deck superstructures are included.

### 7.2—DEFINITIONS

The provisions of Article 6.2 shall apply.

*Plate*—A flat rolled product whose thickness equals or exceeds 0.25 in.

*Sheet*—A flat rolled product whose thickness is between 0.006 in. and 0.25 in.

### 7.3—NOTATION

$A$	= area (in. <sup>2</sup> ) (7.4.2.2)
$A_b$	= nominal bolt area (in. <sup>2</sup> ) (7.14.2.8)
$A_c$	= area of compression element (in. <sup>2</sup> ), consisting of compression flange, plus one-third of the area of web between compression flange and neutral axis (in. <sup>2</sup> ) (7.11.2.1)
$(ADTT)_{SL}$	= single-lane average daily truck traffic (7.6.1.2.4)
$A_t$	= gross area of cross-section of longitudinal stiffener (in. <sup>2</sup> ) (7.11.5.1)
$A_w$	= area of a cross-section lying within 1.0 in. of a weld (in. <sup>2</sup> ) (7.4.2.2)
$a_1$	= shorter dimension of rectangular panel (in.) (7.11.4.2)
$a_2$	= longer dimension of rectangular panel (in.) (7.11.4.2)
$a_e$	= equivalent width of rectangular panel (in.) (7.11.4.2)
$B, D, C$	= buckling formula parameters, with following subscript: (ksi, ksi, dim.) (7.10.1) <i>c</i> —compression in columns <i>p</i> —compression in flat plates <i>t</i> —compression in round tubes <i>tb</i> —bending in round tubes <i>b</i> —bending in rectangular bars <i>s</i> —shear in flat plates
$b$	= width of element; width of compression flange; width of rectangular plate element (in.) (7.5.1.2) (7.11.3.1) (7.12.3.1)
$b_e$	= effective width of a thin element (in.) (7.5.1.2)
$b_L$	= clear width of lip (in.) (7.11.5.3)
$C$	= warping constant (in. <sup>6</sup> ) (7.12.2.1) (7.12.4.1)
$C_1, C_2$	= fatigue resistance constants (7.6.1.2.4)
$c$	= distance from neutral axis to extreme fiber (in.) (7.4.2.2)
$d$	= depth of section or beam (in.) (C7.11.2.1)
$E$	= compressive modulus of elasticity (ksi) (7.4.2)
$F_a$	= factored resistance in terms of stress, $F_r$ , for components subject to compression only (ksi) (7.13.1) (7.13.4)
$F_b$	= factored flexural resistance in terms of stress, $F_r$ , for components subjected to flexure only (ksi) (7.13.1) (7.13.4)
$F_{bf}$	= factored resistance in terms of stress for the flange proper, taken as $F_r$ (ksi) (7.11.3.1)
$F_{bh}$	= factored resistance in terms of stress for webs of flexural members (ksi) (7.11.3.1)
$F_{bu}$	= ultimate bearing strength (ksi) (7.4.2.1)
$F_{by}$	= bearing yield strength (ksi) (7.4.2.1)
$F_{cr}$	= element buckling stress (ksi) (7.5.1.2)
$F_{cy}$	= compressive yield strength (ksi) (7.4.2.1)
$F_n$	= limiting stress for cross-section 1.0 in. or more from weld, ksi, taken from Table 7.4.2.1-1 (7.4.2.2)

$F_{pw}$	= limiting stress on cross-section, part of whose area lies within 1.0-in. of a weld (ksi) (7.4.2.2)
$F_r$	= factored resistance (7.5.3)
$F_{rb}$	= factored resistance in terms of compressive bending stress in beam flange (ksi) (7.11.3.2.1)
$F_s$	= factored resistance in terms of stress for members subjected only to torsion or shear (ksi) (7.13.2)
$F_{su}$	= ultimate shear strength (ksi) (7.4.2.1)
$F_{sy}$	= shear yield strength (ksi) (7.4.2.1)
$F_{tu}$	= ultimate tensile strength (ksi) (7.4.2.1)
$F_{ty}$	= tensile yield strength (ksi) (7.4.2.1) (7.4.2.2)
$F_w$	= limiting stress on cross-section if entire area were to lie within 1.0 in. of a weld (ksi) (7.4.2.2)
$f$	= calculated stress (ksi) (7.11.5.1)
$f_a$	= factored average compressive stress on cross-section of member produced by axial compressive load (ksi) (7.5.1.2) (7.13.1) (7.13.2)
$f_b$	= factored maximum compressive bending stress caused by transverse loads or end moments (ksi) (7.13.1) (7.13.4)
$f_s$	= factored shear stress caused by either torsion or transverse shear (ksi) (7.13.2)
$f_{2b}, f_{2s}$	= factored end stresses (ksi) (7.13.1)
$G$	= shear modulus of elasticity (ksi); grip of rivet or bolt (in.) (7.12.2.1) (7.14.1)
$g$	= spacing of rivet or bolt holes perpendicular to direction of load; gage between fasteners (in.) (7.9.4) (7.14.2.4.2) (7.14.2.4.3)
$h$	= depth of shear web (in.) (7.11.3.1) (7.11.5.4) (7.12.4.1)
$I_b$	= required moment of inertia of bearing stiffener (in. <sup>4</sup> ) (7.11.5.4)
$I_\ell$	= moment of inertia of longitudinal stiffener (in. <sup>4</sup> ) (7.11.5.1)
$I_p$	= polar moment of inertia referred to the shear center (in. <sup>4</sup> ) (7.12.2.1)
$I_s$	= moment of inertia of transverse stiffener (in. <sup>4</sup> ) (7.11.5.2)
$I_y$	= moment of inertia of a beam about axis parallel to web (in. <sup>4</sup> ) (C7.11.2.1)
$I_{yc}$	= moment of inertia of compression element about axis parallel to vertical web (in. <sup>4</sup> ) (7.11.2.1)
$I_1, I_2$	= moment of inertia of the upper and lower flange, respectively, about the y-axis taken as the axis of symmetry (in. <sup>4</sup> ) (7.12.4.1)
$J$	= torsional constant (in. <sup>4</sup> ) (C7.11.2.1)
$K$	= effective length factor (7.10.2)
$KL/r$	= slenderness ratio for columns (7.8.2)
$k_b$	= lateral buckling coefficient (C7.11.2.1)
$k_c$	= coefficient for compression members (7.10.1)
$k_t$	= coefficient for tension members (7.10.1)
$k_1$	= coefficient for determining slenderness limit $S_2$ of sections for which the limit state compressive stress is based on crippling strength (7.10.1)
$k_2$	= coefficient for determining limit state compressive stress in sections with slenderness ratio above $S_2$ for which the limit state compressive stress is based on crippling strength (7.10.1)
$L$	= length of compression member between points of lateral support, or twice the length of a cantilever column, except where analysis shows that a shorter length should be used, length of plates (in.); unsupported plate length (in.) (7.8.2) (7.8.5.2)
$L_b$	= length of beam between points at which the compression flange is supported against lateral movement, or length of cantilever beam from free end to point at which the compression flange is supported against lateral movement (in.) (C7.11.2.1)
$L_t$	= length of tube between circumferential stiffeners (in.) (7.13.3)
$M_1, M_2$	= bending moments at two ends of a beam (kip-in.) (C7.11.2.1)
$N$	= length of bearing at reaction or concentrated load (in.); (365) (75) n ( $ADTT$ ) <sub>SL</sub> (7.5.1.3) (7.6.1.2.4)
$n$	= cycles per truck passage; 1.0 for curved walls or round tubular members, or 2.0 for webs of rectilinear shapes and plates of buildup beams (7.6.1.2.4) (7.13.2)
$P$	= factored reaction force (kip) (7.11.5.4)
$P_c$	= reaction or concentrated load per web (kip) (7.5.1.3)
$p$	= pitch of fasteners (in.) (7.14.2.4)
$R$	= transition radius, the radius of an attachment of the weld detail (in.); outside radius of round tubular column or maximum outside radius of oval tubular column (in.) (7.6.1.2.3) (7.13.3)
$R_b$	= midthickness radius of curvature of curved plates and tubular beam elements (in.) (7.11.2.2)
$r$	= bend radius at juncture of flange and web areas to the inside surface of bend (in.) (7.5.1.3)
$r_L$	= radius of gyration of lip or bulb about face of flange from which lip projects (in.) (7.11.5.3)

$r_y$	= radius of gyration of a beam, about axis parallel to web, for beams that are unsymmetrical about the horizontal axis, $r_y$ should be calculated as though both flanges were the same as the compression flange (in.) (7.11.2.1)
$S_c$	= section modulus of a beam, compression side (in. <sup>3</sup> ) (C7.11.2.1)
$S_2$	= slenderness limits (7.10.2) (7.10.3)
$SR$	= stress ratio, the ratio of minimum stress to maximum stress (7.6.1.2.3)
$s$	= spacing of transverse stiffeners, clear distance between stiffeners for stiffeners consisting of a pair of members, one on each side of the web, center-to-center distance between stiffeners consisting of a member on one side of the web only (in.) (7.11.5.1)
$t$	= thickness of flange, plate, web or tube (in.). For tapered flanges, $t$ is the average thickness (in.) (7.5.1.3)
$V$	= shear force on web at stiffener location (kip) (7.11.5.2)
$\alpha$	= factor equal to 1.0 for a stiffener consisting of equal members on both sides of the web and equal to 3.5 for a stiffener consisting of a member on one side only (7.11.5.1)
$\beta$	= spring constant, transverse force in kip applied to a 1.0-in. length of the member at the compression flange to cause a 1.0-in. deflection of the flange (7.11.2.1)
$\Delta f$	= stress range due to the passage of the fatigue truck (ksi) (7.6.1.2.2)
$(\Delta F)_N$	= nominal fatigue resistance (ksi) (7.6.1.2.2)
$(\Delta F)_{th}$	= constant amplitude fatigue threshold (ksi) (7.6.1.2.4)
$\theta$	= angle $\leq 90^\circ$ between plane of web and plane of bearing surface (7.5.1.3)
$\phi$	= resistance factor (7.5.3) (7.5.4)
$\lambda$	= slenderness parameter (7.10.2)

## 7.4—MATERIALS

### 7.4.1—General

These Specifications shall apply to aluminum alloys and tempers listed herein.

Other aluminum alloys and tempers may be used, however, their engineering properties, including strengths, yield strength and workability shall be established by tests in accordance with [ASTM B557](#) and [ASTM E9](#).

### 7.4.2—Aluminum Sheet, Plate, and Shapes

The compressive modulus of elasticity,  $E$ , shall be taken as 10,100 ksi for Alloys 6061-T6, 6061-T651 and 6063-T6. For all other alloys specified in Table 7.4.2.1-1,  $E$  shall be taken as 10,400 ksi.

The coefficient of linear expansion shall be taken as 0.000013 in./in./°F.

#### 7.4.2.1—Extrusions and Mechanically Fastened Builtup Members

Except as permitted herein, the properties of aluminum sheet, plate, and shapes shall be taken as specified in Table 7.4.2.1-1.

$F_{tu}$  and  $F_{ty}$  for nonwelded material shall be the minimum specified values; otherwise, strength properties for nonwelded material shall be the corresponding expected minimum values.

### C7.4.1

Most alloys of interest in highway construction will have properties and workability available in The Aluminum Association's *Specifications for Aluminum Structures*.

### C7.4.2

The current specification allows the use of any corrosion-resistant alloys and tempers with established minimum mechanical properties and refers to the *Specifications for Aluminum Structures* as a source for this information. Alloy 6063 is commonly used in the T6 temper, is highly corrosion resistant and easily welded, and is listed in the *Specifications for Aluminum Structures*.

#### C7.4.2.1

$F_{tu}$  and  $F_{ty}$  are measured for each lot of material made at the plants of the various aluminum producers. This large database is used to determine statistically-based “minimum properties.” “Expected minimum values” for the other properties are estimated from an analysis of a much smaller database, utilizing the variability obtained from the tensile test data.

Exceptions are as follows:

- Values for other alloys and tempers, and Alloys 5456-H116 and 5083-H321 in thicknesses other than those listed in Table 7.4.2.1-1, may be taken from the latest edition of *Specifications for Aluminum Structures*.
- Plate values listed for Alloy 6061-T6 shall also apply to sheet. Sheet and plate in the thickness range 0.021 to 0.499 in. shall have a minimum elongation of ten percent; other thickness ranges have the same strength values, but a lower minimum elongation.
- Values listed for shapes of Alloys 6061-T651 and 6061-T6 shall be taken to apply to [ASTM B308](#) Standard Structural Shapes and [ASTM B429](#) Extruded Structural Pipe and Tube.

The values in Table 7.4.2.1-1 are substituted in the appropriate criteria in Articles 7.9 through 7.13 to develop component resistance. For welded construction, the additional provisions of Article 7.4.2.2 also apply.

Minimum elongation of Alloy 6061-T6 is dependent on sheet thickness, with the value decreasing for both thinner and thicker sheet. Values for other thickness sheet can be found in the Aluminum Association's *Aluminum Standards and Data*.

**Table 7.4.2.1-1—Minimum Nonwelded Material Properties for Aluminum Sheets, Plates, and Shapes**

ASTM Designation	B209	B209	B209 and B221		B209	B221
Alloy Number	5086-H116	5456-H116	6061-T651 and 6061-T6		5083-H321	6063-T6
Product	Plate	Sheet and Plate	Shapes	Sheet and Plate	Sheet and Plate	Shapes
Thickness (in.)	0.250 to 2.000	0.188 to 1.25	-All-	0.010 to 4.00	0.188 to 1.500	-All-
Tensile Strength (ksi)	$F_{tu}$	40.0	46.0	38.0	42.0	44.0
Tensile Yield Strength (ksi)	$F_{ty}$	28.0	33.0	35.0	35.0	31.0
Compressive Yield Strength (ksi)	$F_{cy}$	26.0	27.0	35.0	35.0	26.0
Shear Strength (ksi)	$F_{su}$	24.0	27.0	24.0	27.0	26.0
Shear Yield Strength (ksi)	$F_{sy}$	16.0	19.0	20.0	20.0	18.0
Bearing Strength (ksi)	$F_{bu}$	78.0	87.0	80.0	88.0	84.0
Bearing Yield Strength (ksi)	$F_{by}$	48.0	56.0	56.0	58.0	53.0

#### 7.4.2.2—Welded Builtup Members

If less than 15 percent of the area of a given cross-section lies within 1.0-in. of a weld, regardless of material thickness, the effect of welding may be neglected, and the limiting stresses for use in Articles 7.9 through 7.13 shall be taken as specified in Table 7.4.2.1-1.

If the area of a cross-section lying within 1.0 in. of a weld,  $A_w$ , is not less than 15 percent of the net area,  $A$ , the limiting stress for use in Articles 7.9 through 7.13 shall be taken as:

$$F_{pw} = F_n - \frac{A_w}{A} (F_n - F_w) \quad (7.4.2.2-1)$$

where:

$F_{pw}$  = effective nominal limiting stress on cross-section, part of whose area lies within 1.0 in. of a weld (ksi)

$F_n$  = limiting stress for cross-section 1.0 in. or more from weld specified in Table 7.4.2.1-1 (ksi)

$F_w$  = limiting stress on cross-section if entire area were to lie within 1.0 in. of a weld, specified in Table 7.4.2.2-1 (ksi)

$A_w$  = area of a cross-section lying within 1.0 in. of a weld ( $\text{in.}^2$ )

$A$  = net area of cross-section of a tension member or tension flange of a beam, or gross area of cross-section of a compression member or compression flange of a beam; in calculating the net area,  $A$ , a beam flange shall be considered to consist of that portion of the member further than  $2c/3$  from the neutral axis ( $\text{in.}^2$ )

$c$  = distance from neutral axis to the extreme fiber (in.)

The following exceptions may be permitted:

- All of the exceptions to Table 7.4.2.1-1 given in Article 7.4.2.1 apply to Table 7.4.2.2-1.
- Plate values of  $F_{ty}$ ,  $F_{cy}$ , and  $F_{sy}$  listed for Alloys 6061-T651 and 6061-T6 shall be taken to apply to material of any thickness when welded with 5183, 5356, or 5556 filler wire; they also apply to material where thickness does not exceed 0.375 in. when welded with 4043, 5154, or 5554 filler alloys. The strength values for material thicker than 0.375 in. that is welded with the latter filler alloys shall be taken as 15.0 ksi for tensile and compressive yield strength and 9.0 ksi for shear yield strength.  $F_y$  and  $F_{cy}$  for welded material shall correspond to the 0.2 percent offset value in a 10.0-in. gage length across a butt weld.

**Table 7.4.2.2-1—Minimum Material Properties near Welds for Aluminum Sheets, Plates, and Shapes**

ASTM Designation		B209	B209	B209 and B221	B209	B221
Alloy Number		5086-H116	5456-H116	6061-T651 and 6061-T6	5083-H321	6063-T6
Product		Plate	Sheet and Plate	Shapes and Plate	Sheet and Plate	Shapes
Thickness (in.)		0.250 to 2.000	0.188 to 1.25	—All—	0.188 to 1.500	—All—
Tensile Strength	$F_{tu}$ (ksi)	35.0	42.0	24.0	40.0	17
Tensile Yield Strength	$F_{ty}$ (ksi)	19.0	26.0	20.0	24.0	11
Compressive Yield Strength	$F_{cy}$ (ksi)	19.0	24.0	20.0	24.0	11
Shear Strength	$F_{su}$ (ksi)	21.0	25.0	15.0	24.0	11
Shear Yield Strength	$F_{sy}$ (ksi)	11.0	15.0	12.0	14.0	6.5
Bearing Strength	$F_{bu}$ (ksi)	70.0	84.0	50.0	80.0	34
Bearing Yield Strength	$F_{by}$ (ksi)	28.0	38.0	30.0	36.0	22

#### 7.4.3—Material for Pins, Rollers, and Expansion Rockers

Material for pins, rollers, and expansion rockers shall be aluminum Alloy 6061-T6 or coated steel conforming to Article 6.4.2.

#### 7.4.4—Fasteners—Rivets and Bolts

#### C7.4.4

Fasteners shall conform to one of the following:

- Power driven aluminum rivets that are made of [ASTM B316](#), Alloy 6061-T6 Material and that conform to the requirements of MIL-R-1150F; or
- Coated AASHTO M 164 ([ASTM A325](#)) high-strength steel bolts or [ASTM F593](#), Alloy Groups 1, 2, or 3 stainless steel bolts; or
- Aluminum, stainless steel, or coated steel lockbolts conforming to the requirements of MIL-P-23469; or
- Coated steel blind fasteners.

Strength of Alloy 6061-T6 rivets shall be as specified in Table 7.4.4-1.

Various proprietary steel blind fasteners are available with strengths that exceed those of aluminum rivets. These blind fasteners are especially useful because they can be installed without access to both sides of the work. They have been widely used on structures subject to fatigue and vibration, such as aircraft and transportation vehicles.

**Table 7.4.4-1—Strength of Aluminum Rivets**

Alloy and Temper	Tensile Strength (ksi)	Tensile Yield Strength (ksi)	Shear Strength (ksi)
6061-T6	42.0	35.0	25.0

### 7.4.5—Weld Metal

Weld metal shall conform to the requirements of ANSI/AWS D1.2, current issue.

For welded sheet and plate material for Alloy 5456-H116 and Alloy 5083-H321, minimum material properties shall be taken from Table 7.4.2.2-1.

$F_u$  shall be taken as the ASME weld qualification test value; other properties shall correspond.

### 7.4.6—Aluminum Castings

Permanent aluminum mold castings shall conform to the requirements of [ASTM B108](#), Alloy A444.0-T4. The tensile strength of Alloy A444.0-T4 shall be 20.0 ksi.

### 7.4.7—Aluminum Forgings

Aluminum forgings and forging stock shall conform to the requirements of [ASTM B247](#), Alloy 6061-T6. Tensile and yield strengths, and elongations for this alloy shall be taken as specified in Table 7.4.7-1.

Compressive yield strength, shear strength, shear yield strength, and bearing yield strength values shall be taken as specified in Table 7.4.2.1-1.

The provisions of Article 7.4.5 shall apply for welded values.

**Table 7.4.7-1—Minimum Material Properties of Aluminum Alloy 6061-T6, Forgings, Specimen Axis Parallel to Grain Flow**

Specified Thickness	Tensile Strength (ksi)	Tensile Yield Strength (ksi)	Elongation in 2.0 in. or 4 × diameter, %	
			Forgings	Separate Test Coupon
To 4.0 in., inclusive	38.0	35.0	7.0	10.0

## 7.5—LIMIT STATES

### 7.5.1—Service Limit State

#### 7.5.1.1—Appearance of Buckling

In applications where any appearance of buckling cannot be tolerated, the stresses for thin sections shall not exceed the values specified in Table 7.5.1.1-1.

**Table 7.5.1.1-1—Element Buckling Stresses**

Article	Buckling Stress, $F_{cr}$
7.10.4—Compressive Resistance of Components of Columns, Gross Section—Flat Plates with Both Edges Supported	
7.11.3.3—Compression in Components of Beams with Component under Uniform Compression, Gross Section, Flat Plates with Both Edges Supported	$\frac{\pi^2 E}{\left(\frac{1.6b}{t}\right)^2}$
7.11.3.6—Webs of Beams, Gross Section—Flat Plates with Both Edges Supported	$\frac{\pi^2 E}{\left(\frac{0.67h}{t}\right)^2}$
7.11.3.7—Webs of Beams with Longitudinal Stiffener, Both Edges Supported	$\frac{\pi^2 E}{\left(\frac{0.29h}{t}\right)^2}$
7.11.3.2—Compression in Components of Beams with Component Under Uniform Compression, Gross Section—Outstanding Flanges	$\frac{\pi^2 E}{\left(\frac{5.1b}{t}\right)^2}$
7.11.3.5—Compression in Components of Beams with Component Under Bending in Own Plane, Gross Section, Flat Plates with Compression Edge Free, Tension Edge Supported	$\frac{\pi^2 E}{\left(\frac{3.5b}{t}\right)^2}$

### 7.5.1.2—Effective Width for Calculation of Deflection of Thin Gage Sections

The effective width,  $b_e$ , of a thin element subjected to direct compression stresses may be taken as:

$$\text{If } f_a \leq \phi F_{cr} \text{ then } b_e = b \quad (7.5.1.2-1)$$

$$\text{If } f_a > \phi F_{cr}, \text{ then } b_e = b \frac{\sqrt{\phi F_{cr}}}{f_a} \quad (7.5.1.2-2)$$

where:

$b_e$  = effective width of flat plate element to be used in deflection calculations (in.)

$b$  = clear width of element (in.)

$F_{cr}$  = buckling stress for element as specified in Article 7.5.1.1 (ksi)

$f_a$  = compressive stress (ksi)

### C7.5.1.2

Where deflection at the service limit state is critical, the effective width concept may be used to determine an effective section to be used in deflection calculations.

Eq. 7.5.1.2-2 may be used to calculate the effective width on the compression side of a web in flexure, in which case the compressive flexural stress due to the applied loads,  $f_b$ , replaces  $f_a$ .

### 7.5.1.3—Web Crippling

The compressive web resistance at points of interior reactions and concentrated loads for flat webs shall be taken as:

$$P_c = \frac{\phi t^2 (N + 5.4) \sin \theta (0.92 F_{cy} + 0.04 \sqrt{EF_{cy}})}{2[0.4 + r(1 - \cos \theta)]} \quad (7.5.1.3-1)$$

The compressive web resistance at points of end reactions shall be taken as:

$$P_c = \frac{0.6\phi t^2 (N + 1.3) \sin \theta (0.92 F_{cy} + 0.04 \sqrt{EF_{cy}})}{[0.4 + r(1 - \cos \theta)]} \quad (7.5.1.3-2)$$

where:

$E$  = compressive modulus of elasticity (ksi)

$F_{cy}$  = specified compressive yield strength of sheet (ksi)

$N$  = length of bearing at reaction or concentrated load (in.)

$P_c$  = reaction or concentrated load (kip)

$r$  = bend radius at juncture of flange and web measured to the inside surface of bend (in.); taken to be equal to zero for filleted web-flange junctures

$t$  = web thickness (in.)

$\phi$  = resistance factor as specified in Table 7.5.4-1

$\theta$  = angle between plane of web and plane of bearing surface (degrees)

### 7.5.1.4—Live Load Deflection

The provisions of Article 2.5.2.6 should be considered.

### 7.5.2—Fatigue and Fracture Limit State

Components and details shall be investigated for fatigue as specified in Article 7.6.

The fatigue load combination specified in Table 3.4.1-1 and the fatigue live load specified in Article 3.6.1.4 shall apply.

### 7.5.3—Strength Limit State

Members and connections shall be designed for all applicable strength load combinations specified in Table 3.4.1-1.

The factored resistance,  $F_r$ , of members, given in terms of stress, shall be taken as:

$$F_r = \phi F_n \quad (7.5.3-1)$$

where:

$\phi$  = resistance factor as applicable to yield or ultimate stress, specified in Table 7.5.4-1

$F_n$  = nominal yield, ultimate stress, or buckling stress specified in Articles 7.9, 7.10, 7.11, 7.12, 7.13, and 7.14 as appropriate (ksi)

### 7.5.4—Resistance Factors

Resistance factors shall be taken as specified in Table 7.5.4-1.

**Table 7.5.4-1—Resistance Factors**

Force Effect		$\phi_v$	$\phi_u$	$\phi_c$	$\phi_s$	$\phi_b$
Web Crippling		—	—	0.80	—	—
Tensile Resistance		0.90	0.75	—	—	—
Column Capacity:	for $\lambda < 1.5$ , $\phi_c = 0.94 - 0.19\lambda \leq 0.90$				0.90	—
	for $\lambda \geq 1.5$ , $\phi_c = 0.52 + 0.09\lambda \leq 0.90$					
Compression in Components of Columns—Outstanding Flanges and Legs		—	—	0.80	0.90	—
Compression in Components of Columns, Gross Section—Flat Plates with Both Edges Supported		—	—	0.80	0.90	—
Compression in Components of Columns, Gross Section—Curved Plates Supported on Both Edges, Walls of Round or Oval Tubes		—	—	0.75	0.90	—
Tension in Extreme Fibers of Beams	Structural Shapes Bent about Strong Axis	0.90	0.80	—	—	—
	Rectangular Tubes	0.90	0.85	—	—	—
Tension in Extreme Fibers of Beams—Round or Oval Tubes—Bolts		0.85	0.75	—	—	—
Tension in Extreme Fibers of Beams—Shapes Bent about Weak Axis, Rectangular Bars, Plates		0.85	0.75	—	—	—
Compression in Beams, Extreme Fiber, Gross Section—Single-Web Beams Bent about Strong Axis		—	—	—	0.90	0.80
Compression in Beams, Extreme Fiber, Gross Section—Round or Oval Tubes		—	—	—	0.85	0.75
Compression in Beams, Extreme Fiber, Gross Section—Solid Rectangular Beams		—	—	—	0.85	0.85
Compression in Beams, Extreme Fiber, Gross Section—Rectangular Tubes and Box Sections		—	—	—	0.90	0.80
Compression in Components of Beams (Component under Uniform Compression), Gross Section—Outstanding Flanges		—	—	0.80	0.90	—
Compression in Components of Beams (Component under Uniform Compression), Gross Section—Flat Plates with Both Edges Supported		—	—	0.80	0.90	—
Compression in Components of Beams—Curved Sections		—	—	0.75	0.85	—
Compression in Components of Beams (Component under Bending in Own Plane), Gross Section—Flat Plates with Compression Edge Free, Tension Edge Supported		—	—	0.80	0.85	—
Compression in Components of Beams (Component Under Bending in Own Plane), Gross Section—Flat Plates with Both Edges Supported		—	—	0.80	0.85	—
Compression in Components of Beams (Component Under Bending in Own Plane), Gross Section—Flat Plates with Horizontal Stiffener, Both Edges Supported		—	—	0.80	0.85	—
Shear—Unstiffened Flat Webs		—	—	0.80	0.90	—
Shear—Stiffened Flat Webs		—	—	0.80	0.90	—
Shear—Transverse Stiffeners				$\phi = 0.90$		
Bearing Stiffeners				$\phi = 0.90$		

## 7.6—FATIGUE AND FRACTURE CONSIDERATIONS

### 7.6.1—Fatigue

#### 7.6.1.1—General

Fatigue shall be categorized as load-induced fatigue or as distortion-induced fatigue.

#### C7.6.1.1

In the 1996 AASHTO Standard Specifications, the provisions explicitly relating to fatigue dealt only with load-induced fatigue.

### 7.6.1.2—Load-Induced Fatigue

#### 7.6.1.2.1—Application

The force effect considered for the fatigue design of an aluminum bridge detail shall be the live load stress range.

Residual stresses shall not be included in the stress range.

These provisions shall only be applied to details subject to a net applied tensile stress. In regions where the permanent loads produce compression, fatigue shall be considered only if this compressive stress is less than twice the maximum tensile live load stress resulting from the fatigue load combination as specified in Table 3.4.1-1.

#### C7.6.1.2.1

Commentary of Article 6.6.1.2.1 is also applicable to aluminum bridges.

#### 7.6.1.2.2—Design Criteria

For load-induced fatigue considerations, each detail shall satisfy:

$$\gamma(\Delta f) \leq (\Delta F)_N \quad (7.6.1.2.2-1)$$

where:

$\gamma$  = load factor specified in Table 3.4.1-1 for the fatigue load combination

$\Delta f$  = the force effect, stress range due to the passage of the fatigue load as specified in Article 3.6.1.4 (ksi)

$(\Delta F)_N$  = the nominal fatigue resistance as specified in Article 7.6.1.2.4 (ksi)

#### C7.6.1.2.2

Rewriting Eq. 7.6.1.2.2-1 in terms of fatigue load and resistance parameters yields:

$$\gamma(\Delta f) \leq \eta\phi(\Delta F)_N \quad (C7.6.1.2.2-1)$$

but for the fatigue limit state,

$\eta = 1.0$ ,

$\phi = 1.0$ .

#### 7.6.1.2.3—Detail Categories

Components and details with fatigue resistance less than or equal to Detail Category C shall be designed to satisfy the requirements of their respective detail categories, as summarized in Table 7.6.1.2.3-1 and shown in Figure 7.6.1.2.3-1. For aluminum orthotropic decks, the details in Table 6.6.1.2.3-1 should also be considered.

**Table 7.6.1.2.3-1—Detail Categories for Fatigue**

Construction	Detail	Detail Category	Illustrative Example Numbers

*a* = detail dimension in the direction of applied stress

*b* = detail dimension normal to the direction of applied stress

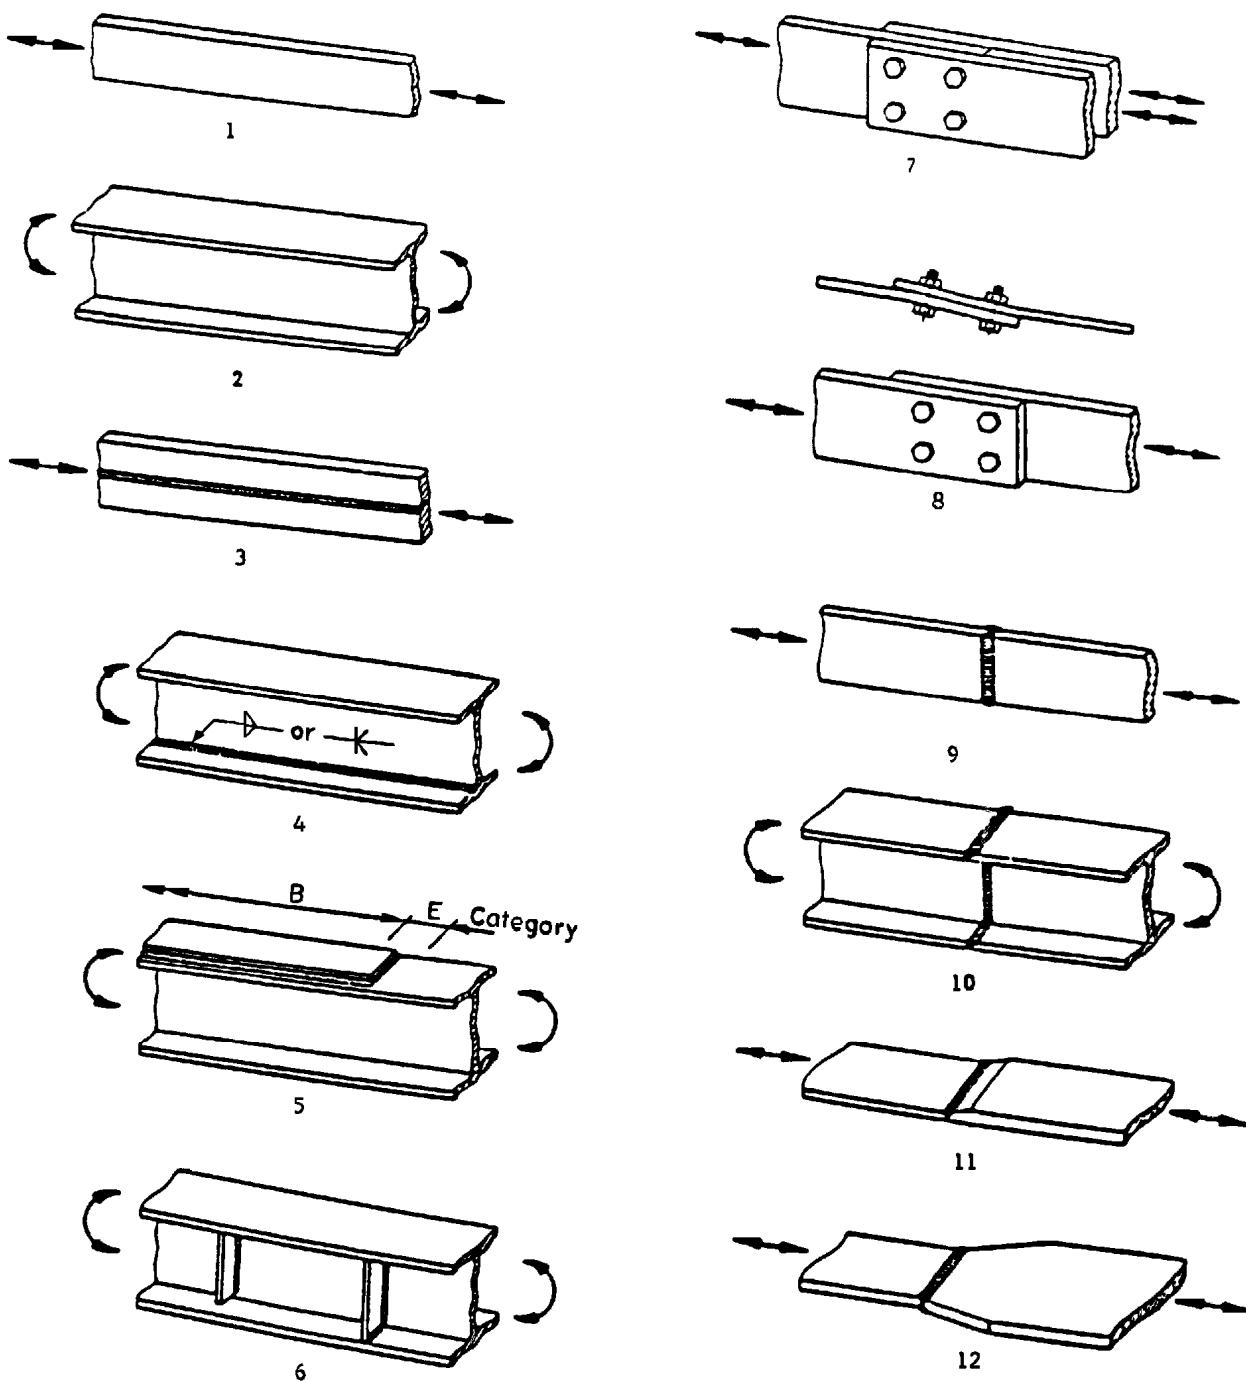

Figure 7.6.1.2.3-1—Illustrative Examples

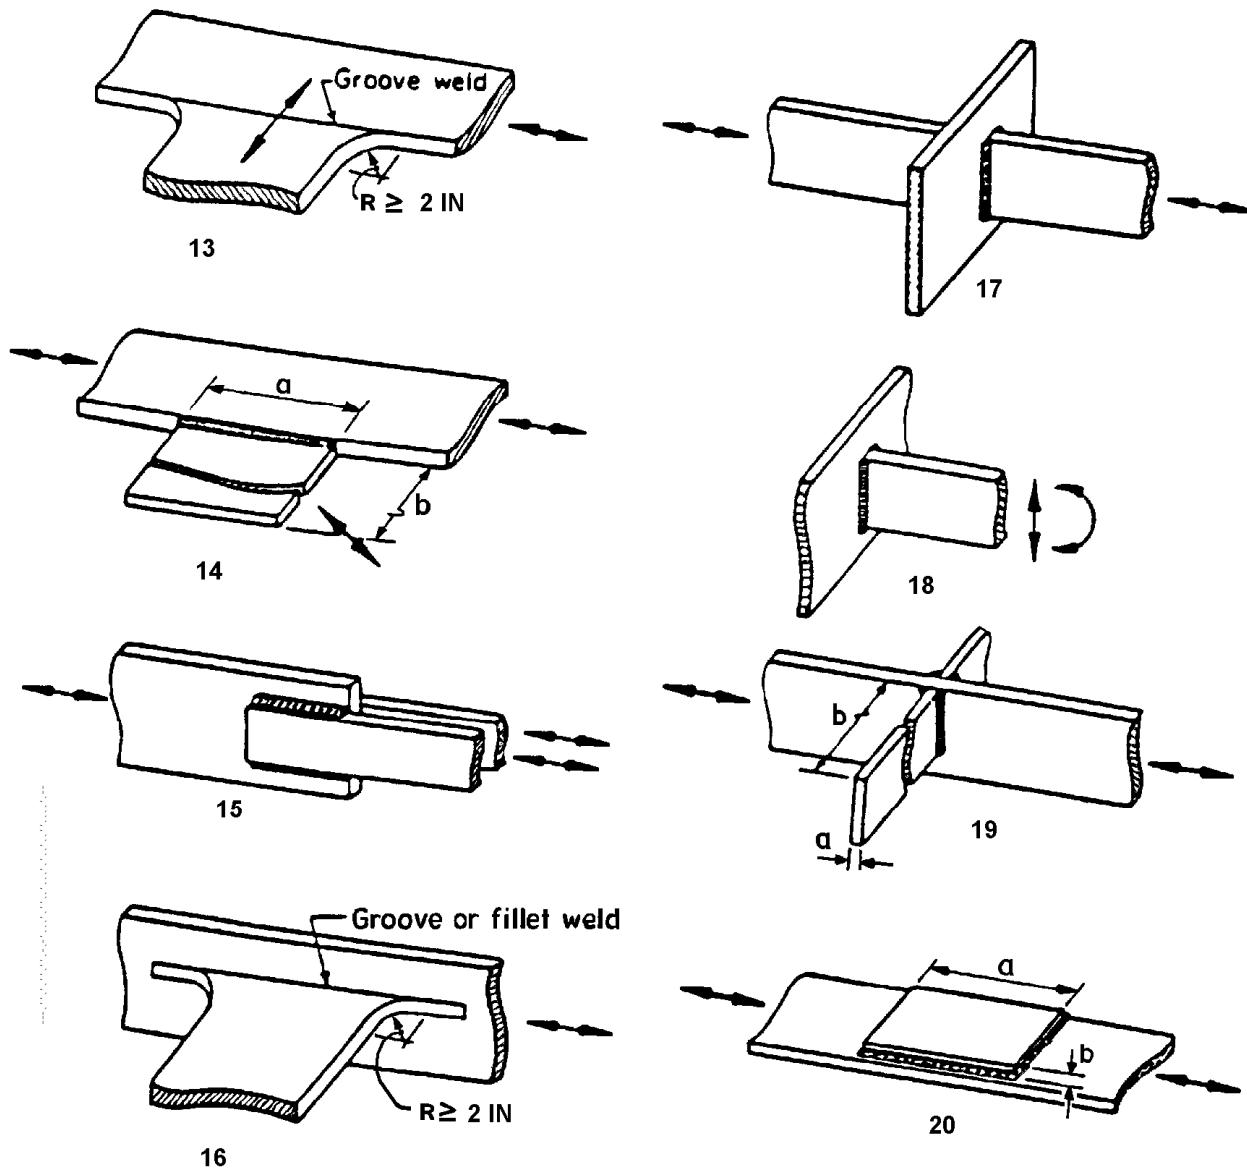

Figure 7.6.1.2.3-1—Illustrative Examples (continued)

#### 7.6.1.2.4—Fatigue Resistance

Nominal fatigue resistance shall be taken as:

$$(\Delta F)_N = \left( \frac{C_1}{N} \right)^{C_2} \geq \frac{1}{2} (\Delta F)_{TH} \quad (7.6.1.2.4-1)$$

in which:

$$N = (365)(75)n(ADTT)SL \quad (7.6.1.2.4-2)$$

where:

$C_1, C_2$  = constant specified in Table 7.6.1.2.4-1

$n$  = number of stress range cycles per truck passage taken from Table 7.6.1.2.4-2

#### C7.6.1.2.4

The requirement on higher traffic volume bridges that the maximum stress range experienced by a detail be less than the constant amplitude fatigue threshold provides a theoretically infinite fatigue life. The maximum stress range is assumed to be twice the live load stress range due to the passage of the fatigue load, factored in accordance with the load factor in Table 3.4.1-1 for the fatigue load combination.

In the 1996 AASHTO Standard Specifications, the constant amplitude fatigue threshold was termed the allowable fatigue stress range for more than 2 million cycles on a redundant load path structure.

The design life has been considered to be 75 yr in the overall development of the Specifications. If a design life other than 75 yr is sought, a number other than 75 may be inserted in the equation for  $N$ .

$(ADTT)_{SL}$  = single lane  $ADTT$  as specified in Article 3.6.1.4  
 $(\Delta F)_{TH}$  = constant-amplitude fatigue threshold specified in Table 7.6.1.2.4-3 (ksi)

**Table 7.6.1.2.4-1—Detail Category Constants**

Detail Category	$C_1 \times 10^8$	$C_2$
A	100,000.0	0.155
B	520.0	0.211
C	36.0	0.237
D	8.4	0.249
E	1.2	0.284
F	0.46	0.292

**Table 7.6.1.2.4-2—Load Cycles,  $n$ , per Truck Passage**

Longitudinal Members	Span Length	
	>40.0 ft	≤40.0 ft
Simple Span Girders	1.0	2.0
Continuous Girders		
1) near interior support	1.5	2.0
2) elsewhere	1.0	2.0
Cantilever Girders		5.0
Trusses		1.0
Transverse Members	Spacing	
	>20.0 ft	≤20.0 ft
	1.0	2.0

**Table 7.6.1.2.4-3—Constant Amplitude Fatigue Thresholds**

Detail Category	Threshold (ksi)
A	9.5
B	6.0
C	4.0
D	3.0
E	2.0
F	1.6

**7.6.1.3—Distortion-Induced Fatigue**

Load paths sufficient to transmit all intended and unintended forces shall be provided by connecting transverse members, either primary or secondary members, to all the components that comprise the longitudinal cross-section of the member. The load paths shall be provided by attaching the various components through either welding or bolting.

**C7.6.1.3**

Distortion-induced stresses are difficult to quantify by routine calculations. The best approach, therefore, is to preclude the development of such stresses by appropriate detailing.

#### 7.6.1.3.1—Transverse Connection Plates

The provisions of Article 6.6.1.3.1 shall apply.

#### 7.6.1.3.2—Lateral Connection Plates

The provisions of Article 6.6.1.3.2 shall apply.

### 7.6.2—Fracture

Mandatory toughness requirements specified herein shall apply only to fracture-critical members.

Fracture-critical members shall be identified in the contract documents.

Fracture-critical members may be evaluated by *R* curve analysis complying with [ASTM E561](#) or evidence of material ductility inferred from reduction of area during tensile tests.

### C7.6.2

Main load-carrying components fabricated with the aluminum alloys described in these Specifications have successful field experience in bridge structures. These alloys are inherently so tough that current testing procedures specified for metals cannot adequately characterize the fracture toughness of the material. Toughness is generally satisfactory, provided fatigue design guidelines are followed.

There are no simple standards for screening the alloys of interest for fracture toughness.

No reasonable Charpy V-notch impact fracture toughness correlation exists for aluminum alloys. Most aluminum alloys show no reduction in toughness with low temperatures and impact loads; in fact, they generally show increased resistance.

Material toughness may be described by the means of *R* curve analysis. In many instances, the *R* curves for structural alloys show no plateau but instead increasing resistance with crack extension (*Kosteas and Graf, 1984*).

## 7.7—DESIGN CONSIDERATIONS

### 7.7.1—Dead Load Camber

Provisions of Article 6.7.2 apply.

### 7.7.2—Welding Requirements

The welding requirements for FCMs shall be as specified in ANSI/AWS D1.2-97, Sections 2, 3, and 5.

Permanent backing for groove welds shall be of aluminum of the same alloy as the base metal. Temporary backing for groove welds may be of austenitic stainless steel, glass tape, ceramic, or anodized aluminum of the same alloy. Copper shall not be used as temporary backing.

The contract documents shall specify that intermittent fillet welding is not permitted.

### C7.7.2

Copper used as temporary backing introduces dangers of weld contamination and corrosion problems.

### 7.7.3—Welding Procedures

The welding procedures shall be as specified in *Structural Welding Code—Aluminum*, ANSI/AWS D1.2, Section 4.

#### 7.7.4—Nondestructive Testing

The nondestructive testing for FCMs shall be as specified in *Structural Welding Code—Aluminum*, ANSI/AWS D1.2, Section 5.7.

#### 7.7.5—Uplift and Slip of Deck Slabs

If noncomposite design is used, the slab should be connected to the supporting members to resist uplift and slip. The connection devices should be designed on the basis of full composite action, even if composite action is neglected in the design of the components supporting the deck.

#### 7.7.6—Composite Sections

The following criteria apply to the design of aluminum beams composite with a concrete deck:

- The elastic design should be used based on the transformed section method.
- The shear connectors shall be of the same alloy and temper as the beam. Adequate strength and fatigue characteristics of shear connections shall be demonstrated by physical testing under representative conditions.
- Thermal stresses between the aluminum beams and the concrete should be considered in accordance with the temperature ranges and gradients specified in Articles 3.12.2 and 3.12.3, respectively.
- Reduction of allowable stresses due to welding shall be considered in accordance with the provisions of Article 7.4.2.2.
- All aluminum in contact with or embedded in concrete shall be coated with a chromate conversion coating.
- Steel reinforcing bars for the concrete deck shall be epoxy coated. For additional protection, the shear connectors may be painted.
- The contract documents shall specify that concrete mixed with chlorides shall be avoided.

#### C7.7.6

Composite action has been used in several aluminum bridges. The basic design principles used are the same as those used for steel bridges.

Shear connectors are usually extruded angles or Z-shapes with thickened sections at points of maximum shear force.

Where possible, welds should be located at points of least moment and be spliced for full strength.

The purpose of these coatings is to prevent galvanic action between dissimilar materials.

The chlorides in concrete will promote galvanic corrosion between steel reinforcement bars and aluminum shear connectors.

### 7.8—GENERAL DIMENSION AND DETAIL REQUIREMENTS

#### 7.8.1—Effective Length of Span

The provisions of Article 6.7.1 shall apply.

### 7.8.2—Slenderness Ratios for Tension and Compression Members

Compression components shall satisfy the slenderness requirements specified herein.

- For main components or those in which more than 50 percent of the stress results from dead and live load:

$$\frac{KL}{r} \leq 100$$

- For bracing components:

$$\frac{KL}{r} \leq 120$$

For the purpose of this Article only, the radius of gyration may be computed on a notional section that neglects part of the area of a component, provided that:

- The capacity of the component based on the actual area and radius of gyration exceeds the factored loads, and
- The capacity of the notional component based on a reduced area and corresponding radius of gyration also exceeds the factored loads.

Where a component contains perforated cover plates, the radius of gyration and the effective area for carrying stress shall be determined for a transverse section taken at the maximum width of perforation. Where perforations are staggered in opposite cover plates, the cross-sectional area of the member shall be considered the same as for a section having perforations in the same transverse plane.

The unbraced length,  $L$ , shall be taken as follows:

- For the top chords of half-through trusses, the length between laterally supported panel points,
- For other main components, the length between panel point intersections or centers of end connections, and
- For secondary components, the length between the centers of the end connections of such components or centers of braced points.

Tension components, except rods, eyebars, cables, and plates, shall satisfy the slenderness ratios specified herein.

- For main components subjected to a reversal of stress:  $\frac{L}{r} \leq 120$
- For other main components:  $\frac{L}{r} \leq 150$
- For bracing components:  $\frac{L}{r} \leq 200$

The possibility of wind-induced vibrations should be considered for components designed for slenderness limits higher than 120.

#### 7.8.3—Minimum Thickness of Aluminum

The thickness of aluminum plate or components shall not be less than 0.1875 in., unless a smaller thickness can be justified through a bridge-specific evaluation of fabrication, shipping, and erection procedures.

#### C7.8.3

The limiting thickness of aluminum depends primarily on the resistance to damage during handling and fabrication, not on the need for corrosion allowance. For large, major components 0.1875 in. is a reasonable minimum thickness.

Aluminum bridges erected in the 1960s and in use today employed thicknesses as small as 0.125 in. Standard extruded aluminum I-beams and channels have webs as thin as 0.13 in. Article 9.8.3.7.2 allows closed ribs in steel orthotropic decks to be as thin as 0.1875 in., and steel is subject to corrosion. Given this information, a 0.1875 in. minimum thickness is deemed appropriate and conservative for aluminum components.

#### 7.8.4—Diaphragms and Cross-Frames

The following Articles of Section 6 shall apply:

- Article 6.7.4.2—Straight I-Beams
- Article 6.7.4.3—Straight Box Beams
- Article 6.7.4.4—Trusses and Arches

Extruded beam and plate girder spans shall be provided with cross-frames or diaphragms at each support and with intermediate cross-frames or diaphragms in all bays and spaced as required for stability and control of wind stresses in flanges of main members.

Diaphragms for extruded beams shall be at least one-third the beam depth. Diaphragms for plate girders shall be as deep as practicable.

End cross-frames or diaphragms shall be proportioned to transmit lateral forces to the bearings. Where the supports are skewed more than 20°, the intermediate cross-frames shall be placed normal to the main components.

Vertical connection plates, such as transverse stiffeners that connect diaphragms or cross-frames to the beam or girder shall be rigidly connected to both top and bottom flanges.

#### C7.8.4

Although this specification permits diaphragms as shallow as one-third of the depth of extruded beams, half-depth diaphragms are preferred where they are practical.

For plate girder bridges, cross-type or V-type intermediate cross-frames are preferred.

## 7.8.5—Lateral Bracing

### 7.8.5.1—General

The following provisions of Section 6 shall apply:

- Article 6.7.5.1—General
- Article 6.7.5.2—Straight I-Section
- Article 6.7.5.3—Straight Box sections
- Article 6.7.5.4—Trusses

### 7.8.5.2—Through-Spans

### C7.8.5.2

Where beams comprise the main components of through-spans, such components shall be stiffened against lateral deformation by gusset plates or knee braces with solid webs connected to the stiffeners on the main components and the floorbeams.

If the unsupported length of the edge of a gusset plate or solid web exceeds the criterion given by Eq. 7.8.5.2-1, the plate or web shall have a stiffening plate or angles connected along its unsupported edge.

This limit allows plate to be stressed to  $F_{cy}$ . Otherwise bracing is needed.

$$\frac{L}{t} \leq \frac{0.29(B_p - F_{cy})}{D_p} \quad (7.8.5.2-1)$$

where:

$L$  = unsupported length of plate (in.)

$t$  = thickness of plate (in.)

$B_p$  = coefficient specified in Table 7.10.1-2

$D_p$  = coefficient specified in Table 7.10.1-2

$F_{cy}$  = compressive yield stress specified in Table 7.4.2.1-1

## 7.8.6—Pins and Pin-Connected Elements

Pins shall be proportioned for the maximum shears and bending moments produced by the components connected.

The following Articles of Section 6 shall apply:

- Article 6.7.6.1—Location
- Article 6.8.7.2—Pin Plates
- Article 6.7.6.4—Pins and Nuts
- Article 6.8.6—Eyebars
- Article 6.8.7—Pin-Connected Plates

## 7.9—TENSION MEMBERS

### 7.9.1—General

In general, the section should be compact and proportioned to minimize the eccentricity between the gravity axis of the section and the applied factored load or working line. Consideration should also be given to the convenience of connection with other members or gusset plates.

### 7.9.2—Tensile Resistance

The factored resistance in terms of stress,  $F_r$ , shall be taken as the values given by Eqs. 7.9.2-1 and 7.9.2-2:

$$F_r = \phi_y F_{ty} \quad (7.9.2-1)$$

$$F_r = \phi_u \frac{F_{tu}}{k_t} \quad (7.9.2-2)$$

where:

$F_{ty}$  = tensile yield strength specified in Table 7.4.2.1-1 (ksi)

$F_{tu}$  = tensile ultimate strength specified in Table 7.4.2.1-1 (ksi)

$\phi_y, \phi_u$  = resistance factors specified in Table 7.5.4-1

$k_t$  = value specified in Table 7.10.1-1

The tensile resistance given by Eq. 7.9.2-1 shall be compared to a tensile stress computed by dividing the factored load by the area of the component without deduction for fastener holes. The resistance given by Eq. 7.9.2-2 shall be compared to a tensile stress based on the net section.

### 7.9.3—Effective Area of Angle and T-Sections

The effective area of a single-angle tension member, a T-section tension member, or each angle of a double-angle tension member in which the shapes are connected back-to-back on the same side of a gusset plate shall be assumed as the net area of the connected leg or flange, plus one-half of the area of the outstanding leg.

If a double-angle or T-section tension member is connected with the angles or flanges back-to-back on opposite sides of a gusset plate, the full net area of the shapes shall be considered effective.

Lug angles may be considered effective in transmitting stress, provided that they are connected with at least one-third more fasteners than required by the stress to be carried by the lug angle.

Where angles connect to separate gusset plates and the angles are connected by stay plates located as near the gusset as practicable or by other adequate means, the full net area of the angles shall be considered effective. If the angles are not so connected, only 80 percent of the net areas shall be considered effective.

#### 7.9.4—Net Area

Unless modified herein, the provisions of Article 6.8.3 shall apply.

Unless larger holes are permitted in accordance with Article 7.14.2.2, the effective diameter of the hole shall be taken as 0.0625 in. greater than the nominal diameter of the hole.

### 7.10—COMPRESSION MEMBERS

#### 7.10.1—General

Compressive resistance parameters shall be as specified in Tables 7.10.1-1, 7.10.1-2, and 7.10.1-3.

The cross-section of a compression member may be composed of several thin elements. The factored resistance for the section as a whole may be considered to be the weighted average factored resistance for the individual elements, where the resistance for each element is weighted in accordance with the ratio of the area of the element to the total area of the section. The factored resistance for the section as a whole used as a column shall not exceed that specified by Eq. 7.10.2-1 or Eq. 7.10.2-2.

#### C7.10.1

Formula for buckling constants for other alloys and tempers are given in the latest edition of the *Specifications for Aluminum Structures*.

**Table 7.10.1-1—Value of Coefficients  $k_1$ ,  $k_2$ ,  $k_c$ , and  $k_t$**

Designation	ASTM B209	ASTM B209, B221, B308, B429

### 7.10.2—Compressive Resistance of Columns

Unless further reduced by plate or component slenderness considerations, the factored compressive resistance in terms of stress shall be taken as:

- If  $\lambda \leq S_2$ , then:

$$F_r = \phi_c [B_c - D_{cc}\lambda] \leq \phi_s \frac{F_{cy}}{k_c} \quad (7.10.2-1)$$

- If  $\lambda \geq S_2$ , then:

$$F_r = \frac{\phi_c F_{cy}}{\lambda^2} \quad (7.10.2-2)$$

in which:

$$\lambda = \left( \frac{KL}{r} \right) \left( \frac{1}{\pi} \right) \sqrt{\frac{F_{cy}}{E}} \quad (7.10.2-3)$$

$$D_{cc} = \pi D_c \sqrt{\frac{E}{F_{cy}}} \quad (7.10.2-4)$$

$$S_2 = \frac{C_c}{\pi} \sqrt{\frac{F_{cy}}{E}} \quad (7.10.2-5)$$

where:

$\phi_s, \phi_c$  = resistance factors specified in Table 7.5.4-1

$B_c, C_c$   
 $D_c$  = parameters specified in Table 7.10.1-2 or 7.10.1-3

$k_c$  = constants specified in Table 7.10.1-1

$r$  = radius of gyration (in.)

$K$  = column effective length factor specified in Article 4.6.2.5

$F_{cy}$  = parameter specified in Table 7.4.2.1-1 (ksi)

$E$  = compressive modulus of elasticity specified in Article 7.4.2 (ksi)

$L$  = length of compression member between points of lateral supports (in.)

### 7.10.3—Compressive Resistance of Components of Columns—Outstanding Flanges and Legs

The factored compressive resistance in terms of stress shall be taken as:

- If  $\frac{b}{t} \leq S_2$ , then:

$$F_r = \phi_c \left[ B_p - 5.1 D_p \frac{b}{t} \right] \leq \phi_s \frac{F_{cy}}{k_c} \quad (7.10.3-1)$$

- If  $\frac{b}{t} \geq S_2$ , then:

$$F_r = \frac{\phi_c \pi^2 E}{\left( 5.1 \frac{b}{t} \right)^2} \quad (7.10.3-2)$$

in which:

$$S_2 = \frac{C_p}{5.1} \quad (7.10.3-3)$$

where:

$b$  = width (in.)

$t$  = thickness (in.)

$k_c$  = coefficient specified in Table 7.10.1-1

### C7.10.3

It is assumed that the strength of columns is limited by the local buckling strength of the legs and flanges. No allowance is made for the postbuckling strength in such members. Note that the formulas are in the same form as those of Eqs. 7.10.2-1 and 7.10.2-2. In Eqs. 7.10.3-1 and 7.10.3-2, the slenderness for plate buckling is assumed to be  $5.1b/t$ , where the coefficient 5.1 is the value that applies to a plate free on one edge and simply supported on the other.

Open section members that are unsymmetrical about one or both principal axes may be subject to failure by combined torsion and flexure. For single or double-angles and T-sections, an adequate factor of safety is provided against this type of failure. Other unsymmetrical, open shapes, such as channels, lipped angles, or hat shapes, should not be used as columns unless an analysis is made of the resistance to buckling by combined torsion and flexure.

$C_p, D_p$   
 $B_p$  = parameters specified in Table 7.10.1-2 or  
 7.10.1-3

$\phi_c, \phi_s$  = resistance factors specified in Table 7.5.4-1

$F_{cy}$  = parameter specified in Table 7.4.2.1-1 (ksi)

#### 7.10.4—Compressive Resistance of Components of Columns, Gross Section—Flat Plates with Both Edges Supported

##### 7.10.4.1—General

The factored compressive resistance in terms of stress shall be taken as:

- If  $\frac{b}{t} \leq S_2$ , then:

$$F_r = \phi_c \left[ B_p - 1.6D_p \frac{b}{t} \right] \leq \phi_s \frac{F_{cy}}{k_c} \quad (7.10.4.1-1)$$

- If  $\frac{b}{t} \geq S_2$ , but is less than 60 percent of the maximum column slenderness,  $kL/r$ , then:

$$F_r = \frac{\phi_c k_2 \sqrt{B_p E}}{1.6 \frac{b}{t}} \quad (7.10.4.1-2)$$

in which:

$$S_2 = \frac{k_1 B_p}{1.6 D_p} \quad (7.10.4.1-3)$$

where:

$B_p, D_p$  = parameters specified in Tables 7.10.1-2 and 7.10.1-3

$\phi_c, \phi_s$  = resistance factors specified in Table 7.5.4-1

$k_1, k_2$   
 and  $k_c$  = constants specified in Table 7.10.1-1

$F_{cy}$  = parameter from Table 7.4.2.1-1 (ksi)

$F_r$  = factored resistance (ksi)

$kL/r$  = maximum slenderness ratio of column

$b/t$  = width to thickness ratio for column flange

$E$  = compressive modulus of elasticity specified in Article 7.4.2 (ksi)

##### C7.10.4.1

The equivalent slenderness ratio is  $1.6b/t$ , the value that applies to a plate simply supported on both longitudinal edges. In this range of  $b/t$  values, the local buckling strength is essentially the same as the ultimate or “crippling” strength.

Eq. 7.10.4.1-2 is based on the crippling strength of a plate simply supported on both longitudinal edges. This strength may be appreciably greater than the local buckling strength for thin sections.

These provisions take advantage of the postbuckling strength of plate elements supported on two edges because in general such elements may buckle without causing failure of the member. However, there are cases where the reduced stiffness that accompanies local buckling of these elements may necessitate a reduction in the factored resistance determined from Article 7.10.1. Article 7.10.3 does not take advantage of postbuckling strength; therefore, no provision is needed for any additional effect of local buckling of the types of elements covered.

#### 7.10.4.2—Effect of Local Buckling of Elements on Column Strength

If the maximum  $b/t$  for the flange of a rectangular tube or formed-closed shape is greater than the value of  $S_2$  and also greater than 60 percent of the maximum slenderness ratio for the column, the factored resistance shall be taken as:

$$F_r = \frac{\phi_c \pi^2 E}{\left(\frac{kL}{r}\right)^{2/3} \left(\frac{1.6b}{t}\right)^{4/3}} \quad (7.10.4.2-1)$$

where:

- $\phi_c$  = resistance factor specified in Table 7.5.4-1
- $kL/r$  = maximum slenderness ratio of column
- $b/t$  = width to thickness ratio for column flange
- $E$  = compressive modulus of elasticity specified in Article 7.4.2 (ksi)

#### 7.10.5—Compressive Resistance of Components of Columns, Gross Section—Curved Plates Supported on Both Edges, Walls of Round, or Oval Tubes

The factored compressive resistance in terms of stress shall be taken as:

- If  $\frac{R}{t} \leq S_2$ , then:

$$F_r = \phi_c \left( B_t - D_t \sqrt{\frac{R}{t}} \right) \leq \phi_s \frac{F_{cy}}{k_c} \quad (7.10.5-1)$$

- If  $\frac{R}{t} \geq S_2$ , then:

$$F_r = \frac{\phi_c \pi^2 E}{16 \left( \frac{R}{t} \right) \left[ 1 + \sqrt{\frac{R}{1225t}} \right]^2} \quad (7.10.5-2)$$

where:

- $S_2$  =  $C_t$
- $B_t, D_t$  = parameters specified in Table 7.10.1-2 and 7.10.1-3 (ksi)
- $\phi_c, \phi_s$  = resistance factor specified in Table 7.5.4-1
- $k_c$  = values specified in Table 7.10.1-1
- $E$  = compressive modulus of elasticity specified in Article 7.4.2 (ksi)

#### C7.10.4.2

Eq. 7.10.4.2-1 applies only to those cases in which local buckling of an element precipitates overall buckling of the entire column. This equation reduces the factored resistance to account for that situation.

#### C7.10.5

Formulas are based on the local buckling strength of tubes in direct compression.

*R* = maximum midthickness radius (in.)

*t* = thickness (in.)

## 7.11=FLEXURAL MEMBERS

#### 7.11.1—Tensile Resistance of Flexural Member

### 7.11.1.1—Net Section

No reduction in the cross-section area shall be made for bolt holes in any flexural member, unless the reduction in the cross-section area, as determined in accordance with Article 7.9.4 and Article 7.9.3, exceeds 15 percent of the gross cross-section, in which case the excess over 15 percent shall be deducted.

### **7.11.1.2—Tension in Extreme Fibers of Beams, Structural Shapes Bent about Strong Axis, Rectangular Tubes**

The factored resistance in terms of stress shall be taken as the lesser of the values specified by either Eq. 7.11.1.2-1 or 7.11.1.2-2.

$$F_r = \phi_v F_{tv} \quad (7.11.1.2-1)$$

$$F_r = \phi_u \frac{F_{tu}}{k_t} \quad (7.11.1.2-2)$$

where:

$F_{ty}$  = tensile yield strength specified in Table 7.4.2.1-1 (ksi)

$F_{tu}$  = tensile strength specified in Table 7.4.2.1-1 (ksi)

$\phi_v, \phi_u$  = resistance factors specified in Table 7.5.4-1

### **7.11.1.3—Tension in Extreme Fibers of Beams, Round, or Oval Tubes**

The factored resistance in terms of stress shall be taken as the lesser of the values specified by either Eq. 7.11.1.3-1 or 7.11.1.3-2.

$$F_r = \phi_v 1.17 F_{v_r} \quad (7.11.1.3-1)$$

$$F_r = \phi_u 1.24 \frac{F_{tu}}{k_s} \quad (7.11.1.3-2)$$

C7.11.1.3

The resistance in terms of tensile stress for round and oval tubes subjected to flexure is somewhat higher than for structural shapes. Analysis and tests have demonstrated that yielding or failure of tubular beams does not occur until the moment considerably exceeds the value predicted by the flexure formula based on triangular stress distribution. The constants of 1.17 and 1.24 were developed on the basis and are analogous to shape factors. The factor  $k_t$  is provided for the tensile strength for some alloys that do not develop sufficiently high tensile properties in the presence of stress concentrations.

#### 7.11.1.4—Tension in Extreme Fibers of Beams—Shapes Bent about Weak Axis, Rectangular Bars, Plates

The factored resistance in terms of stress shall be taken as the lesser of the values specified by either Eq. 7.11.1.4-1 or 7.11.41.4-2.

$$F_r = \phi_y 1.30 F_{ty} \quad (7.11.1.4-1)$$

$$F_r = \phi_u 1.42 \frac{F_{tu}}{k_t} \quad (7.11.1.4-2)$$

#### 7.11.2—Compressive Resistance of Flexural Members

##### 7.11.2.1—Compression in Beams, Extreme Fiber, Gross Section, Single-Web Beams Bent about Strong Axis

The factored resistance in terms of stress shall be taken as:

- If  $\frac{L_b}{r_y} \leq S_2$ , then:

$$F_r = \phi_b \left( B_c - \frac{D_c L_b}{1.2 r_y} \right) \leq \phi_s F_{cy} \quad (7.11.2.1-1)$$

- If  $\frac{L_b}{r_y} \geq S_2$ , then:

$$F_r = \frac{\phi_b \pi^2 E}{\left( \frac{L_b}{1.2 r_y} \right)^2} \quad (7.11.2.1-2)$$

in which:

$$S_2 = 1.2 C_c \quad (7.11.2.1-3)$$

where:

$C_c, D_c$   
 $B_c$  = parameters specified in Table 7.10.1-3

$r_y$  = radius of gyration of the beam about axis parallel to the web (in.)

$\phi_b, \phi_s$  = resistance factors specified in Table 7.5.4-1

$L_b$  = length of beam between points at which the compression flange is supported against lateral movement, or length of cantilever beam from free end to point at which the compression flange is supported against lateral movement (in.)

#### C7.11.1.4

As in the case of round tubes, theory and tests have shown that aluminum alloy members of these shapes can undergo bending moments that are considerably higher than those predicted on the basis of triangular stress distribution.

#### C7.11.2.1

The compressive stresses in single-web structural shapes and buildup sections bent about the strong axis are based on the lateral torsional buckling strength of beams. The first formula for resistance in the inelastic stress range for beams is based on the straight line approximation to the tangent modulus buckling curve that is also used for columns. In deriving the resistance in terms of stress for beams, it was assumed that the beam is held in an upright position at the supported ends. The strengthening effect of any restraint against rotation of the flanges at the supports was neglected. The second formula is based on a conservative approximation to the elastic buckling strength of beams, with  $L_b/r_y$  replacing a more complicated function of the length and cross-section properties.

Because of the approximation, the formulas give very conservative results for certain conditions, namely for values of  $L_b/r_y$  exceeding about 50; for load distributions such that the bending moment near the center of the beam is appreciably less than the maximum bending moment in the beam; and for beams with transverse loads applied to a flange and acting away from the shear center. To compute more precise values of factored compressive resistance in terms of stress for these cases, the value of  $r_y$  may be replaced by  $r_{ye}$  given by one of the following formulas:

- For beam spans subjected to end moment only or to transverse loads applied at the neutral axis of the beam:

$$r_{ye} = \frac{k_b}{1.7} \sqrt{\frac{I_y d}{S_c}} \sqrt{1 + 0.152 \frac{J}{I_y} \left( \frac{L_b}{d} \right)^2} \quad (C7.11.2.1-1)$$

- For beams subjected to transverse loads applied on the top or bottom flange, where the load is free to move laterally with the beam if the beam should buckle:

$E$  = compressive modulus of elasticity specified in Article 7.4.2 (ksi)

The factored resistance of elastically supported flanges, including the compression flange of a hat-shaped beam loaded with the two flanges in compression, shall be determined with the following effective value of  $L_b/r_y$  substituted into Eqs. 7.11.2.1-1 and 7.11.2.1-2:

$$\left(\frac{L_b}{r_y}\right)_{\text{effective}} = 2.7 \sqrt{\frac{EA_c^2}{\beta I_{yc}}} \quad (7.11.2.1-4)$$

where:

$A_c$  = area of compression element taken as that of the compression flange plus one-third of the area of web between compression flange and neutral axis (in.<sup>2</sup>)

$\beta$  = spring constant taken as the magnitude of a transverse force applied at the compression flange to a 1.0-in. long strip of the member to cause a 1.0-in. deflection of the flange (kip/in./in.); the strip shall be supported to be stable but not cause additional restraint or distortion

$I_{yc}$  = moment of inertia of compression element about axis parallel to vertical web (in.<sup>4</sup>)

$E$  = compressive modulus of elasticity specified in Article 7.4.2 (ksi)

$$r_{ye} = \frac{k_b}{1.7} \sqrt{\frac{I_y d}{S_c} \left[ \pm 0.5 + \sqrt{1.25 + 0.152 \frac{J}{I_y} \left( \frac{L_b}{d} \right)^2} \right]} \quad (\text{C7.11.2.1-2})$$

where:

$I_y$  = moment of inertia of beam about axis parallel to web (in.<sup>4</sup>)

$S_c$  = section modulus of beam, compression side (in.<sup>3</sup>)

$J$  = torsional inertia of beam; an approximate value of  $J$  may be calculated by assuming the section to be composed of rectangles and letting  $J$  equal the sum of the terms  $bt^3/3$  for each rectangle (in.<sup>4</sup>)

$L_b$  = length of beam between points at which the compression flange is supported against lateral movement or length of cantilever beam from free end to point at which the compression flange is supported against lateral movement (in.)

$d$  = depth of beam (in.)

The plus sign in front of the term "0.5" applies if the load is on the tension flange; the minus sign applies if the load is on the compression flange.

Values of the coefficient  $k_b$  are tabulated below:

- For beams restrained against lateral displacement at both ends of span.

(1) uniform bending moment, uniform transverse load, or two equal concentrated loads equidistant from the center of the span 1.00

(2) bending moment varying uniformly from a value of  $M_1$  at one end to  $M_2$  at the other end

$M_1/M_2 = 0.5$	1.14
$M_1/M_2 = 0$	1.33
$M_1/M_2 = -0.5$	1.53
$M_1/M_2 = -1.0$	1.60
Concentrated load at center of span	1.16

- For cantilever beams

(1) concentrated load at end of span 1.13

(2) uniform transverse load 1.43

For beams that are unsymmetrical about the horizontal axis,  $r_y$ ,  $I_y$ ,  $S_c$ , and  $J$  should be determined as though both flanges were the same as the compression flange.

### 7.11.2.2—Compression in Beams, Extreme Fiber, Gross Section, Round or Oval Tubes

The factored resistance in terms of stress shall be taken as:

If  $\frac{R_b}{t} \leq S_2$ , then:

$$F_r = \phi_b \left[ B_{tb} - D_{tb} \sqrt{\frac{R_b}{t}} \right] \leq 1.17 \phi_s F_{cy} \quad (7.11.2.2-1)$$

where:

$R_b$  = midthickness radius of curvature of plates (in.)

$S_2$  =  $C_{tb}$

$C_{tb}$ ,  $B_{tb}$

$D_{tb}$  = parameters specified in Table 7.10.1-3

$\phi_b$ ,  $\phi_s$  = resistance factor specified in Table 7.5.4-1

$t$  = thickness (in.)

For  $R_b/t$  values greater than  $S_2$ , the allowable bending stress shall be determined from the relevant formula for tubes in compression as specified in Article 7.10.5.

### 7.11.2.3—Compression in Beams, Extreme Fiber, Gross Section, Solid Rectangular Beams

The factored resistance in terms of stress shall be taken as:

### C7.11.2.3

The formulas for rectangular beams are based on the lateral, torsional buckling strength of the beams.

- If  $\frac{d}{t} \sqrt{\frac{L_b}{d}} \leq S_2$ , then:

$$F_r = \phi_b \left[ B_b - 2.3 D_b \frac{d}{t} \sqrt{\frac{L_b}{d}} \right] \leq 1.3 \phi_s F_{cy} \quad (7.11.2.3-1)$$

- If  $\frac{d}{t} \sqrt{\frac{L_b}{d}} > S_2$ , then:

$$F_r = \frac{\phi_b \pi^2 E}{5.29 \left( \frac{d}{t} \right)^2 \left( \frac{L_b}{d} \right)} \quad (7.11.2.3-2)$$

in which:

$$S_2 = \frac{C_b}{2.3} \quad (7.11.2.3-3)$$

where:

$B_b, D_b$   
 $C_b$  = parameters specified in Tables 7.10.1-2  
 and 7.10.1-3 (ksi)

$\phi_b, \phi_s$  = resistance factors specified in Table 7.5.4-1

$E$  = compressive modulus of elasticity  
 specified in Article 7.4.2 (ksi)

#### 7.11.2.4—Compression in Beams, Extreme Fiber, Gross Section, Rectangular Tubes, and Box Sections

The factored resistance in terms of stress shall be taken as:

- If  $\frac{L_b S_c}{I_y} \leq S_2$ , then:

$$F_r = \phi_b \left( B_c - 1.6 D_c \sqrt{\frac{L_b S_c}{I_y}} \right) \leq \phi_s F_{cy} \quad (7.11.2.4-1)$$

- If  $\frac{L_b S_c}{I_y} \geq S_2$ , then:

$$F_r = \frac{\phi_b \pi^2 E}{2.56 \left( \frac{L_b S_c}{I_y} \right)} \quad (7.11.2.4-2)$$

in which:

$$S_2 = \left( \frac{C_c}{1.6} \right)^2 \quad (7.11.2.4-3)$$

where:

$B_c, D_c$   
 $C_c$  = parameters specified in Table 7.10.1-3

$\phi_s, \phi_b$  = resistance factors specified in Table 7.5.4-1

$E$  = compressive modulus of elasticity  
 specified in Article 7.4.2 (ksi)

#### C7.11.2.4

The formulas for box beams are based on the lateral, torsional buckling strength of the beams. In deriving these formulas, it was recognized that lateral buckling will govern the design only for relatively deep, narrow box beams and for these members the torsion constant  $J$  is roughly proportional to  $I_v$ .

### 7.11.3—Compressive Resistance of Flexural Members Limited by Plate Slenderness

#### 7.11.3.1—General

#### C7.11.3.1

Where the factored resistance in terms of stress for individual elements are determined from Articles 7.11.3.2 through 7.11.3.7, the process of determining the weighted average resistance for the beam flanges may be applied. The beam flange may be considered to consist of the flange proper plus one-sixth of the area of the web or webs.

The weighted average compressive resistance in terms of stress,  $F_{ba}$ , for a trapezoidally formed sheet beam, determined according to Article 7.10.1, may be taken as:

$$F_{ba} = \frac{F_{bf} + F_{bh} \left( \frac{h}{3b} \right)}{1 + \frac{h}{3b}} \quad (7.11.3.1-1)$$

where:

$F_{bf}$  = factored resistance in terms of stress for the flange proper; taken as  $F_r$  as specified in Article 7.10.4 (ksi)

$F_{bh}$  = factored resistance in terms of stress for webs; taken as  $F_r$  as specified in Article 7.11.3.6 or Article 7.11.3.7 (ksi)

$h$  = height of shear web as specified in Article 7.11.3.6 (in.)

$b$  = width of compression flange (in.)

Eq. 7.11.3.1-1 may also be applied to the factored resistance in terms of tensile stress in trapezoidally formed sheet beams. In regions of positive moments with load applied to concave side of the deformed beam,  $F_{ba}$  shall be taken as the weighted average factored resistance in terms of tensile stress,  $F_{bf}$  shall be taken as  $F_r$  as specified in Article 7.9.2, and  $F_{bh}$  shall be taken as  $F_r$  as specified in Article 7.11.1.4.

In regions of negative moments with load applied to convex side of the deformed beam, the factored resistance in terms of tensile stress on the tension flange of a formed sheet beam shall not exceed the compressive stress that would be allowed on the same flange if it were in compression.

This provision is required to take account of the effects of flange curling, the tendency of the tension flange to bend toward the neutral axis. It governs design only where the tension flange is wider than the compression flange.

### 7.11.3.2—Compression in Components of Beams with Component under Uniform Compression, Gross Section, Outstanding Flanges

#### 7.11.3.2.1—General

The factored resistance in terms of stress shall be taken as:

- If  $\frac{b}{t} \leq S_2$ , then:

$$F_r = \phi_c \left[ B_p - 5.1D_p \left( \frac{b}{t} \right) \right] \leq \phi_s F_{cy} \quad (7.11.3.2.1-1)$$

- If  $\frac{b}{t} \geq S_2$ , but is less than  $0.16 \frac{L_b}{r_y}$ , then:

$$F_r = \frac{\phi_c k_2 \sqrt{B_p E}}{\left( 5.1 \frac{b}{t} \right)} \quad (7.11.3.2.1-2)$$

in which:

$$S_2 = \frac{k_1 B_p}{5.1 D_p} \quad (7.11.3.2.1-3)$$

where:

$F_r$  = factored resistance in terms of compressive bending stress in beam flange (ksi)

$L_b/r_y$  = slenderness ratio for beam

$b/t$  = width to thickness ratio for beam flange

$E$  = compressive modulus of elasticity specified in Article 7.4.2 (ksi)

$B_p, D_p$  = parameters specified in Table 7.10.1-3 (ksi)

$k_1, k_2$  = constants specified in Table 7.10.1-1

$\phi_s, \phi_c$  = resistance factors specified in Table 7.5.4-1

Eqs. 7.11.3.2.1-1 and 7.11.3.2.1-2 are based on the crippling strength of an outstanding flange simply supported on one edge.

#### C7.11.3.2.1

**7.11.3.2.2—Effect of Local Buckling of Elements on Resistance**

If the value of  $b/t$  for outstanding flanges is greater than the value of  $S_2$  and also greater than  $0.16(L_b/r_y)$ , the factored resistance in terms of stress shall be taken as:

$$F_{rb} = \frac{\phi_c \pi^2 E}{\left(\frac{L_b}{1.2r_y}\right)^{\frac{2}{3}} \left(\frac{5.1b}{t}\right)^{\frac{4}{3}}} \quad (7.11.3.2.2-1)$$

**C7.11.3.2.2**

These provisions take advantage of the postbuckling strength of thin elements. They take account of the effect that the reduced stiffness due to local buckling may have on the lateral buckling strength of single-web beams. Any such effects on multiweb beams are considered to be negligible because of their high torsional stiffness.

**7.11.3.3—Compression in Components of Beams with Component under Uniform Compression, Gross Section, Flat Plates with Both Edges Supported**

The factored resistance in terms of stress shall be taken as:

- If  $\frac{b}{t} \leq S_2$ , then:

$$F_r = \phi_c \left[ B_p - 1.6D_p \left( \frac{b}{t} \right) \right] \leq \phi_s F_{cy} \quad (7.11.3.3-1)$$

- If  $\frac{b}{t} > S_2$ , then:

$$F_r = \frac{\phi_c k_2 \sqrt{B_p E}}{1.6 \frac{b}{t}} \quad (7.11.3.3-2)$$

**C7.11.3.3**

Formulae are based on the crippling strength of a plate simply supported on both edges.

in which:

$$S_2 = \frac{k_1 B_p}{1.6 D_p} \quad (7.11.3.3-3)$$

where:

$B_p, D_p$  = parameters specified in Table 7.10.1-3 (ksi)

$k_1, k_2$  = constants specified in Table 7.10.1-1

$\phi_s, \phi_c$  = resistance factors specified in Table 7.5.4-1

$E$  = compressive modulus of elasticity specified in Article 7.4.2 (ksi)

#### 7.11.3.4—Compression in Components of Beams—Curved Sections

The factored resistance in terms of stress shall be taken as:

- If  $\frac{R_b}{t} \leq S_2$ , then:

$$F_r = \phi_c \left[ B_t - D_t \sqrt{\frac{R_b}{t}} \right] \leq 1.17 \phi_s F_{cy} \quad (7.11.3.4-1)$$

- If  $\frac{R_b}{t} > S_2$ , then:

$$F_r = \frac{\phi_c \pi^2 E}{16 \left( \frac{R_b}{t} \right) \left( 1 + \sqrt{\frac{R_b}{1225t}} \right)^2} \quad (7.11.3.4-2)$$

in which:

$$S_2 = C_t \quad (7.11.3.4-3)$$

where:

$B_b, D_t$  = parameters specified in Table 7.10.1-3 (ksi)

$\phi_c, \phi_s$  = resistance factors specified in Table 7.5.4-1

$E$  = compressive modulus of elasticity specified in Article 7.4.2 (ksi)

$t$  = thickness (in.)

$R_b$  = midthickness radius (in.)

#### 7.11.3.5—Compression in Components of Beams with Component under Bending in Own Plane, Gross Section, Flat Plates with Compression Edge Free, Tension Edge Supported

The factored resistance in terms of stress shall be taken as:

- If  $\frac{b}{t} \leq S_2$ , then:

$$F_r = \phi_c \left[ B_b - 3.5 D_b \left( \frac{b}{t} \right) \right] \leq 1.3 \phi_s F_{cy} \quad (7.11.3.5-1)$$

- If  $\frac{b}{t} \geq S_2$ , then:

#### C7.11.3.4

The expressions for curved sections are taken from ASCE Structural Division Paper 6744 *Guide for the Design of Aluminum Formed Sheet Building Sheathing* (1969). They apply to curved components of beams other than tubes, the latter being covered by Article 7.11.2.2.

#### C7.11.3.5

The coefficients in the first formula for inelastic buckling strength were assumed to be the same as for rectangular beams because calculations and tests have shown that the apparent stress ( $Mc/I$ ) at which the yield strength is reached in the outer fiber of sections such as tees, angles, and channels is even higher than for rectangular beams. The equivalent slenderness ratio was assumed to be  $3.5b/t$ , which implies partial restraint against rotation at the supported edge.

The second formula is based on elastic buckling strength. This type of component is assumed to have negligible postbuckling strength.

$$F_r = \frac{\phi_c \pi^2 E}{\left(3.5 \frac{b}{t}\right)^2} \quad (7.11.3.5-2)$$

in which:

$$S_2 = \frac{C_b}{3.5} \quad (7.11.3.5-3)$$

where:

$B_b, D_b$ ,  
 $C_b$  = parameters specified in Tables 7.10.1-2  
 and 7.10.1-3 (ksi)

$\phi_c, \phi_s$  = resistance factors specified in Table 7.5.4-1  
 $E$  = compressive modulus of elasticity  
 specified in Article 7.4.2 (ksi)  
 $t$  = thickness (in.)  
 $b$  = width (in.)

### 7.11.3.6—Webs of Beams, Gross Section, Flat Plates with Both Edges Supported

The factored resistance in terms of stress shall be taken as:

- If  $\frac{h}{t} \leq S_2$ , then:

$$F_r = \phi_c \left[ B_b - 0.67 D_b \left( \frac{h}{t} \right) \right] \leq 1.3 \phi_s F_{cy} \quad (7.11.3.6-1)$$

- If  $\frac{h}{t} \geq S_2$ , then:

$$F_r = \frac{\phi_c k_2 \sqrt{B_b E}}{0.67 \left( \frac{h}{t} \right)} s \quad (7.11.3.6-2)$$

in which:

$$S_2 = \frac{k_1 B_b}{0.67 D_b} \quad (7.11.3.6-3)$$

where:

$h$  = depth of the web (in.)  
 $t$  = thickness of web (in.)  
 $B_b, D_b$  = parameters specified in Tables 7.10.1-2  
 and 7.10.1-3 (ksi)

### C7.11.3.6

The equivalent slenderness ratio used is  $0.67h/t$ , which applies to a plate in bending, which is simply supported on both edges.

The second formula is based on crippling strength.

$\phi_c, \phi_s$  = resistance factors specified in Table 7.5.4-1

$E$  = compressive modulus of elasticity specified in Article 7.4.2 (ksi)

### 7.11.3.7—Webs of Beams with Longitudinal Stiffener, Both Edges Supported

The factored resistance in terms of stress shall be taken as:

- If  $\frac{h}{t} \leq S_2$ , then:

$$F_r = \phi_c \left[ B_b - 0.29 D_b \left( \frac{h}{t} \right) \right] \leq 1.3 \phi_s F_{cy} \quad (7.11.3.7-1)$$

- If  $\frac{h}{t} \geq S_2$ , then:

$$F_r = \frac{\phi_c k_2 \sqrt{B_b E}}{0.29 \left( \frac{h}{t} \right)} \quad (7.11.3.7-2)$$

in which:

$$S_2 = \frac{k_1 B_b}{0.29 D_b} \quad (7.11.3.7-3)$$

where:

$B_b, D_b$  = parameters specified in Table 7.10.1-3 (ksi)

$k_1, k_2$  = constants specified in Table 7.10.1-1

$\phi_c, \phi_s$  = resistance factors specified in Table 7.5.4-1

$E$  = compressive modulus of elasticity specified in Article 7.4.2 (ksi)

$t$  = thickness (in.)

$h$  = depth of web (in.)

### 7.11.4—Shear Resistance

#### 7.11.4.1—Shear—Unstiffened Flat Webs

The factored resistance in terms of stress shall be taken as:

- If  $\frac{h}{t} \leq S_2$ , then:

#### C7.11.3.7

The equivalent slenderness ratio is  $0.29h/t$ , based on simple support at the edges and at the stiffener.

The second formula is based on crippling strength.

#### C7.11.4.1

Resistance shear stresses in unstiffened flat webs are determined by the calculated buckling strength for a web with partial restraint against rotation at the attachment to the flanges. The corresponding value of the equivalent slenderness ratio is  $1.25h/t$ .

$$F_r = \phi_s \left[ B_s - 1.25 D_s \left( \frac{h}{t} \right) \right] \leq \phi_s F_{sy} \quad (7.11.4.1-1)$$

- If  $\frac{h}{t} \geq S_2$ , then:

$$F_r = \frac{\phi_c \pi^2 E}{\left( 1.25 \frac{h}{t} \right)^2} \quad (7.11.4.1-2)$$

where:

$S_2$  = for 6061-T6, 6061-T651, and 6063-T6,  
 $S_2 = C_s/1.36$ ; for 5083-H321, 5086-H116,  
and 5456-H116,  $S_2 = C_s/1.58$

$B_s, D_s$  = parameters specified in Table 7.10.1-3 (ksi)

$\phi_s, \phi_c$  = resistance factors specified in Table 7.5.4-1

$E$  = compressive modulus of elasticity  
specified in Article 7.4.2 (ksi)

$t$  = thickness (in.)

$h$  = depth of web (in.)

$F_{sy}$  = parameter specified in Table 7.4.2.1-1 (ksi)

#### 7.11.4.2—Shear in Webs—Stiffened Flat Webs

#### C7.11.4.2

The factored resistance in terms of stress shall be taken as:

- If  $\frac{a_e}{t} \leq S_2$ , then:

$$F_r = 1.375 \phi_s \left[ B_s - 1.25 D_s \left( \frac{a_e}{t} \right) \right] \leq \phi_s F_{sy} \quad (7.11.4.2-1)$$

- If  $\frac{a_e}{t} \geq S_2$ , then:

$$F_r = \frac{1.375 \phi_c \pi^2 E}{\left( 1.25 \frac{a_e}{t} \right)^2} \quad (7.11.4.2-2)$$

in which:

$$a_e = \frac{a_1}{\sqrt{1 + 0.7 \left( \frac{a_1}{a_2} \right)^2}} \text{ (in.)} \quad (7.11.4.2-3)$$

Resistance stresses for stiffened flat webs are determined on the basis of assumptions similar to those used for unstiffened webs except that a factor of 1.375 is applied to the buckling strength of stiffened beam webs. Tests have demonstrated that shear stresses in such webs can considerably exceed the calculated buckling strength without appreciably affecting the behavior of the beam.

where:

$S_2$  = for 6061-T6, 6061-T651, and 6063-T6,  
 $S_2 = C_s/1.36$ ; for 5083-H321, 5086-H116,  
and 5456-H116,  $S_2 = C_s/1.58$

$B_s, D_s$  = parameters specified in Table 7.10.1-3 (ksi)

$a_e$  = equivalent width of rectangular panel (in.)

$a_1$  = shorter dimension of rectangular panel (in.)

$a_2$  = longer dimension of rectangular panel (in.)

$\phi_c, \phi_s$  = resistance factors specified in Table 7.5.4-1

$E$  = compressive modulus of elasticity  
specified in Article 7.4.2 (ksi)

$F_{sy}$  = parameter specified in Table 7.4.2.1-1 (ksi)

$t$  = thickness (in.)

## 7.11.5—Design of Stiffeners

### 7.11.5.1—Longitudinal Stiffeners for Webs

If a longitudinal stiffener is used on a beam web, it shall be located so that the distance from the toe of the compression flange to the centroid of the stiffener is 0.4 times the distance from the toe of the compression flange to the neutral axis of the beam.

The moment of inertia of a longitudinal stiffener,  $I_\ell$ , shall satisfy:

$$I_\ell \geq \frac{0.02f\alpha t^3}{E} \left[ \left( 1 + \frac{6A_\ell}{ht} \right) \left( \frac{s}{h} \right)^2 + 0.4 \right] \quad (7.11.5.1-1)$$

where:

$I_\ell$  = moment of inertia of the longitudinal stiffener about the web of the beam (in.<sup>4</sup>)

$\alpha$  = 1.0 for stiffener consisting of equal members on both sides of the web

$\alpha$  = 3.5 for stiffener consisting of member on only one side of web

$h$  = depth of web between flanges (in.)

$t$  = thickness of web (in.)

$f$  = unfactored compressive stress at toe of flange (ksi)

$s$  = distance between transverse stiffeners (in.)

$A_t$  = gross area of cross-section of longitudinal stiffener (in.<sup>2</sup>)

$E$  = compressive modulus of elasticity specified in Article 7.4.2 (ksi)

For a stiffener consisting of equal elements on both sides of the web, the moment of inertia shall be the sum of the moments of inertia about the centerline of the web.

For a stiffener consisting of a member on one side only, the moment of inertia shall be taken about the face of the web in contact with the stiffener.

#### 7.11.5.2—Transverse Stiffeners for Shear in Webs

#### C7.11.5.2

The moment of inertia of transverse web stiffeners,  $I_s$ , shall not be less than the value specified by either Eq. 7.11.5.2-1 or 7.11.5.2-2:

- If  $\frac{s}{h} \leq 0.4$ , then:

$$I_s = \frac{Vh^2}{3.07\phi E} \frac{s}{h} \quad (7.11.5.2-1)$$

- If  $\frac{s}{h} > 0.4$ , then:

$$I_s = \frac{Vh^2}{19.2\phi Es} h \quad (7.11.5.2-2)$$

where:

$I_s$  = moment of inertia of transverse stiffener (in.<sup>4</sup>)

$V$  = factored shear force on the web at location of stiffener (kip)

$h$  = depth of web (in.)

$s$  = stiffener spacing (in.)

$\phi$  = resistance factor specified in Table 7.5.4-1

Where a transverse stiffener is composed of a pair of elements, one on each side of the web, the stiffener spacing shall be taken as the clear distance between the pairs of stiffeners. When a transverse stiffener is composed of an element on only one side of the web, the stiffener spacing shall be taken as the distance between lines of connection to the web.

For a transverse stiffener composed of elements of equal size on each side of the web, the moment of inertia of the stiffener shall be taken about the centerline of the web. For a transverse stiffener composed of an element on one side only of the web, the moment of inertia of the stiffener shall be taken about the face of the web in contact with the stiffener.

In determining the moment of inertia, the depth of web shall be taken as the full depth of the web, regardless of whether a longitudinal stiffener is present.

Transverse stiffeners shall extend from flange-to-flange but need not be connected to either flange, unless the stiffener is functioning as a connection plate, in which case the provisions of Article 7.6.1.3.1 shall apply.

Unless the outer edge of a stiffener leg is continuously stiffened, its thickness shall not be less than one-twelfth the width of the leg.

If the transverse stiffener is not connected to either flange, the contract documents should require support to prevent distortion of the beam during transportation.

### 7.11.5.3—Stiffeners for Outstanding Flanges

Outstanding flanges stiffened at the free edge shall be considered as being supported on both edges if:

- The radius of gyration of the lip or bulb satisfies:

$$r_L \geq b/5, \text{ or} \quad (7.11.5.3-1)$$

- A simple rectangular lip, having the same thickness as the flange, satisfies:

$$b_L \geq b/3 \quad (7.11.5.3-2)$$

where:

$r_L$  = radius of gyration of lip or bulb about the midthickness of the flange from which it projects (in.)

$b$  = clear width of flange (in.)

$b_L$  = clear width of lip (in.)

The factored resistance of flanges meeting the foregoing requirements shall be determined in accordance with the provisions of Article 7.10.4 or Article 7.11.3.3. The factored resistance of stiffeners in terms of stress shall be determined in accordance with Article 7.10.3 or Article 7.11.3.2. The area of stiffening lips or bulbs may be included with the area of the rest of the section in determining stresses caused by the loads.

**7.11.5.4—Bearing Stiffeners****C7.11.5.4**

Where possible, vertical stiffeners shall be placed in pairs at bearings and other points of concentrated load. The stiffeners shall be connected to the web to distribute the reaction force into the web and shall be fitted to form a tight and uniform bearing against the loaded flanges, unless welds designed to transmit the full reaction or load are provided between flange and stiffener.

Only that part of a stiffener cross-section that lies outside the fillet of the flange angle shall be considered as effective in bearing. Bearing stiffeners shall not be crimped.

The moment of inertia of the bearing stiffener,  $I_b$ , shall satisfy:

$$I_b \geq I_s + \frac{Ph^2}{\phi\pi^2 E} \quad (7.11.5.4-1)$$

where:

$I_b$  = required moment of inertia of bearing stiffener (in.<sup>4</sup>)

$I_s$  = moment of inertia required to resist shear buckling (in.<sup>4</sup>)

$P$  = factored reaction force (kip)

$h$  = depth of web between flanges (in.)

$\phi$  = resistance factor specified in Table 7.5.4-1

$E$  = compressive modulus of elasticity (ksi)

In the terminology of the aluminum industry, crimping is often referred to as “joggling.”

**7.12—TORSION****7.12.1—General****C7.12.1**

Structural members shall be braced against lateral deflection and twisting in order to prevent lateral-torsional buckling prior to reaching their full in-plane capacity.

Torsion may be categorized as:

- Pure torsion, or St. Venant's torsion, and
- Warping torsion.

Pure torsion produces only shear stress, but warping torsion produces both shear stress and bending stress.

**7.12.2—Compression Members Subjected to Torsion**

Compression members shall be braced in such a way that the equivalent radius of gyration,  $r_e$ , shall be at least equal to the radius of gyration used in the column strength formula in Article 7.10.2.

### 7.12.2.1—Members with Double-Axis Symmetry

The equivalent radius of gyration,  $r_e$ , shall be taken as:

$$r_e = \left[ \frac{C}{I_p} + \frac{GJ}{EI_p} \frac{L^2}{\pi^2} \right]^{\frac{1}{2}} \quad (7.12.2.1-1)$$

where:

$G$  = shear modulus of elasticity (ksi)

$J$  = St. Venant torsional inertia specified in Articles 7.12.3.1 and 7.12.3.2 (in.<sup>4</sup>)

$C$  = warping torsion constant specified in Article 7.12.4

$I_p$  = polar moment of inertia referred to the shear center (in.<sup>4</sup>)

$L$  = distance between bracing points (in.)

### 7.12.2.2—Members with Single-Axis Symmetry

The equivalent radius of gyration,  $r_e$ , shall be taken as:

$$\frac{1}{r_e^2} = \frac{1}{2} \left( \frac{1}{r_\beta^2} + \frac{1}{r_y^2} \right) + \left[ \frac{1}{4} \left( \frac{1}{r_\beta^2} - \frac{1}{r_y^2} \right)^2 + \left( \frac{y_o}{r_\beta r_y r_p} \right)^2 \right]^{\frac{1}{2}} \quad (7.12.2.2-1)$$

where:

$r_y$  = radius of gyration for axis of symmetry (in.)

$r_p$  = polar radius of gyration about the shear center (in.)

$y_o$  = distance from the shear center of section to the center of gravity (in.)

$r_\beta$  =  $r_e$  specified in Article 7.12.2.1

## 7.12.3—St. Venant Torsion

### 7.12.3.1—Open Section

The torsional inertia,  $J$ , for an open section may be taken as:

- If  $\frac{b}{t} \geq 2$ , then:

$$J = \sum \left( \frac{1}{3} \right) b t^3 \left( 1 - 0.63 \frac{t}{b} \right) \quad (7.12.3.1-1)$$

- If  $1 \leq \left( \frac{b}{t} \right) < 2$ , then:

$$J = \sum \left[ -0.044 + 0.235 \left( \frac{b}{t} \right) - 0.05 \left( \frac{b}{t} \right)^2 \right] b t^3 \quad (7.12.3.1-2)$$

where:

$b$  = width of the rectangular plate element (in.)

$t$  = thickness of the plate (in.)

### 7.12.3.2—Box Section

The torsional inertia,  $J$ , for a box section may be taken as:

$$J = 4 \frac{A^2}{\sum \frac{b}{t}} \quad (7.12.3.2-1)$$

where:

$A$  = area enclosed by the plate of the box section (in.<sup>2</sup>)

$b$  = width of rectangular plate element (in.)

$t$  = thickness of plate (in.)

### 7.12.4—Warping Torsion

#### 7.12.4.1—Open Sections

The warping constant,  $C$ , for an open section with double-axis symmetry may be taken as:

$$C = \left( \frac{1}{4} \right) I_y h^2 \quad (7.12.4.1-1)$$

The warping constant,  $C$ , for an open section with single-axis symmetry may be taken as:

$$C = \frac{h^2 I_1 I_2}{(I_1 + I_2)} \quad (7.12.4.1-2)$$

where:

$I_y$  = moment of inertia about minor axis (in.<sup>4</sup>)

$I_1, I_2$  = moment of inertial of the upper and lower flange, respectively, about the y-axis taken as the axis of symmetry (in.<sup>4</sup>)

$h$  = depth of section taken between midthickness of flanges (in.)

#### 7.12.4.2—Box Section

#### C7.12.4.2

The warping constant,  $C$ , for a closed box section shall be taken to be equal to 0.0.

Box sections are torsionally stiff.

### 7.13—COMBINED FORCE EFFECTS

#### 7.13.1—Combined Compression and Flexure

A component subjected to axial compression and flexure due to lateral and/or eccentric loads shall satisfy Eqs. 7.13.1-1 and 7.13.1-2:

$$\frac{f_a}{F_a} + \frac{f_{2b}\delta_b + f_{2s}\delta_s}{F_b} \leq 1.0 \quad (7.13.1-1)$$

$$\frac{f_a}{F_a} + \frac{f_b}{F_b} \leq 1.0 \quad (7.13.1-2)$$

where:

$f_a$  = factored average compressive stress on cross-section (ksi)

$f_b$  = factored maximum compressive bending stress (ksi)

$F_a$  = factored resistance in terms of stress,  $F_r$ , for components subjected to compression only (ksi)

$F_b$  = factored flexural resistance in terms of stress,  $F_r$ , for components subjected to flexure only (ksi)

$\delta_b, \delta_s$  = moment magnification factors specified in Article 4.5.3.2.2b

$f_{2b}, f_{2s}$  = factored end stresses specified in Article 4.5.3.2.2b (ksi)

#### 7.13.2—Combined Shear, Compression, and Flexure

Combinations of shear, compression, and flexure in the web of a beam column or in the wall of a tube shall satisfy:

$$\frac{f_a}{F_a} + \left( \frac{f_b}{F_b} \right)^n + \left( \frac{f_s}{F_s} \right)^2 \leq 1.0 \quad (7.13.2-1)$$

where:

- $f_a$  = factored average compressive stress (ksi)
- $F_a$  = factored resistance in terms of stress,  $F_r$ , for components subjected to compression only (ksi)
- $f_b$  = maximum factored compressive bending stress (ksi)
- $F_b$  = factored flexural resistance in terms of stress,  $F_r$ , for components subjected to flexure only (ksi)
- $f_s$  = factored shear stress due to torsion and shear (ksi)
- $F_s$  = factored resistance in terms of stress,  $F_r$ , for component subjected only to torsion or shear (ksi)
- $n$  = 1.0 for curved walls or round tubular members or 2.0 for webs of rectilinear shapes and plates of buildup beams

### 7.13.3—Torsion and Shear in Tubes

Factored resistance of round or oval tubes due to torsion and/or shear shall be determined in accordance with the provisions of Article 7.11.4.1, with the ratio  $h/t$  replaced by an equivalent  $h/t$  taken as:

$$\left(\frac{h}{t}\right) \text{equiv.} = 2.9 \left(\frac{R}{t}\right)^{\frac{5}{8}} \left(\frac{L_t}{R}\right)^{\frac{1}{4}} \quad (7.13.3-1)$$

where:

- $R$  = outside radius of round tube or maximum outside radius of oval tube (in.)
- $t$  = thickness of tube (in.)
- $L_t$  = length of tube between circumferential stiffeners (in.)

### 7.13.4—Combined Compression and Flexure—Webs

Combinations of compression and flexure in the web of a beam shall satisfy:

$$\left(\frac{f_b}{F_b}\right)^{1.5} + \left(\frac{f_u}{F_a}\right)^{1.5} \leq 1 \quad (7.13.4-1)$$

where:

$f_b$  = factored maximum compressive flexural stress (ksi)

$F_b$  = factored flexural resistance in terms of stress,  $F_r$ , for components subjected to flexure only (ksi)

$f_u$  = factored axial stress (ksi)

$F_a$  = factored axial resistance in terms of stress per web for component subjected only to axial forces (ksi)

## 7.14—CONNECTIONS AND SPLICES

### 7.14.1—General

Bolted joints in aluminum shall be designed as bearing-type connections.

In proportioning aluminum fasteners, the effective diameter of rivets shall be taken as the lesser of the hole diameter or 104 percent of the nominal rivet diameter, and the effective diameter of bolts shall be taken as the nominal diameter.

All bolts shall have single self-locking nuts or double nuts and hardened washers placed under the turned elements.

Bolt threads shall be excluded from the shear planes of the contact surfaces between the connected parts. In determining whether the bolt threads are excluded from the shear planes, the thread length of bolts shall be calculated as two thread lengths greater than the specified thread length.

Rivets and bolts subjected to calculated stress and having a grip in excess of 4.5 diameters shall be increased in number by a factor of  $[1/2 + G/(9d)]$ , where  $G$  is the grip and  $d$  the nominal diameter of the rivet or bolt.

### 7.14.2—Bolted Connections

#### 7.14.2.1—Bolts and Nuts

Bolt assemblies shall be galvanized according to requirements of AASHTO M 164 ([ASTM A325](#)) or cadmium coated. The nuts shall be heavy hexagonal nuts. The grade and finish of the nuts for each type of galvanized bolt shall be as specified in Table 7.14.2.1-1:

**Table 7.14.2.1-1—Grade and Finish of Nuts**

Bolt Type	Nut, Specification Grade, and Finish
M 164	M 291
1 and 2 Galvanized	Hot-Dipped Galvanized

### C7.14.1

Aluminum fasteners are proportioned by using an “effective” diameter equal to the hole diameter, i.e., nominal diameter, plus four percent maximum, for rivets or the nominal diameter for bolts. This differentiation for aluminum rivets is based upon the need for the rivet to completely fill the hole in order to be effective in bearing.

The two thread lengths is specified as an allowance for thread run out.

#### 7.14.2.2—Holes

Hole diameter shall not exceed the nominal bolt diameter by more than 0.0625 in.

The factored resistance of slotted holes shall be taken as two-thirds of the factored bearing resistance.

Oversize holes, short-slotted holes, long-slotted holes, and enlarged holes should be avoided. If slotted holes for bolts are necessary, approval of the Engineer shall be required. Oversize or slotted holes for riveted construction shall not be permitted.

#### **7.14.2.3—Size of Fasteners**

Fasteners less than 0.1875 in. diameter shall not be used.

#### **7.14.2.4—Spacing of Fasteners**

#### **7.14.2.4.1—Minimum Pitch and Clear Distance**

### C7.14.2.4.1

The distance between centers of fasteners shall not be less than 2.5 times the diameter of the fastener. The clear distance between holes shall not be less than the bolt diameter.

The minimum distance for rivet centers is 3 times the nominal rivet diameter versus 3.5 times for steel bolts, but the minimum distance for bolt centers is 2.5 times the nominal bolt diameter (*Aluminum Association, 1994*).

#### **7.14.2.4.2—Maximum Pitch for Sealing Fasteners**

## C7.14.2.4.2

For sealing bolts, the pitch on a single line adjacent to a free edge of an outside plate or shape shall satisfy:

Pitch values for aluminum are approximately 70 percent of those for steel.

$$p \leq 3.0 + 3.0t \leq 5.0 \quad (7.14.2.4.2-1)$$

If there is a second line of fasteners uniformly staggered with those in the line adjacent to the free edge, at a gage less than  $(1.0 + 3.0t)$  therefrom, the staggered pitch,  $p$ , in two such lines, considered together shall satisfy:

$$p \leq 3.0 + 3.0t - 0.75g \leq 5.0 \quad (7.14.2.4.2-2)$$

The staggered pitch need not be less than one-half the requirement for a single line.

where:

*t* = thickness of the thinner outside plate or shape (in.)

*g* = gage between fasteners (in.)

**7.14.2.4.3—Maximum Pitch for Stitch Fasteners**

In compression members, the pitch of stitch fasteners on any single line in the direction of stress shall not exceed 8.5 $t$  in. except that, if the fasteners on adjacent lines are staggered and the gage,  $g$ , between the line under consideration and the farther adjacent line is less than 17 $t$  in., the staggered pitch in the two lines, considered together, shall satisfy:

$$p \leq 10.0t - 0.375g \leq 8.5t \quad (7.14.2.4.3-1)$$

The gage between adjacent lines of fasteners shall not exceed 17 $t$  in.

In tension members, the pitch shall not exceed twice that specified for compression members, and the gage shall not exceed that specified for compression members.

**7.14.2.4.4—Stitch Fasteners at the End of Compression Members**

In buildup members, the factored compressive resistance in the direction of stress shall not be greater than the resistance determined by treating outside sheets and shapes as columns having a length equal to the pitch of the fasteners.

**7.14.2.4.5—End and Edge Distances**

The distance from the center of any fastener to a sheared, sawed, or extruded end shall not be less than 2.0 times the hole diameter. The distance from any edge shall not exceed either 5.5 times the thickness of the thinnest outside plate or 3.5 in. The distance from the center of any fastener to a sheared, sawed, or extruded edge shall not be less than 1.5 times the hole diameter.

**7.14.2.5—Shear Resistance of Fasteners**

The shear strength of aluminum fasteners shall be determined in the same manner as specified in Article 6.13.2.7 for steel fasteners, but the value of tensile strength,  $F_{tu}$  shall be taken as specified in Table 7.14.2.5-1:

**Table 7.14.2.5-1—Values of Bolt Tensile Strength**

Alloy	$F_{tu}$ (ksi)
6061-T6	42.0
7075-T73	68.0

The shear strength of stainless steel fasteners shall be determined in the same manner as for steel fasteners, but the value of  $F_{tu}$  shall be equal to that stated for  $F_{nt}$  in the *ASCE Standard Specification for the Design of Cold-Formed Stainless Steel Structural Members*.

**C7.14.2.4.3**

In buildup members where two or more plates or shapes are in contact, stitch fasteners should be used to ensure uniform action and, in compression members, to prevent buckling.

#### 7.14.2.6—Slip-Critical Connections

Slip-critical connections shall not be used in aluminum components.

#### 7.14.2.7—Bearing Resistance at Fastener Holes

##### 7.14.2.7.1—General

The effective bearing area of a fastener shall be its effective diameter multiplied by the thickness of the metal on which it bears. In elements less than 0.375 in. thick, countersunk rivets or turned and fitted bolts shall not be assumed to carry stress. In elements 0.375 in. thick and greater, one-half the depth of countersink shall be omitted in determining the bearing area.

##### 7.14.2.7.2—Bearing Resistance at Rivet and Bolt Holes

When the ratio of edge distance to fastener diameter is not less than 2.0, the factored resistance in terms of bearing stress shall be taken as the lesser of the values given by either Eq. 7.14.2.7.2-1 or Eq. 7.14.2.7.2-2.

$$F_r = \phi_y F_{by} \quad (7.14.2.7.2-1)$$

$$F_r = \phi_u \frac{F_{bu}}{1.2} \quad (7.14.2.7.2-2)$$

where:

$F_{bu}$  = bearing strength specified in Table 7.4.2.1-1 (ksi)

$F_{by}$  = bearing yield stress specified in Table 7.4.2.1-1 (ksi)

$\phi_y, \phi_u$  = resistance factor specified in Table 7.5.4-1

For edge distance to diameter ratios smaller than 2.0, the resistance stress calculated on the basis of Eqs. 7.14.2.7.2-1 and 7.14.2.7.2-2 shall be multiplied by the ratio of the edge distance to twice the fastener diameter.

##### 7.14.2.7.3—Bearing on Flat Surfaces and Pins

The factored resistance in bearing of flat surfaces and pins shall be taken as two-thirds of that for fasteners as specified in Article 7.14.2.7.2.

#### 7.14.2.8—Tension

The resistance of high-strength bolts in direct tension shall be determined on the basis of nominal bolt area and shall be taken as independent of any initial tightening force. Any tension resulting from prying action produced by deformation of the connected parts shall be added to the direct tensile force.

The factored resistance of the bolts shall be taken as:

$$P_r = \phi_u 0.75 A_b F_{tu} \quad (7.14.2.8-1)$$

where:

$P_r$  = factored tensile resistance (kip)

$\phi_u$  = resistance factor taken from Table 7.5.4-1

$A_b$  = nominal bolt area ( $\text{in.}^2$ )

$F_{tu}$  = nominal tensile strength of a fastener as specified in Table 7.14.2.5-1 (ksi)

### 7.14.3—Block Shear or End Rupture

The provisions of Article 6.13.4 shall apply, except that the net section that includes staggered holes in the cut shall be computed in accordance with the provisions of Article 7.9.4. In Eq. 6.13.4-1, all occurrences of  $F_y$  and  $F_u$  shall be replaced with  $F_{ty}$  and  $F_{tu}$ , respectively.

### 7.14.4—Splices

#### 7.14.4.1—General

The resistance of members connected by high-strength bolts shall be determined using:

- The gross cross-section for compression members, and
- The net section specified in Articles 7.11.1.1 and 7.9.4 for tension components, flexural components, and splice material.

Bolted flange angle splices shall include two angles, one on each side of the flexural component. The provisions of Article 6.13.1 shall apply.

#### 7.14.4.2—Tension Members

For determining the net cross-section and the resistance, the provisions of Article 7.9.4 shall apply.

#### 7.14.4.3—Compression Members

The provisions of Article 6.13.6.1.3 shall apply.

#### 7.14.4.4—Flexural Members

The provisions of Articles 6.13.6.1.4b and 6.13.6.1.4c shall apply.

#### 7.14.4.5—Welding

Welded splice design and details shall conform to the requirements of the latest edition of the *ANSI/AWS Structural Welding Code—Aluminum D1.2* and the following provisions:

- Tension and compression members may be spliced by full penetration butt welds. Splice plates should be used.
- Welded field splices should be arranged to minimize overhead welding.
- In welded splices, any filler plate not less than 0.25 in. in thickness shall extend beyond the edges of the splice plate and shall be welded to the part on which it is fitted, with weld to transmit the splice plate force effects applied at the surface of the filler as an eccentric load.
- Filler plates less than 0.25 in. in thickness shall not be considered to transfer force effects. These plates shall be kept flush with the welded edges of the load-carrying part.

### 7.15—PROVISIONS FOR STRUCTURE TYPES

#### 7.15.1—Floor System

The provisions of this Article shall apply to components of aluminum superstructures other than orthotropic deck systems. The provisions of Article 9.8.4 shall apply to aluminum orthotropic deck systems.

#### 7.15.2—Lateral Bracing

Floorbeam connections shall be located so that the lateral bracing system will engage both the floorbeam and the main supporting members. Where the lateral bracing system intersects a joint formed by a floorbeam and a main longitudinal member, the lateral shall be rigidly connected to both members.

#### 7.15.3—Beam and Girder Framing

For skew bridges, end cross-frames or diaphragms shall be placed along the skew line. Where the skew angle exceeds 20°, all interior cross-frames or diaphragms shall be placed at the right angle to beams or girders.

#### 7.15.4—Trusses

##### 7.15.4.1—General

The following Articles of Section 6 shall apply:

- Article 6.14.2.1—General

##### C7.15.4.1

Chord and web truss members can be extruded in a variety of shapes due to the versatility of the extrusion process. Such shapes can take the place of shapes built up from plate and sheet.

- Article 6.14.2.2—Truss Members
- Article 6.14.2.3—Secondary Stresses
- Article 6.14.2.4—Diaphragms
- Article 6.14.2.5—Camber
- Article 6.14.2.6—Working Lines and Gravity Axes
- Article 6.14.2.8—Gusset Plates, except that if the length of the unsupported edge of a gusset plate exceeds the value of  $2.06 (E/F_{cy})^{0.5}$  times its thickness, the edge shall be stiffened.

Elements of individual truss members may be connected by welds, rivets, or bolts.

#### 7.15.4.2—Portal and Sway Bracing

The provisions of Article 6.14.2.7 shall apply with the following additions:

- Through-truss spans shall have sway bracing of not less than 5.0 ft deep at each intermediate panel point;
- Top lateral struts shall be at least as deep as the top chord;
- Deck truss spans shall have sway bracing in the plane of the end posts and at all intermediate panel points;
- The point of support shall be the inner line of fasteners or fillet welds connecting the perforated plate to the flanges;
- For plate butt welded to the flange edge of segments, the point of support may be taken as the weld wherever the ratio of the outstanding flange width to flange thickness of the extruded segment is less than 7.0;
- Unless otherwise specified, the point of support shall be the root of the flange of the segment; and
- The periphery of the perforation at all points shall have a minimum radius of 1.5 in.

#### 7.15.5—Arches

Provisions of Article 6.14.4 for steel arch structures shall apply for design of aluminum arch structures, except that plate slenderness shall comply with the provisions of Articles 7.10 and 7.11, as applicable.

## SECTION 8

# WOOD STRUCTURES

### 8.1—SCOPE

This Section specifies design requirements for structural components made of sawn lumber products, stressed wood, glued laminated timber, wood piles, and mechanical connections.

### 8.2—DEFINITIONS

*Adjusted Design Value*—Reference design value multiplied by applicable adjustment factors.

*Beams and Stringers (B&S)*—Beams and stringers are rectangular pieces that are 5.0 or more in. thick (nominal), with a depth more than 2.0 in. (nominal) greater than the thickness. B&S are graded primarily for use as beams, with loads applied to the narrow face.

*Bent*—A type of pier consisting of two or more columns or column-like components connected at their top ends by a cap, strut, or other component holding them in their correct positions.

*Bonded Reinforcement*—A reinforcing material that is continuously attached to a glulam beam through adhesive bonding.

*Bumper Lamination*—A sacrificial wood lamination continuously bonded to the outer face of reinforcement to protect the reinforcement from damage, fire, or for visual appearance. The bumper lam is an option, not a requirement.

*Cap*—A sawn lumber or glulam component placed horizontally on an abutment or pier to distribute the live load and dead load of the superstructure. Also, a metal, wood, or mastic cover to protect exposed wood end grain from wetting.

*Combination Symbol*—A product designation used by the structural glued laminated timber industry; see AITC 117-2004.

*Conventional Lamstock*—Solid sawn wood laminations with a net thickness of 2.0 in. or less, graded either visually or through mechanical means, finger-jointed and face-bonded to form a glulam per [ASTM D7199](#).

*Crib*—A structure consisting of a foundation grillage and a framework providing compartments that are filled with gravel, stones, or other material satisfactory for supporting the structure to be placed thereon.

*Decking*—A subcategory of dimension lumber, graded primarily for use with the wide face placed flatwise.

*Delamination*—Adhesive failure causing the separation of laminations.

*Diaphragm*—Blocking between two main longitudinal beams consisting of solid lumber, glued laminated timber, or steel cross bracing.

*Dimension Lumber*—Lumber with a nominal thickness of from 2.0 up to but not including 5.0 in. and having a nominal width of 2.0 in. or more.

*Dowel*—A relatively short length of round metal bar used to interconnect or attach two wood components in a manner to minimize movement and displacement.

*Development Length*—The length of the bond line along the axis of the beam required to develop the design tensile strength of the reinforcement.

*Dressed Lumber*—Lumber that has been surfaced by a planing machine on one or more sides or edges.

*Dry*—The condition of having a relatively low moisture content, i.e., not more than 19 percent for sawn lumber and 16 percent for glued laminated timber.

**E-Glass**—A low alkali (borosilicate glass) electrical grade glass fiber commonly used by the composite industry for the manufacture of FRP composites.

**Fiber-Reinforced Polymer (FRP)**—Any material consisting of at least two distinct components: reinforcing fibers and a binder matrix (a polymer). The reinforcing fibers are permitted to be either synthetic (e.g. glass), metallic, or natural (e.g. bamboo), and are permitted to be long and continuously-oriented or short and randomly oriented. The binder matrix is permitted to be either thermoplastic (e.g. polypropylene or nylon) or thermosetting (e.g. epoxy or vinyl-ester).

*Frame Bent*—A type of framed timber substructure.

*Grade*—The designation of the material quality of a manufactured piece of wood.

**Grade Mark**—The identification of lumber with symbols or lettering to certify its quality or grade.

**Grain**—The direction, size, arrangement, appearance, or quality of the fibers in wood or lumber.

**Green Wood**—A freshly sawn or undried wood. Wood that has become completely wet after immersion in water would not be considered green but may be said to be in the green condition.

**Hardwood**—Generally one of the botanical groups of trees that have broad leaves or the wood produced by such trees. The term has no reference to the actual hardness of the wood.

**Horizontally Laminated Timber**—Laminated wood in which the laminations are arranged with their wider dimension approximately perpendicular to the direction of applied transverse loads.

**Laminate**—A product made by bonding together two or more layers (laminations) of material or materials.

**Laminated Wood**—An assembly made by bonding layers of veneer or lumber with an adhesive, nails, or stressing to provide a structural continuum so that the grain of all laminations is essentially parallel.

**Laminating**—The process of bonding laminations together with adhesive, including the preparation of the laminations, preparation and spreading of adhesive, assembly of laminations in packages, application of pressure, and curing.

**Lamination**—A full width and full length layer contained in a component bonded together with adhesive. The layer itself may be composed of one or several wood pieces in width or length.

**Machine Evaluated Lumber (MEL)**—Mechanically graded lumber certified as meeting the criteria of a specific commercial grading system.

*Machine Stress Rated (MSR) Lumber*—Mechanically graded lumber certified as meeting the criteria of a specific commercial grading system.

**Mechanically Graded Lumber**—Solid sawn lumber graded by mechanical evaluation in addition to visual examination.

**Modulus of Rupture (MOR)**—The maximum stress at the extreme fiber in bending, calculated from the maximum bending moment on the basis of an assumed stress distribution.

**Moisture Content**—An indication of the amount of water contained in the wood, usually expressed as a percentage of the weight of the oven dry wood.

**NDS®—National Design Specification® for Wood Construction** by the American Forest and Paper Association

NEIMA Grading rules by Northeastern Lumber Manufacturers Association

NLGA Grading rules by National Lumber Grades Authority

**Net Size.** The size used in design to calculate the resistance of a component. Net size is close to the actual dry size.

**Nominal Size.**—As applied to timber or lumber, the size by which it is specified and sold; often differs from the actual size.

**NSLB**—Grading rules by Northern Softwood Lumber Bureau.

***Oil-Borne Preservative***—A preservative that is introduced into wood in the form of an oil-based solution.

**Plank**—A broad board, usually more than 1.0 in. thick, laid with its wide dimension horizontal and used as a bearing surface or riding surface.

***Posts and Timber (P&T)***—Posts and timbers pieces with a square or nearly square cross-section, 5.0 by 5.0 in. (nominal) and larger, with the width not more than 2.0 in. (nominal) greater than the thickness. Lumber in the P&T size classification is graded primarily for resisting axial loads.

***Preservative***—Any substance that is effective in preventing the development and action of wood-decaying fungi, borers of various kinds, and harmful insects.

***Reinforcement (for Glulam)***—Any material that is not a conventional lamstock lumber whose mean (ultimate) longitudinal unit strength exceeds 20 ksi for tension and compression, and whose mean tension and compression modulus of elasticity exceeds 3,000 ksi. Acceptable reinforcing materials include but are not restricted to: Fiber-Reinforced Polymer (FRP) plates and bars, and metallic plates and bars.

***Reference Design Value***—The allowable stress value or modulus of elasticity specified in the *NDS*<sup>®</sup>.

***Rough Sawn Lumber***—Lumber that has not been dressed but that has been sawn, edged, and trimmed.

***Sawn Lumber***—The product of a sawmill not further manufactured other than by sawing, resawing, passing lengthwise through a standard planing mill, drying, and cross-cutting to length.

***Sawn Timbers***—Lumber that is nominally 5.0 in. or more in least dimension.

***Softwood***—Generally, one of the conifers or the wood produced by such trees. The term has no reference to the actual hardness of the wood.

***SPIB***—Grading rules by Southern Pine Inspection Bureau.

***Stress Grades***—Lumber grades having assigned working stress and modulus of elasticity in accordance with accepted principles of resistance grading.

***Structural Glued Laminated Timber (glulam)***—An engineered, stress-rated product of a timber laminating plant comprised of assemblies of specially selected and prepared wood laminations securely bonded together with adhesives. The grain of all laminations is approximately parallel longitudinally. Glued laminated timber is permitted to be comprised of pieces end joined to form any length, of pieces placed or bonded edge to edge to make any width, or of pieces bent to cabled form during bonding.

***Structural Lumber***—Lumber that has been graded and assigned design values based on standardized procedures to ensure acceptable reliability.

***Tension Reinforcement***—Reinforcement placed on the tension side of a flexural member on the first glueline or on the face of the beam.

***Vertically Laminated Timber***—Laminated wood in which the laminations are arranged with their wider dimension approximately parallel to the direction of load.

***Visually Graded Lumber***—Structural lumber graded solely by visual examination.

***Waterborne Preservative***—A preservative that is introduced into wood in the form of a water-based solution.

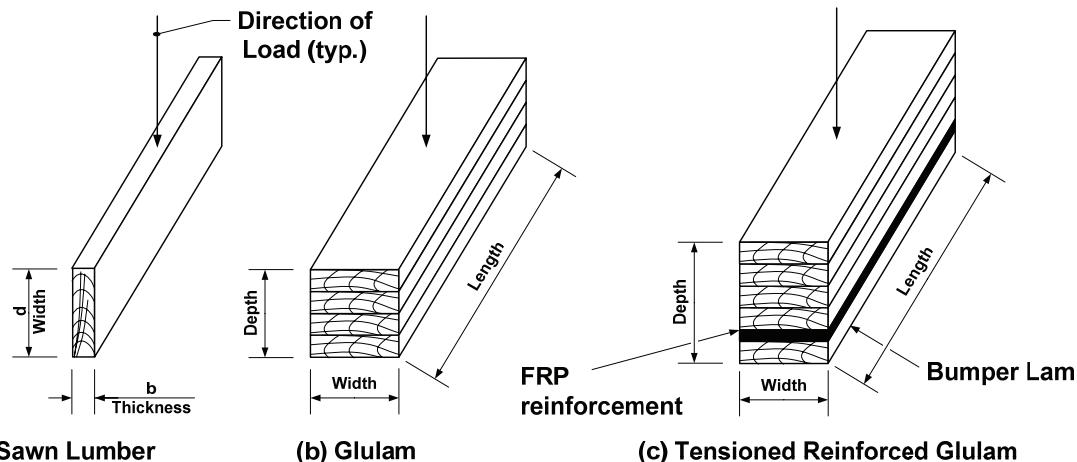

***WCLIB***—Grading rules by West Coast Lumber Inspection Bureau.

**Wet-Use**—Use conditions where the moisture content of the wood in service exceeds 16 percent for glulam and 19 percent for sawn lumber.

**WWPA**—Grading rules by Western Wood Products Association.

### 8.3—NOTATION

$A$	= parameter for beam stability (8.6.2)
$A_b$	= bearing area ( $\text{in.}^2$ ) (8.8.3)
$A_g$	= gross cross-sectional area of the component ( $\text{in.}^2$ ) (8.8.2)
$A_n$	= net cross-sectional area of the component ( $\text{in.}^2$ ) (8.9)
$a$	= coefficient (8.4.4.5)
$B$	= parameter for compression (8.8.2)
$b$	= width of the glued laminated timber component; thickness of lumber component (see Figure 8.3-1) (in.) (8.4.4.5)
$C_b$	= bearing factor (8.8.3)
$C_c$	= curvature factor (8.4.1.2)
$C_d$	= deck factor (8.4.4.8)
$C_F$	= size factor (8.4.4.4)
$C_{fu}$	= flat use factor (8.4.4.6)
$C_i$	= incising factor (8.4.4.7)
$C_{KF}$	= format conversion factor (8.4.4.2)
$C_L$	= beam stability factor (8.6.2)
$C_M$	= wet service factor (8.4.4.3)
$C_P$	= column stability factor (8.8.2)
$C_V$	= volume factor (8.4.4.5)
$C_\lambda$	= time effect factor (8.4.4.9)
$d$	= depth of the beams or stringers or width of the dimension lumber component (8.4.4.4) or glulam depth (8.4.4.5) as shown in Figure 8.3-1 (in.)
$E$	= adjusted modulus of elasticity (ksi) (8.4.4.1)
$E_o$	= reference modulus of elasticity (ksi) (8.4.1.1.4)
$F$	= adjusted design value (ksi) (8.4.4.1)
$F_b$	= adjusted design value in flexure (ksi) (8.4.4.1)
$F_{bo}$	= reference design value of wood in flexure (ksi) (8.4.1.1.4)
$F_c$	= adjusted design value of wood in compression parallel to grain (ksi) (8.4.4.1)
$F_{co}$	= reference design value of wood in compression parallel to grain (ksi) (8.4.1.1.4)
$F_{cp}$	= adjusted design value of wood in compression perpendicular to grain (ksi) (8.4.4.1)
$F_{cpo}$	= reference design value of wood in compression perpendicular to grain (ksi) (8.4.1.1.4)
$F_o$	= reference design value (ksi) (8.4.4.1)
$F_t$	= adjusted design value of wood in tension (ksi) (8.4.4.1)
$F_{to}$	= reference design value of wood in tension (ksi) (8.4.1.1.4)
$F_v$	= adjusted design value of wood in shear (ksi) (8.4.4.1)
$F_{vo}$	= reference design value of wood in shear (ksi) (8.4.1.1.4)
$G$	= specific gravity (8.4.1.1.4)
$K$	= effective buckling length factor (8.8.2)
$L$	= length (ft) (8.4.4.5)
$L_e$	= effective length (in.) (8.6.2)
$L_u$	= laterally unsupported length of the component (in.) (8.6.2)
$M_n$	= nominal flexural resistance (kip-in.) (8.6)
$M_r$	= factored flexural resistance, $\phi M_n$ (kip-in.) (8.6)
$M_u$	= factored moment (kip-in.) (8.10)
$P_n$	= nominal compression or tension resistance (kips) (8.8) (8.9)
$P_r$	= factored axial resistance (kips) (8.8) (8.9)
$P_u$	= factored axial load (kips) (8.10)
$S$	= section modulus ( $\text{in.}^3$ ) (8.6.2)
$V_n$	= nominal shear resistance (kips) (8.7)
$V_r$	= factored shear resistance, $\phi V_n$ (kips) (8.7)
$\phi$	= resistance factor (8.5.2.2)

**Figure 8.3-1—Dimensions as Defined for Various Types of Wood Products**

## 8.4—MATERIALS

#### **8.4.1—Wood Products**

Nominal resistance for wood products shall be based on specified size and conditions of use with respect to moisture content and time effect. To obtain nominal resistance and stiffness values for design, the reference design values specified in Tables 8.4.1.1.4-1, 8.4.1.1.4-2 8.4.1.1.4-3, 8.4.1.2.3-1, 8.4.1.2.3-2, 8.4.1.3.4-1, and 8.4.1.4-1 shall be adjusted for actual conditions of use in accordance with Article 8.4.4.

C8.4.1

Reference design values are based on dry-use conditions, with the wood moisture content not exceeding 19 percent for sawn lumber and 16 percent for structural glued laminated timber. Reference design values are applied to material preservatively treated in accordance with AASHTO M 133.

Reference design values have been taken from the *National Design Specification® (NDS®) for Wood Construction*. The *NDS®* publishes reference values for allowable stress design (ASD) and provides format conversion factors for use of these values with the load and resistance factor design (LRFD) methodology. To facilitate the direct use of the values developed by the wood products industry and included in the *NDS®*, the same format has been adopted for AASHTO LRFD design.

Reference design values for tension-reinforced glulams have been developed following procedures in [ASTM D7199](#) and AC 280 (ICC-ES).

#### **8.4.1.1—Sawn Lumber**

#### **8.4.1.1.1—General**

Sawn lumber shall comply with the requirements of AASHTO M 168.

When solid sawn beams and stringers are used as continuous or cantilevered beams, the grading provisions applicable to the middle third of the length shall be applied to at least the middle two-thirds of the length of pieces to be used as two-span continuous beams and to the entire length of pieces to be used over three or more spans or as cantilevered beams.

#### 8.4.1.1.2—Dimensions

Structural calculations shall be based on the actual net dimensions for the anticipated use conditions.

Dimensions stated for dressed lumber shall be the nominal dimensions. Net dimensions for dressed lumber shall be taken as 0.5 in. less than nominal, except that the net width of dimension lumber exceeding 6.0 in. shall be taken as 0.75 in. less than nominal.

For rough-sawn, full-sawn, or special sizes, the actual dimensions and moisture content used in design shall be indicated in the contract documents.

#### C8.4.1.1.2

These net dimensions depend on the type of surfacing, whether dressed, rough-sawn, or full-sawn.

The designer should specify surface requirements on the plans. Rough-sawn lumber is typically 0.125 in. larger than standard dry dressed sizes, associated with the  $F_{bo}$  value in Table 8.4.1.1.4-2 and full-sawn lumber, which is not widely used, is cut to the same dimensions as the nominal size. In both of the latter cases, thickness and width dimensions are variable, depending on the sawmill equipment. Therefore, it is impractical to use rough-sawn or full-sawn lumber in a structure that requires close dimensional tolerances.

For more accurate dimensions, surfacing can be specified on one side (S1S), two sides (S2S), one edge (S1E), two edge (S2E), combinations of sides and edges (S1S1E, S2S1E, S1S2E) or all sides (S4S).

#### 8.4.1.1.3—Moisture Content

The moisture content of dimension lumber shall not be greater than 19 percent at the time of installation.

#### 8.4.1.1.4—Reference Design Values

Reference design values for visually graded sawn lumber shall be as specified in Table 8.1.1.4-1.

Reference design values for mechanically graded dimension lumber shall be as specified in Table 8.1.1.4-2.

Unless otherwise indicated, reference design value in flexure for dimension lumber and posts and timbers shall apply to material where the load is applied to either the narrow or wide face. Reference design value in flexure for decking grades shall apply only with the load applied to the wide face.

Values for specific gravity,  $G$ , shear parallel to grain,  $F_v$ , and compression perpendicular to grain,  $F_{cpo}$ , for mechanically graded dimension lumber shall be taken as specified in Table 8.1.1.4-3. For species or species groups not given in Table 8.1.1.4-3, the  $G$ ,  $F_{vo}$ , and  $F_{cpo}$  values for visually graded lumber may be used.

Reference design values for lumber grades not given in Table 8.1.1.4-1 and Table 8.1.1.4-2 shall be obtained from the *National Design Specification® (NDS®) for Wood Construction*.

Where the  $E_o$  or  $F_{lo}$  values shown on a grade stamp differ from Table 8.1.1.4-2 values associated with the  $F_{bo}$  on the grade stamp, the values on the stamp shall be used in design, and the  $F_{co}$  value associated with the  $F_{bo}$  value in Table 8.1.1.4-2 shall be used.

For machine evaluated lumber (MEL) commercial grades M-17, M-20 and M-27,  $F_{co}$ , requires qualification and quality control shall be required.

#### C8.4.1.1.4

In calculating design values in Table 8.1.1.4-2, the natural gain in strength and stiffness that occurs as lumber dries has been taken into consideration as well as the reduction in size that occurs when unseasoned lumber shrinks. The gain in load carrying capacity due to increased strength and stiffness resulting from drying more than offsets the design effect of size reductions due to shrinkage.

Reference design values specified in Table 8.1.1.4-2 shall be taken as applicable to lumber that will be used under dry conditions. For 2.0-in. to 4.0-in. thick lumber, the dry dressed sizes shall be used regardless of the moisture content at the time of manufacture or use.

For any given bending design value,  $F_{bo}$ , the modulus of elasticity,  $E_o$ , and tension parallel to grain,  $F_{to}$ , design value may vary depending upon species, timber source or other variables. The  $E_o$  and  $F_{to}$  values included in the  $F_{bo}$ - $E_o$  grade designations in Table 8.1.1.4-2 are those usually associated with each  $F_{bo}$  level. Grade stamps may show higher or lower values if machine rating indicates the assignment is appropriate.

Higher  $G$  values may be claimed when (a) specifically assigned by the rules writing agency or (b) when qualified by test, quality controlled for  $G$  and provided for on the grade stamp. When a different  $G$  value is provided on the grade stamp, higher  $F_{vo}$  and  $F_{cpo}$  design values may be calculated in accordance with the grading rule requirements.

#### 8.4.1.2—Structural Glued Laminated Timber (Glulam)

##### 8.4.1.2.1—General

Structural glued laminated timber shall be manufactured using wet-use adhesives and shall comply with the requirements of ANSI/AITC A190.1-2002. Glued laminated timber may be manufactured from any lumber species, provided that it meets the requirements of ANSI/AITC A190.1 and is treatable with wood preservatives in accordance with the requirements of Article 8.4.3.

The contract documents shall require that each piece of glued laminated timber be distinctively marked and provided with a Certificate of Conformance by an accredited inspection and testing agency, indicating that the requirements of ANSI/AITC A190.1 have been met and that straight or slightly cambered bending members have been stamped TOP on the top at both ends so that the natural camber, if any, shall be positioned opposite to the direction of applied loads.

##### C8.4.1.2.1

When wet-use adhesives are used, the bond between the laminations, which is stronger than the wood, will be maintained under all exposure conditions. Dry-use adhesives will deteriorate under wet conditions. For bridge applications, it is not possible to ensure that all areas of the components will remain dry. ANSI/AITC A190.1-2002 requires the use of wet-use adhesives for the manufacture of structural glued laminated timber.

Industrial appearance grade, as defined in AITC 110-2001, *Standard Appearance Grades for Structural Glued Laminated Timber*, shall be used, unless otherwise specified.

Structural glued laminated timber is available in four standard appearance grades: framing, industrial, architectural, and premium. Architectural and premium grades are typically planed or sanded, and exposed irregularities are filled with a wood filler that may crack and dislodge under exterior exposure conditions. Framing grade is surfaced hit-or-miss to produce a timber with the same net width as standard lumber for concealed applications where matching the width of framing lumber is important. Framing grade is not typically used for bridge applications. In addition to the four standard appearance grades, certain manufacturers will use special surfacing techniques to achieve a desired look, such as a rough sawn look. Individual manufacturers should be contacted for details.

#### 8.4.1.2.2—Dimensions

Dimensions stated for glued laminated timber shall be taken as the actual net dimensions.

In design, structural calculations shall be based on the actual net dimensions. Net width of structural glued laminated timber shall be as specified in Table 8.4.1.2.2-1 or other dimensions as agreed upon by buyer and seller.

#### C8.4.1.2.2

Structural glued laminated timber can be manufactured to virtually any shape or size. The most efficient and economical design generally results when standard sizes are used. Acceptable manufacturing tolerances are given in ANSI/AITC A190.1-2002.

The use of standard sizes constitutes good practice and is recommended whenever possible. Nonstandard sizes should only be specified after consultation with the laminator.

Southern Pine timbers are typically manufactured from 1.375-in. thick laminations, while timbers made from Western Species and Hardwoods are commonly manufactured from 1.5-in. thick laminations. Curved members may be manufactured from thinner laminations depending on the radius of curvature. Radii of curvature of less than 27.0 ft, 6.0 in. normally require the use of thinner laminations.

**Table 8.4.1.2.2-1—Net Dimensions of Glued Laminated Timber**

Nominal Width of Laminations (in.)	Western Species Net Finished Dimension (in.)	Southern Pine Net Finished Dimension (in.)
3	2 1/8 or 2 1/2	2 1/8 or 2 1/2
4	3 1/8	3.0 or 3 1/8
6	5 1/8	5.0 or 5 1/8
8	6 3/4	6 3/4
10	8 3/4	8 1/2
12	10 3/4	10 1/2
14	12 1/4	12.0
16	14 1/4	14.0

The total glulam net depth shall be taken as the product of the thickness of the laminations and the number of laminations.

#### 8.4.1.2.3—Reference Design Values

Grade combinations for structural glued laminated timber shall be as provided in AITC 117-2004, *Standard Specifications for Structural Glued Laminated Timber of Softwood Species*, or AITC 119-96, *Standard Specifications for Structural Glued Laminated Timber of Hardwood Species*.

Reference Design Values for structural glued laminated timber shall be as specified in Tables 8.4.1.2.3-1 and 8.4.1.2.3-2:

- Table 8.4.1.2.3-1 contains design values for timbers with layups optimized to resist bending loads applied perpendicular to the wide face of the laminations (bending about the  $x$ - $x$  axis). Design values are also included, however, for axial loads and bending loads applied parallel to the wide faces of the laminations. The design values in Table 8.4.1.2.3-1 are applicable to timbers with four or more laminations.
- Table 8.4.1.2.3-2 contains design values for timbers with uniform-grade layups. These layups are intended primarily for timbers loaded axially or in bending due to loads applied parallel to the wide faces of the laminations (bending about the  $y$ - $y$  axis). Design values are also included, however, for bending due to loads applied perpendicular to the wide faces of the laminations. The design values in Table 8.4.1.2.3-2 are applicable to timbers with two or more laminations.

In Table 8.4.1.2.3-1, the tabulated design values,  $F_{bx}$ , for bending about the  $x$ - $x$  axis ( $F_{bx}$ ), require the use of special tension laminations. If these special tension laminations are omitted, value shall be multiplied by 0.75 for members greater than or equal to 15 in. in depth or by 0.85 for members less than 15 in. in depth.

In Table 8.4.1.2.3-1, the design value for shear,  $F_{vx}$ , shall be decreased by multiplying by a factor of 0.72 for nonprismatic members, notched members, and for all members subject to impact or cyclic loading. The reduced design value shall be used for design of members at connections that transfer shear by mechanical fasteners. The reduced design value shall also be used for determination of design values for radial tension and torsion. Design values,  $F_{vy}$ , shall be used for timbers with laminations made from a single piece of lumber across the width or multiple pieces that have been edge bonded. For timber manufactured from multiple-piece laminations (across width) that are not edge-bonded, in addition to other reduction, design value shall be multiplied by 0.4 for members with five, seven, or nine laminations or by 0.5 for all other members. If combination 24F-V4 contain lumber with wane, then, in addition, the design value for shear parallel to grain,  $F_{vx}$ , shall be multiplied by 0.67 if wane is allowed on both sides. If wane is limited to one side,  $F_{vx}$ , shall be multiplied by 0.83.

#### C8.4.1.2.3

The combinations in Table 8.4.1.2.3-1 are applicable to members consisting of four or more laminations and are intended primarily for members stressed in bending due to loads applied perpendicular to the wide faces of the laminations. However, design values are tabulated for loading both perpendicular and parallel to the wide faces of the laminations. The combinations and design values applicable to members loaded primarily axially or parallel to the wide faces of the laminations, are specified in Table 8.4.1.2.3-2. Design values for members of two or three laminations, are specified in Table 8.4.1.2.3-2.

In Table 8.4.1.2.3-2, for members with two or three laminations, the shear design value for transverse loads parallel to the wide faces of the laminations,  $F_{vy}$ , shall be reduced by multiplying by a factor of 0.84 or 0.95, respectively. For members with five, seven, or nine laminations, in addition,  $F_{vy}$ , shall be multiplied by 0.4 for members manufactured from multiple-piece laminations (across width) that are not edge bonded. The shear design value,  $F_{vy}$ , shall be multiplied by 0.5 for all other members manufactured from multiple-piece laminations with unbonded edge joints.

In Table 8.4.1.2.3-2, the design value for shear,  $F_{vx}$ , shall be decreased by multiplying by a factor of 0.72 for nonprismatic members, notched members, and for all members subject to impact or cyclic loading. The reduced design value shall be used for design of members at connections that transfer shear by mechanical fasteners. The reduced design value shall also be used for determination of design values for radial tension and torsion.

In Table 8.4.1.2.3-2, the tabulated design values shall apply to timbers without special tension laminations. If special tension laminations are used, for members to 15 in. deep the design value for bending,  $F_{bx}$ , may be increased by multiplying by 1.18. For members greater than 15 in. deep and without special tension laminations, the bending design value,  $F_{bx}$ , shall be reduced by multiplying by a factor of 0.88.

Reference design values for combinations not given in Table 8.4.1.2.3-1 or Table 8.4.1.2.3-2 shall be obtained from AITC 117-2004.

### 8.4.1.3—Tension-Reinforced Glulams

#### 8.4.1.3.1—General

Tension-reinforced glulams shall incorporate a continuous reinforcement material placed on the tension side of a flexural member to increase its flexural bending strength and stiffness. Reinforcement may be any material that is not a conventional lamstock whose mean longitudinal unit strength exceeds 20 ksi for tension and compression mean ultimate strength, and whose mean tension and compression modulus of elasticity exceeds 3,000 ksi, when placed into a glulam timber. Acceptable reinforcing materials include but are not restricted to: Fiber-Reinforced Polymer (FRP) plates and bars using E-glass fibers (GFRP) or carbon fibers (CFRP), and metallic plates and bars.

The reinforced ratio,  $\rho$ , shall be determined as the cross-sectional area of tension reinforcement divided by cross-sectional area of beam above the center of gravity of tension reinforcement, expressed in percent. Typical reinforcement ratios and modulus of elasticity values for various types of reinforcement given in Table 8.4.1.3.1-1 shall apply.

**Table 8.4.1.3.1-1—Typical Reinforcement Ratios**

	Reinforcement Material			
	E-Glass FRP	Aramid FRP	Carbon FRP	Steel Plate
MOE (ksi)	6,000	10,000	20,000	30,000
Min. $\rho$ %	1	0.6	0.3	0.2
Typical $\rho$ %	2	1.2	0.6	0.4
Max. $\rho$ %	3	1.8	0.9	0.6

Tension-reinforced glued laminated timber shall be manufactured using wet-use adhesives in accordance with applicable provisions of ANSI/AITC 190.1, and shall comply with the requirements listed in Article 8.4.1.2, except as described in detail in [ASTM D7199](#). The additional requirements cited in [ASTM D7199](#) to be investigated shall include bond strength and durability requirements for the tension reinforcement, preservative treatment, volume factor, and fatigue considerations.

#### 8.4.1.3.2—Dimensions

Dimensions stated for tension-reinforced glued laminated timber shall be taken as the actual net dimensions.

In design, structural calculations shall be based on the actual net dimensions. Net width of tension-reinforced structural glued laminated timber shall be as specified in Table 8.4.1.2.2-1 or other dimensions as agreed upon by buyer and seller. The total reinforced glulam net depth shall be the sum of the thicknesses of all laminations including the thickness of the tension reinforcement lamination(s). The gross section properties shall be calculated using the net depth and the net width.

#### C8.4.1.3.1

The determination of reinforcement ratio,  $\rho$ , is analogous to that used for reinforced concrete.

The scope of [ASTM D7199](#) pertains to the analysis of FRP-glulams in bending. The addition of FRP reinforcement in the tension region of the glulam does not require new test or analytical methods to determine the secondary design properties (shear, compression perpendicular to grain, tension parallel to grain, compression parallel to grain, etc.). These properties are determined for glulam layups following [ASTM D3737](#).

Tension-reinforced glulam beams subject to axial compression loads are outside the scope of this Specification. This Specification does not cover unbonded reinforcement (i.e. material not continuously bonded to the beam), prestressed reinforcement (i.e. material pretensioned before being bonded or anchored to the beam), nor shear reinforcement (i.e. material intended to increase the shear strength of the beam).

[ASTM D7199](#) also provides a mechanics-based approach for predicting the mechanical properties of tension-reinforced glulams, and may be used by engineers who have applications with unique reinforcement requirements. [ASTM D7199](#) addresses methods to obtain bending properties parallel to grain about the  $x$ - $x$  axis ( $MOR_{5\%}$  and  $MOE$ ) for horizontally-laminated reinforced glulam beams. Secondary properties such as bending about the  $y$ - $y$  axis ( $F_{by-y}$ ), shear parallel to grain ( $F_v$ ), tension parallel to grain ( $F_t$ ), compression parallel to grain ( $F_c$ ), and compression perpendicular to grain ( $F_{c\perp}$ ) are determined following methods described in [ASTM D3737](#) or testing according to other applicable methods such as [ASTM D198](#) or [ASTM D143](#).

#### 8.4.1.3.3—Fatigue

Except as noted herein, tension reinforcement shall extend the full length of the beam or girder and be confined by the supports.

For E-glass FRP reinforcement produced using the pultrusion process, beams which satisfy the requirements for design for static loads specified herein may be considered to have adequate fatigue design capacity. For reinforcements other than pultruded E-glass reinforcements, coupon level fatigue testing of the reinforcing material per [ASTM D3479](#) or a similar procedure shall be required to develop the strength-load cycle relationship for the reinforcing material. A minimum of three representative FRP samples shall be tested to establish the strength-load cycle relationship. This strength-load cycle relationship shall be the basis for checking fatigue capacity of the FRP under specific end-use environment.

Full-scale fatigue testing shall be required where partial-length reinforcement is used to evaluate the effectiveness of reinforcement end-confinement detail. The reinforcement termination for partial-length FRP reinforcement shall be confined over the length at least equal to the width of the reinforcing material. Unconfined, partial-length reinforcement shall not be permitted in bridge applications where fatigue loading exists.

Full-scale fatigue testing shall be required on FRP-glulam beams where the allowable stress is more than 75 percent greater than conventional glulam ( $F_b > 4000$  psi).

Where fatigue is a design consideration, the reinforcement used shall not increase the  $MOR_{5\%}$  of the beam by more than 75 percent relative to the strength of the unreinforced beam.

#### C8.4.1.3.3

The research that was performed utilized confinement achieved by end-bearing support. Confinement proposed by alternative methods may require full-scale testing.

Under the specified conditions, testing has shown that the fatigue resistance of tension-reinforced glulam beams is similar to that of conventional glulam beams. These tests have included both fatigue and hygrothermal cyclic tests (Davids et al., 2005 and 2008).

For pultruded E-glass FRP reinforcement, full-scale tension-reinforced glulam beam flexural fatigue tests, where the reinforcement extends the full-length of the beam, have shown that the reinforced beams properly designed for static loads will have fatigue design capacity in excess of two million constant-amplitude sinusoidal cycles. Each of these cycles applied an extreme fiber stress range starting from the dead load bending stress to a bending stress equivalent to the full allowable design stress. Under these conditions, no degradation in bending strength or stiffness has been observed.

Full-scale fatigue testing has been performed on FRP-reinforced glulam beams, considering both full-length and partial-length reinforced glulams. These tests were conducted for tension-reinforced beams where the allowable design stresses were up to 75 percent greater than the conventional unreinforced glulam. This testing has shown that premature failure due to fatigue in FRP-glulams is not a concern if (1) the FRP reinforcement has been fatigue-tested at the coupon level and (2) the FRP tension reinforcement runs for the full length of the glulam over the supports. For partial-length reinforcement (where the FRP is terminated before the supports) and for FRP-glulams where the allowable stress is more than 75 percent greater than conventional glulam ( $F_b > 4000$  psi), full-scale fatigue testing is required. Guidance on performing such tests can be found in Davids et al. (2005 and 2008). Fatigue tests where  $MOR_{5\%}$  has been increased by more than 75 percent, flexural compression and shear failures have been observed in addition to flexural tension failures.

FRP coupon fatigue design data should be available from reinforced beam manufacturers or FRP suppliers. The vast majority of applications will not require full-scale fatigue testing of beams.

#### 8.4.1.3.4—Reference Design Values for Tension-Reinforced Glulams

Reference design values for tension-reinforced glulams shall be taken as specified in Table 8.4.1.3.4-1 for beams with no bumper-lams. For the beam lay-ups given in Table 8.4.1.3.4-1, the volume factor shall be taken equal to one. The values are for dry use, with adjustment factors given in Article 8.4.4.3 and shall be used in the same manner as conventional glulam design values except as specified in Article 8.4.1.3. These design values shall be used with the overall gross section properties of the beam, including the reinforcement.

#### C8.4.1.3.4

Axial compression is outside the scope of this Specification. For tension-reinforced glulam subjected to axial compression, [ASTM D3737](#) provides a method to account for the Neutral Axis (NA) change in unbalanced layups. FRP stiffness and shift in the neutral axis shall be accounted for when developing axial compression design values. Bending properties about the y-y axis may be conservatively taken as those of the wood-portion of the beam, neglecting the reinforcement.

Analysis has shown that with the level of FRP extreme fiber tension reinforcement typically envisioned (up to three percent GFRP or one percent CFRP), the maximum shear stress at the reinforced beam neutral axis is very similar to that of an unreinforced rectangular section. In addition, under the same conditions, the shear stress at the FRP-wood interface is always significantly smaller than the shear stress at the reinforced beam neutral axis.

**Table 8.4.1.3.4-1—Reference Design Values for Tension-Reinforced Structural Glued Laminated Douglas Fir Combinations (ksi)<sup>1</sup>**

Combination Symbol	Species (Outer/Core)	Bending about $x$ - $x$ Axis					
		Extreme Fiber in Bending		Compression Perpendicular to Grain		Shear	Modulus of Elasticity $E_{xo} \times 10^3$
		Tension Zone Stressed in Tension $F_{bxo+}$	Compression Zone Stressed in Tension $F_{bxo-}$	Tension Face $F_{cpo}$	Compression Face $F_{cpo}$		
30F-1.9E							
30F-V1R	DF/DF	3.000	1.900	0.56	0.56	0.265	1.9
30F-2.0E							
30F-V4R	DF/DF	3.000	1.900	0.56	0.56	0.265	2.0
30F-2.1E							
30F-V7R	DF/DF	3.000	2.100	0.56	0.56	0.265	2.1
32F-2.1E							
32F-V1R	DF/DF	3.200	2.100	0.56	0.56	0.265	2.2
34F-2.2E							
34F-V1R	DF/DF	3.400	2.100	0.56	0.56	0.265	2.2

<sup>1</sup> Species other than Douglas Fir may be used if evaluated in accordance with [ASTM D7199](#).

#### 8.4.1.3.5—Volume Effect

Volume factors for the tension-reinforced glulams listed in Table 8.4.1.3.4-1 shall be taken equal to one except where the unreinforced compression zone is stressed in tension. In this latter case, the volume factor used in conventional glulams shall apply for the determination of this value.

#### C8.4.1.3.5

The addition of tension reinforcement diminishes the volume effect in glulams, and with enough reinforcement in tension, the volume effect disappears (Lindyberg, 2000). The tension reinforcement that is necessary to eliminate the volume effect varies with the wood species and grade, as well as the type of reinforcement used (e.g. E-glass, carbon, or Aramid FRP). For example, western species glulam reinforced with E-glass FRP in tension, approximately 1.5–3 percent FRP by volume will eliminate the volume effect (Lindyberg, 2000). For the particular glulams listed in Table 8.4.1.3.4-1, the E-glass tension reinforcement ratio is over three percent, and the corresponding volume factor is equal to one. If the tension reinforcement ratio is reduced the actual volume factor is a function of the reinforcement ratio and the reinforcement longitudinal stiffness. A numerical model that predicts the volume factor for reinforced glulams for any layup and type of reinforcement is available (Lindyberg, 2000).

**8.4.1.3.6—Preservative Treatment**

Designers shall specify that the effect of preservative treatment on the properties of the FRP reinforcement and on the strength and durability of the FRP-wood bond shall be evaluated as described in [ASTM D7199](#). Preservative treatment shall be applied after bonding of the reinforcement. GFRP reinforced beams shall not be post-treated with CCA preservatives.

**8.4.1.4—Piles**

Wood piles shall comply with the requirements of AASHTO M 168.

Reference design values for round wood piles shall be as specified in Table 8.4.1.4-1.

**Table 8.4.1.4-1—Reference Design Values for Piles, ksi**

Species	$F_{co}$	$F_{bo}$	$F_{cpo}$	$F_{vo}$	$E_o$
Pacific Coast Douglas-Fir <sup>1</sup>	1.25	2.45	0.23	0.115	1500
Red Oak <sup>2</sup>	1.10	2.45	0.35	0.135	1250
Red Pine <sup>3</sup>	0.90	1.90	1.55	0.085	1280
Southern Pine <sup>4</sup>	1.20	2.40	0.25	0.11	1500

<sup>1</sup> For connection design, use Douglas Fir-Larch reference design values.

<sup>2</sup> Red Oak reference strengths apply to Northern and Southern Red Oak.

<sup>3</sup> Red Pine reference strengths apply to Red Pine grown in the U.S. For connection design, use Northern Pine reference design values.

<sup>4</sup> Southern Pine reference strengths apply to Loblolly, Longleaf, Shortleaf, and Slash Pine.

**C8.4.1.3.6**

CCA preservative has been shown to cause severe cracking in the E-glass reinforcement.

**C8.4.1.4**

The reference design values for wood piles are based on wet-use conditions.

**8.4.2—Metal Fasteners and Hardware****8.4.2.1—General**

Structural metal, including shapes, plates, bars, and welded assemblies, shall comply with the applicable material requirements of Section 6.

**8.4.2.2—Minimum Requirements****8.4.2.2.1—Fasteners**

Bolts and lag screws shall comply with the dimensional and material quality requirements of ANSI/ASME B18.2.1, *Square and Hex Bolts and Screws—Inch Series*. Strengths for low-carbon steel bolts, Grade 1 through Grade 8, shall be as specified in Society of Automotive Engineers Specification SAE-429, *Mechanical and Material Requirements for Externally Threaded Fasteners*. Bolt and lag screw grades not given in SAE-429 shall have a minimum tensile yield strength of 33.0 ksi.

**8.4.2.2.2—Prestressing Bars**

Prestressing bars shall comply with the requirements of AASHTO M 275/M 275 ([ASTM A722/A722M](#)) and the applicable provisions of Section 5.

#### 8.4.2.2.3—*Split Ring Connectors*

Split ring connectors shall be manufactured from hot-rolled carbon steel complying with the requirements of Society of Automotive Engineers Specification SAE-1010. Each circular ring shall be cut through in one place in its circumference to form a tongue and slot.

#### 8.4.2.2.4—*Shear Plate Connectors*

Shear plate connectors shall be manufactured from pressed steel, light gage steel, or malleable iron. Pressed steel connectors shall be manufactured from hot-rolled carbon steel meeting Society of Automotive Engineers Specification SAE-1010. Malleable iron connectors shall be manufactured in accordance with [ASTM A47](#), Grade 32510.

Each shear plate shall be a circle with a flange around the edge, extending at right angles to the plate face from one face only.

#### 8.4.2.2.5—*Nails and Spikes*

Nails and spikes shall be manufactured from common steel wire or high-carbon steel wire that is heat-treated and tempered. When used in withdrawal-type connections, the shank of the nail or spike shall be annularly or helically threaded.

#### 8.4.2.2.6—*Drift Pins and Bolts*

Drift pins and drift bolts shall have a minimum flexural yield strength of 30.0 ksi.

#### 8.4.2.2.7—*Spike Grids*

Spike grids shall conform to the requirements of [ASTM A47](#), Grade 32510, for malleable iron casting.

#### 8.4.2.2.8—*Toothed Metal Plate Connectors*

Metal plate connectors shall be manufactured from galvanized sheet steel that complies with the requirements of [ASTM A653](#), Grade A, or better, with the following minimum mechanical properties:

Yield Point .....	33.0 ksi
Ultimate Strength .....	45.0 ksi
Elongation in 2.0 in. ....	20 percent

### 8.4.2.3—Corrosion Protection

#### 8.4.2.3.1—Metallic Coating

Except as permitted by this Section, all steel hardware for wood components shall be galvanized in accordance with AASHTO M 232/M 232 ([ASTM A153/A153M](#)) or cadmium plated in accordance with AASHTO M 299 ([ASTM B696](#)).

Except as otherwise permitted, all steel components, timber connectors, and castings other than malleable iron shall be galvanized in accordance with AASHTO M 111/M 111 ([ASTM A123/A123M](#)).

#### 8.4.2.3.2—Alternative Coating

Alternative corrosion protection coatings may be used when the demonstrated performance of the coating is sufficient to provide adequate protection for the intended exposure condition during the design life of the bridge. When epoxy coatings are used, minimum coating requirements shall comply with AASHTO M 284/M 284.

Heat-treated alloy components and fastenings shall be protected by an approved alternative protective treatment that does not adversely affect the mechanical properties of the material.

### 8.4.3—Preservative Treatment

#### 8.4.3.1—Requirement for Treatment

All wood used for permanent applications shall be pressure impregnated with wood preservative in accordance with the requirements of AASHTO M 133.

Insofar as is practicable, all wood components should be designed and detailed to be cut, drilled, and otherwise fabricated prior to pressure treatment with wood preservatives. When cutting, boring, or other fabrication is necessary after preservative treatment, exposed, untreated wood shall be specified to be treated in accordance with the requirements of AASHTO M 133.

#### 8.4.3.2—Treatment Chemicals

Unless otherwise approved, all structural components that are not subject to direct pedestrian contact shall be treated with oil-borne preservatives. Pedestrian railings and nonstructural components that are subject to direct pedestrian contact shall be treated with water-borne preservatives or oil-borne preservatives in light petroleum solvent.

#### C8.4.2.3.1

Galvanized nuts should be retapped to allow for the increased diameter of the bolt due to galvanizing.

Protection for the high-strength bars used in stress-laminated decks should be clearly specified. Standard hot-dip galvanizing can adversely affect the properties of high-strength post-tensioning materials. A lower temperature galvanizing is possible with some high-strength bars. The manufacturer of the bars should be consulted on this issue.

#### C8.4.3.2

The oil-borne preservative treatments have proven to provide adequate protection against wood attacking organisms. In addition, the oil provides a water repellent coating that reduces surface effects caused by cyclic moisture conditions. Water-borne preservative treatments do not provide the water repellency of the oil-borne treatment, and components frequently split and check, leading to poor field performance and reduced service life.

Direct pedestrian contact is considered to be contact that can be made while the pedestrian is situated anywhere in the access route provided for pedestrian traffic.

Treating of glued laminated timbers with water-borne preservatives after gluing is not recommended. Use of water-borne treatments for glued laminated timber after gluing may result in excessive warping, checking, or splitting of the components due to post-treatment re-drying.

#### **8.4.3.3—Inspection and Marking**

Preservative treated wood shall be tested and inspected in accordance with the requirements of AASHTO M 133. Where size permits, each piece of treated wood that meets treatment requirements shall be legibly stamped, branded, or tagged to indicate the name of the treater and the specification symbol or specification requirements to which the treatment conforms.

When requested, a certification indicating test results and the identification of the inspection agency shall be provided.

#### **8.4.3.4—Fire Retardant Treatment**

Fire retardant treatments shall not be applied unless it is demonstrated that they are compatible with the preservative treatment used, and the usable resistance and stiffness are reduced as recommended by the product manufacturer and applicator.

#### **C8.4.3.4**

Use of fire retardant treatments is not recommended because the large sizes of timber components typically used in bridge construction have inherent fire resistance characteristics. The pressure impregnation of wood products with fire retardant chemicals is known to cause certain resistance and stiffness losses in the wood. These resistance and stiffness losses vary with specific resistance characteristic, i.e., bending resistance, tension parallel to grain resistance, etc., treatment process, wood species and type of wood product, i.e., solid sawn, glued laminated, or other.

#### **8.4.4—Adjustment Factors for Reference Design Values**

##### **8.4.4.1—General**

Adjusted design values shall be obtained by adjusting reference design values by applicable adjustment factors in accordance with the following equations:

$$F_b = F_{bo} C_{KF} C_M (C_F \text{ or } C_v) C_{fu} C_i C_d C_\lambda \quad (8.4.4.1-1)$$

$$F_v = F_{vo} C_{KF} C_M C_i C_\lambda \quad (8.4.4.1-2)$$

$$F_t = F_{to} C_{KF} C_M C_F C_i C_\lambda \quad (8.4.4.1-3)$$

$$F_c = F_{co} C_{KF} C_M C_F C_i C_\lambda \quad (8.4.4.1-4)$$

$$F_{cp} = F_{cpo} C_{KF} C_M C_i C_\lambda \quad (8.4.4.1-5)$$

$$E = E_o C_M C_i \quad (8.4.4.1-6)$$

where:

$F$  = applicable adjusted design values  $F_b$ ,  $F_v$ ,  $F_t$ ,  $F_c$ , or  $F_{cp}$  (ksi)

$F_o$  = reference design values  $F_{bo}$ ,  $F_{vo}$ ,  $F_{to}$ ,  $F_{co}$ , or  $F_{cpo}$  specified in Article 8.4 (ksi)

$E$  = adjusted modulus of elasticity (ksi)

$E_o$  = reference modulus of elasticity specified in Article 8.4. (ksi)

$C_{KF}$  = format conversion factor specified in Article 8.4.4.2

$C_M$  = wet service factor specified in Article 8.4.4.3

$C_F$  = size factor for visually-graded dimension lumber and sawn timbers specified in Article 8.4.4.4

$C_V$  = volume factor for structural glued laminated timber specified in Article 8.4.4.5

$C_{fu}$  = flat-use factor specified in Article 8.4.4.6

$C_i$  = incising factor specified in Article 8.4.4.7

$C_d$  = deck factor specified in Article 8.4.4.8

$C_\lambda$  = time effect factor specified in Article 8.4.4.9

#### 8.4.4.2—Format Conversion Factor, $C_{KF}$

The reference design values in Tables 8.4.1.1.4-1, 8.4.1.1.4-2, 8.4.1.1.4-3, 8.4.1.2.3-1, 8.4.1.2.3-2, 8.4.1.3.4-1, and 8.4.1.4-1 and reference design values specified in the *NDS*<sup>®</sup> shall be multiplied by a format conversion factor,  $C_{KF}$ , for use with load and resistance factor design (LRFD).  $C_{KF} = 2.5/\phi$ , except for compression perpendicular to grain which shall be obtained by multiplying the allowable stress by a format conversion factor of  $C_{KF} = 2.1/\phi$ .

#### C8.4.4.2

The conversion factors were derived so that LRFD design will result in same size member as the allowable stress design (ASD) specified in *NDS*<sup>®</sup>. For example, a rectangular component in flexure has to satisfy:

$$1.25 M_{DL} + 1.75 M_{LL} \leq \phi S F_{bo} C_{KF} C_M (C_F \text{ or } C_v) C_{fu} C_i C_d C_\lambda C_L \quad (\text{C8.4.4.2-1})$$

or:

$$(1.25 M_{DL} + 1.75 M_{LL}) / (\phi C_{KF} C_\lambda) \leq S F_{bo} C_M (C_F \text{ or } C_v) C_{fu} C_i C_d C_L \quad (\text{C8.4.4.2-2})$$

where:

$M_{DL}$  = moment due to dead load

$M_{LL}$  = moment due to live load

On the other hand, the allowable stress design (ASD) has to satisfy:

$$M_{DL} + M_{LL} \leq S F_{bo} C_M (C_F \text{ or } C_v) C_{fu} C_i C_d C_D C_L \text{ or} \\ (M_{DL} + M_{LL}) / (C_D) \leq S F_{bo} C_M (C_F \text{ or } C_v) C_{fu} C_i C_d C_L \quad (\text{C8.4.4.2-3})$$

Therefore:

$$(1.25 M_{DL} + 1.75 M_{LL}) / (\phi C_{KF} C_\lambda) = (M_{DL} + M_{LL}) / (C_D) \quad (\text{C8.4.4.2-4})$$

$$C_{KF} = [(1.25 M_{DL} + 1.75 M_{LL})(C_D)] / [(M_{DL} + M_{LL})(\phi C_\lambda)] \quad (\text{C8.4.4.2-5})$$

The format conversion factor is calculated assuming the ratio of  $M_{DL}$  and  $M_{LL}$  is 1:10,  $\phi = 0.85$ ,  $C_\lambda = 0.8$ , and  $C_D = 1.15$ .

#### 8.4.4.3—Wet Service Factor, $C_M$

The reference design values specified in Tables 8.4.1.1.4-1, 8.4.1.1.4-2, 8.4.1.1.4-3, 8.4.1.2.3-1, 8.4.1.2.3-2, 8.4.1.3.4-1, and 8.4.1.4-1 are for dry use conditions and shall be adjusted for moisture content using the wet service factor,  $C_M$ , specified below:

- For sawn lumber with an in-service moisture content of 19 percent or less,  $C_M$  shall be taken as 1.0.
- For glued laminated timber with an in-service moisture content of 16 percent or less,  $C_M$  shall be taken as 1.0.
- Otherwise,  $C_M$  shall be taken as specified in Tables 8.4.4.3-1 for sawn lumber and Table 8.4.4.3-2 for reinforced and unreinforced glued laminated timber, respectively.

Reference design values for Southern Pine and Mixed Southern Pine sawn timbers 5 in.  $\times$  5 in. and larger shall be taken to apply to wet or dry use.

The wet service factors for reinforced and unreinforced glued laminated timber shall be the same.

#### C8.4.4.3

An analysis of in-service moisture content should be based on regional, geographic, and climatological conditions. In the absence of such analysis, wet-use conditions should be assumed.

Reduction for wet-use is not required for Southern Pine and Mixed Southern Pine sawn timbers 5 in.  $\times$  5 in. and larger.

**Table 8.4.4.3-1—Wet Service Factor for Sawn Lumber,  $C_M$**

Nominal Thickness	$F_{bo}C_F \leq 1.15$ ksi	ksi	$F_{to}$	$F_{co}C_F \leq 0.75$ ksi	ksi	$F_{vo}$	$F_{cpo}$	$E_o$
$\leq 4$ in.	1.00	0.85	1.00	1.00	0.80	0.97	0.67	0.90
>4.0 in.	1.00	1.00	1.00	0.91	0.91	1.00	0.67	1.00

**Table 8.4.4.3-2—Wet Service Factor for Glued Laminated Timber and Tension-Reinforced Glued Laminated Timber,  $C_M$**

$F_{bo}$	$F_{vo}$	$F_{to}$	$F_{co}$	$F_{cpo}$	$E_o$
0.80	0.875	0.80	0.73	0.53	0.833

#### 8.4.4.4—Size Factor, $C_F$ , for Sawn Lumber

The size factor,  $C_F$ , shall be 1.0 unless specified otherwise herein.

For visually-graded dimension lumber of all species except Southern Pine and Mixed Southern Pine,  $C_F$  shall be as specified in Table 8.4.4.4-1.

Reference design values for Southern Pine and Mixed Southern Pine dimension lumber have been size-adjusted; no further adjustment for size shall be applied.

For Southern Pine and Mixed Southern Pine dimension lumber wider than 12.0 in., the tabulated bending, compression, and tension parallel to grain design values, for the 12.0 in. depth, shall be multiplied by the size factor,  $C_F = 0.9$ .

#### C8.4.4.4

$C_F$  does not apply to mechanically-graded lumber (MSR, MEL) or to structural glued laminated timber.

Tabulated design values for visually-graded lumber of Southern Pine and Mixed Southern Pine species groups have already been adjusted for size. Further adjustment by the size factor is not permitted.

**Table 8.4.4.4-1—Size Effect Factor,  $C_F$ , for Sawn Dimension Lumber**

Grade	Width (in.)	$F_{bo}$	$F_{lo}$	$F_{co}$	All Other Properties
		Thickness			
		2.0 in. and 3.0 in.	4.0 in.	All	All
		Structural Light Framing: 2.0 in × 2.0 in. through 4.0 in. × 4.0 in. Structural Joists and Planks: 2.0 in × 5.0 in. through 4.0 in. × 16.0 in.			
Sel. Str.	≤4	1.5	1.54	1.5	1.15
No. 1	5	1.4	1.4	1.4	1.1
No. 2	6	1.3	1.3	1.3	1.1
	8	1.2	1.3	1.2	1.05
	10	1.1	1.2	1.1	1.0
	12	1.0	1.1	1.0	1.0
	≥14	0.9	1.0	0.9	0.9

For sawn beams and stringers with loads applied to the narrow face and posts and timbers with loads applied to either face,  $F_{bo}$  shall be adjusted by  $C_F$  determined as:

- If  $d \leq 12.0$  in., then

$$C_F = 1.0 \quad (8.4.4.4-1)$$

- If  $d > 12.0$  in., then

$$C_F = \left( \frac{12}{d} \right)^{\frac{1}{9}} \quad (8.4.4.4-2)$$

where:

$d$  = net width as shown in Figure 8.3-1

For beams and stringers with loads applied to the wide face,  $F_{bo}$  shall be adjusted by  $C_F$  as specified in Table 8.4.4.4-2.

**Table 8.4.4.4-2—Size Factor,  $C_F$ , for Beams and Stringers with Loads Applied to the Wide Face**

Grade	$F_{bo}$	$E_o$	Other Properties
SS	0.86	1.00	1.00
No. 1	0.74	0.90	1.00
No. 2	1.00	1.00	1.00

#### 8.4.4.5—Volume Factor, $C_V$ , (Glulam)

For horizontally laminated glulam, with loads applied perpendicular to the wide face of the laminations,  $F_{bo}$  shall be reduced by  $C_V$ , given below, when the depth, width, or length of a glued laminated timber exceeds 12.0 in., 5.125 in., or 21.0 ft, respectively:

$$C_V = \left[ \left( \frac{12.0}{d} \right) \left( \frac{5.125}{b} \right) \left( \frac{21}{L} \right) \right]^a \leq 1.0 \quad (8.4.4.5-1)$$

where:

$d$  = depth of the component (in.)

$b$  = width of the component (in.) For layups with multiple piece laminations (across the width)  $b$  = width of widest piece. Therefore:  $b \leq 10.75$  in.

$L$  = length of the component measured between points of contraflexure (ft)

$a$  = 0.05 for Southern Pine and 0.10 for all other species.

The volume factor,  $C_V$ , shall not be applied simultaneously with the beam stability factor,  $C_L$ , therefore, the lesser of these factors shall apply.

The conventional glulam volume factor shall not be applied to tension-reinforced glulams except when unreinforced compression zone is stressed in tension (see Article C8.4.1.3.5). For tension-reinforced glulam beams where unreinforced compression zone is stressed in tension the volume factor,  $C_V$ , the same as for conventional glulam, shall be used.

#### 8.4.4.6—Flat-Use Factor, $C_{fu}$

When dimension lumber graded as *Structural Light Framing* or *Structural Joists and Planks* is used flatwise (load applied to the wide face), the bending reference design value shall be multiplied by the flat use factor specified in Table 8.4.4.6-1.

The flat-use factor shall not apply to dimension lumber graded as Decking.

**Table 8.4.4.6-1—Flat-Use Factor,  $C_{fu}$ , for Dimension Lumber**

Width (in.)	Thickness (in.)	
	2 and 3	4
2 and 3	1.0	—
4	1.1	1.0
5	1.1	1.05
6	1.15	1.05
8	1.15	1.05
$\geq 10$	1.2	1.1

Reference design values for flexure of vertically laminated glulam (loads applied parallel to wide faces of laminations) shall be multiplied by the flat use factors specified in Table 8.4.4.6-2 when the member dimension parallel to wide faces of laminations is less than 12.0 in.

#### C8.4.4.6

Design values for flexure of dimension lumber adjusted by the size factor,  $C_F$ , are based on edgewise use (load applied to the narrow face). When dimension lumber is used flatwise (load applied to the wide face), the bending reference design value should also be multiplied by the flat use factor specified in Table 8.4.4.6-1.

Design values for dimension lumber graded as Decking are based on flatwise use. Further adjustment by the flat-use factor is not permitted.

**Table 8.4.4.6-2—Flat-Use Factor,  $C_{fu}$ , for Glulam**

Member dimension parallel to wide faces of laminations (in.)	$C_{fu}$
10 3/4 or 10 1/2	1.01
8 3/4 or 8 1/2	1.04
6 3/4	1.07
5 1/8 or 5	1.10
3 1/8 or 3	1.16
2 1/2 or 2 1/8	1.19

**8.4.4.7—Incising Factor,  $C_i$** 

Reference design values for dimension lumber shall be multiplied by the incising factor specified in Table 8.4.4.7-1 when members are incised parallel to grain a maximum depth of 0.4 in., a maximum length of 3/8 in., and a density of incisions up to 1100/in.<sup>2</sup>. Incising factors shall be determined by test or by calculation using reduced section properties for incising patterns exceeding these limits.

**Table 8.4.4.7-1—Incising Factor for Dimension Lumber**

Design Value	$C_i$
$E_o$	0.95
$F_{bo}, F_{to}, F_{co}, F_{vo}$	0.80
$F_{cpo}$	1.00

**8.4.4.8—Deck Factor,  $C_d$** 

Unless specified otherwise in this Article, the deck factor,  $C_d$ , shall be equal to 1.0.

For stressed wood, nail-laminated, and spike-laminated decks constructed of solid sawn lumber 2.0 in. to 4.0 in. thick,  $F_{bo}$  may be adjusted by  $C_d$  as specified in Table 8.4.4.8-1.

**Table 8.4.4.8-1—Deck Factor for Stressed Wood and Laminated Decks**

Deck Type	Lumber Grade	
Stressed Wood	Select Structural No. 1 or No. 2	1.30 1.50
Spike-Laminated or Nail-Laminated	All	1.15

**C8.4.4.8**

Mechanically laminated decks made of stressed wood, spike laminated, or nail-laminated solid sawn lumber exhibit an increased resistance in bending. The resistance of mechanically laminated solid sawn lumber decks is calculated by multiplying  $F_{bo}$  in Table 8.4.1.1.4-1 by the deck factor.

Deck factor is used instead of the repetitive member factor that is used in *NDS*<sup>®</sup>.

For planks 4 × 6 in., 4 × 8 in., 4 × 10 in. and 4 × 12 in., used in plank decks with the load applied to the wide face of planks,  $F_{bo}$  may be adjusted by  $C_d$  as specified in Table 8.4.4.8-2.

**Table 8.4.4.8-2—Deck Factor for Plank Decks**

Size (in.)	$C_d$
4 × 6	1.10
4 × 8	1.15
4 × 10	1.25
4 × 12	1.50

The deck factors for planks in plank decks shall not be applied cumulatively with the flat use factor,  $C_{fu}$ , specified in Article 8.4.4.6.

#### 8.4.4.9—Time Effect Factor, $C_\lambda$

The time effect factor,  $C_\lambda$  shall be chosen to correspond to the appropriate strength limit state as specified in Table 8.4.4.9-1.

**Table 8.4.4.9-1—Time Effect Factor**

Limit State	$C_\lambda$
Strength I	0.8
Strength II	1.0
Strength III	1.0
Strength IV	0.6
Extreme Event I	1.0

## 8.5—LIMIT STATES

### 8.5.1—Service Limit State

The provisions of Article 2.5.2.6.2 should be considered.

### 8.5.2—Strength Limit State

#### 8.5.2.1—General

Factored resistance shall be the product of nominal resistance determined in accordance with Article 8.6, 8.7, 8.8, and 8.9 and the resistance factor as specified in Article 8.5.2.2.

The specified deck factors for planks in plank decks are based test results comparing the modulus of rupture (MOR) for plank specimens with load applied in narrow face and wide face (*Stankiewicz and Nowak, 1997*). These deck factors can be applied cumulatively with the size factor,  $C_f$ , specified in Article 8.4.4.4.

#### C8.4.4.9

*NDS®* and AITC 117-2004 reference design values (based on 10-yr loading) multiplied by the format conversion factors specified in Article 8.4.4.2, transform allowable stress values to strength level stress values based on 10-min. loading. It is assumed that a cumulative duration of bridge live load is two months and the corresponding time effect factor for Strength I is 0.8. A cumulative duration of live load in Strength II is shorter and the corresponding time effect factor for Strength II is 1.0. Resistance of wood subjected to long-duration loads is reduced. Load combination IV consists of permanent loads, including dead load and earth pressure.

### 8.5.2.2—Resistance Factors

Resistance factors,  $\phi$ , shall be as given below:

Flexure .....	$\phi = 0.85$
Shear .....	$\phi = 0.75$
Compression Parallel to Grain .....	$\phi = 0.90$
Compression Perpendicular to Grain .....	$\phi = 0.90$
Tension Parallel to Grain .....	$\phi = 0.80$
Resistance During Pile Driving.....	$\phi = 1.15$
Connections .....	$\phi = 0.65$

### C8.5.2.2

In the case of timber pile foundations, the resistance factor may be raised to 1.0 when, in the judgment of the Engineer, a sufficient number of piles is used in a foundation element to consider it to be highly redundant. This is indicated to be a judgment issue because there are no generally accepted quantitative guidelines at this writing.

For timber piles, the resistance factor to be applied when determining the maximum allowable driving resistance accounts for the short duration of the load induced by the pile driving hammer.

### 8.5.2.3—Stability

The structure as a whole or its components shall be proportioned to resist sliding, overturning, uplift, and buckling.

### 8.5.3—Extreme Event Limit State

For extreme event limit state, the resistance factor shall be taken as 1.0.

## 8.6—COMPONENTS IN FLEXURE

### 8.6.1—General

The factored resistance,  $M_r$ , shall be taken as:

$$M_r = \phi M_n \quad (8.6.1-1)$$

where:

$M_n$  = nominal resistance specified herein (kip-in.)

$\phi$  = resistance factor specified in Article 8.5.2

### 8.6.2—Rectangular Section

The nominal resistance,  $M_n$ , of a rectangular component in flexure shall be determined from:

$$M_n = F_b S C_L \quad (8.6.2-1)$$

in which:

$$C_L = \frac{1+A}{1.9} - \sqrt{\frac{(1+A)^2}{3.61} - \frac{A}{0.95}} \quad (8.6.2-2)$$

$$A = \frac{F_{bE}}{F_b} \quad (8.6.2-3)$$

### C8.6.2

If lateral support is provided to prevent rotation at the points of bearing, but no other lateral support is provided throughout the bending component length, the unsupported length,  $L_u$ , is the distance between such points of intermediate lateral support.

The volume factor for the tension-reinforced glulams listed in Table 8.4.1.3.4-1 is equal to one; therefore, for these beams,  $C_L$  will always be less or equal to  $C_V$ , and  $C_L$  will control the modification factor for the allowable bending strength  $F_b$ .

$$F_{bE} = \frac{K_{bE} E}{R_B^2} \quad (8.6.2-4)$$

$$R_b = \sqrt{\frac{L_e d}{b^2}} \leq 50 \quad (8.6.2-5)$$

where:

$K_{bE}$  = 0.76 for visually graded lumber

$K_{bE}$  = 0.98 for MEL lumber

$K_{bE}$  = 1.06 for MSR lumber

$K_{bE}$  = 1.10 for glulam and tension-reinforced glulam

$F_b$  = adjusted design value in flexure specified in Article 8.4.4 (ksi)

$E$  = adjusted modulus of elasticity specified in Article 8.4.4 (ksi)

$C_L$  = beam stability factor for both conventional glulam and tension-reinforced glulam

$d$  = net depth specified in Article 8.4.1.1.2 (in.)

$b$  = net width, as specified in Article 8.4.1.1.2 (in.)

$L_e$  = effective unbraced length (in.)

$S$  = section modulus (in.<sup>3</sup>)

Where the depth of a flexural component does not exceed its width, or where lateral movement of the compression zone is prevented by continuous support and where points of bearing have lateral support to prevent rotation, the stability factor,  $C_L = 1.0$ . For other conditions, the beam stability factor shall be determined in accordance with the provisions specified herein.

The beam stability factor shall not be applied simultaneous with the volume factor for structural glued laminated timber, therefore, the lesser of these factors shall apply.

The effective unbraced length,  $L_e$ , may be determined as:

- If  $L_u/d < 7$ , then  $L_e = 2.06 L_u$
- If  $7 \leq L_u/d \leq 14.3$ , then  $L_e = 1.63 L_u + 3d$
- If  $L_u/d > 14.3$ , then  $L_e = 1.84 L_u$

where:

$L_u$  = distance between point of lateral and rotational support (in.)

$d$  = net depth specified in Article 8.4.1.1.2 (in.)

### 8.6.3—Circular Section

The nominal resistance,  $M_n$ , of a circular component in flexure shall be taken as:

$$M_n = F_b S \quad (8.6.3-1)$$

## 8.7—COMPONENTS UNDER SHEAR

Shear shall be investigated at a distance away from the face of support equal to the depth of the component. When calculating the maximum design shear, the live load shall be placed so as to produce the maximum shear at a distance from the support equal to the lesser of either three times the depth,  $d$ , of the component or one-quarter of the span  $L$ .

The factored shear resistance,  $V_r$ , of a component of rectangular cross-section shall be calculated from:

$$V_r = \phi V_n \quad (8.7-1)$$

in which:

$$V_n = \frac{F_v bd}{1.5} \quad (8.7-2)$$

where:

$\phi$  = resistance factor specified in Article 8.5.2

$F_v$  = adjusted design value of wood in shear, specified in Article 8.4.1 (ksi)

## 8.8—COMPONENTS IN COMPRESSION

### 8.8.1—General

The factored resistance in compression,  $P_r$ , shall be taken as:

$$P_r = \phi P_n \quad (8.8.1-1)$$

where:

$P_n$  = nominal resistance as specified in Article 8.8.2 and 8.8.3 (kips)

$\phi$  = resistance factor specified in Article 8.5.2

### 8.8.2—Compression Parallel to Grain

Where components are not adequately braced, the nominal stress shall be modified by the column stability factor,  $C_p$ . If the component is adequately braced,  $C_p$  shall be taken as 1.0.

The nominal resistance,  $P_n$ , of a component in the compression parallel to grain shall be taken as:

## C8.7

The critical section is between one and three depths from the support.

The critical shear in flexural components is horizontal shear acting parallel to the grain of the component. The resistance of bending components in shear perpendicular to grain need not be investigated.

Note that Eq. 4.6.2.2.2a-1 requires a special distribution factor in the calculation of the live load force effect when investigating shear parallel to the grain.

## C8.8.2

The coefficient of variation of the bending Modulus of Rupture ( $MOR$ ) of tension-reinforced glulams has been shown through extensive testing to be less than or equal to that of conventional unreinforced glulams. Therefore, it is conservative to use  $K_{cE} = 0.76$  for tension-reinforced glulams.

$$P_n = F_c A_g C_p \quad (8.8.2-1)$$

in which:

$$C_p = \frac{1+B}{2c} - \sqrt{\left(\frac{1+B}{2c}\right)^2 - \frac{B}{c}} \leq 1.0 \quad (8.8.2-2)$$

$$B = \frac{F_{cE}}{F_c} \leq 1.0 \quad (8.8.2-3)$$

$$F_{cE} = \frac{K_{cE} Ed^2}{L_e^2} \quad (8.8.2-4)$$

where:

$c$  = 0.8 for sawn lumber

$c$  = 0.85 for round timber piles

$c$  = 0.9 for glulam

$K_{cE}$  = 0.52 for visually graded lumber

$K_{cE}$  = 0.67 for MEL lumber

$K_{cE}$  = 0.73 for MSR lumber

$K_{cE}$  = 0.76 for glulam, tension-reinforced glulam, and round piles

$F_c$  = adjusted design value in compression parallel to the grain specified in Article 8.4.4 (ksi)

$L_e$  = effective length taken as  $KL$  (in.)

$A_g$  = gross cross-sectional area of the component ( $\text{in.}^2$ )

### 8.8.3—Compression Perpendicular to Grain

The nominal resistance,  $P_n$ , of a component in compression perpendicular to the grain shall be taken as:

$$P_n = F_{cp} A_b C_b \quad (8.8.3-1)$$

where:

$F_{cp}$  = adjusted design value in compression perpendicular to grain, as specified in Article 8.4.4 (ksi)

$A_b$  = bearing area ( $\text{in.}^2$ )

$C_b$  = bearing adjustment factor specified in Table 8.8.3-1

When the bearing area is in a location of high flexural stress or is closer than 3.0 in. from the end of the component,  $C_b$  shall be taken as 1.0. In all other cases,  $C_b$  shall be as specified in Table 8.8.3-1.

**Table 8.8.3-1—Adjustment Factors for Bearing**

$C_b$	Length of bearing measured along the grain, in.						
	0.5	1.0	1.5	2.0	3.0	4.0	$\geq 6.0$
	1.75	1.38	1.25	1.19	1.13	1.10	1.00

## 8.9—COMPONENTS IN TENSION PARALLEL TO GRAIN

The factored resistance,  $P_r$ , of a component in tension shall be taken as:

$$P_r = \phi P_n \quad (8.9-1)$$

in which:

$$P_n = F_t A_n \quad (8.9-2)$$

where:

$F_t$  = adjusted design value of wood in tension specified in Article 8.4.4 (ksi)

$A_n$  = smallest net cross-sectional area of the component ( $\text{in.}^2$ )

$\phi$  = resistance factor specified in Article 8.5.2

## 8.10—COMPONENTS IN COMBINED FLEXURE AND AXIAL LOADING

### 8.10.1—Components in Combined Flexure and Tension

Components subjected to flexure and tension shall satisfy:

$$\frac{P_u}{P_r} + \frac{M_u}{M_r^*} \leq 1.0 \quad (8.10.1-1)$$

and

$$\frac{\frac{M_u - \frac{d}{6} P_u}{M_r^{**}}}{\frac{6}{M_r}} \leq 1.0 \quad (8.10.1-2)$$

where:

$P_u$  = factored tensile load (kips)

$P_r$  = factored tensile resistance calculated as specified in Article 8.9 (kips)

$M_u$  = factored flexural moment (kip-in.)

$M_r^* = F_b S$

$M_r^{**} =$  factored flexural resistance adjusted by all applicable adjustment factors except  $C_V$

### C8.10.1

Satisfying Eq. 8.10.1-1 ensures that stress interaction on the tension face of the bending member does not cause beam rupture.  $M_r^*$  in this formula does not include modification by the beam stability factor,  $C_L$ .

Eq. 8.10.1-2 is applied to ensure that the bending/tension member does not fail due to lateral buckling of the compression face.

### 8.10.2—Components in Combined Flexure and Compression Parallel to Grain

Components subjected to flexure and compression parallel to grain shall satisfy:

$$\left(\frac{P_u}{P_r}\right)^2 + \frac{M_u}{M_r \left(1 - \frac{P_u}{F_{cE} A_g}\right)} \leq 1.0 \quad (8.10.2-1)$$

where:

$P_u$  = factored compression load (kips)

$P_r$  = factored compressive resistance calculated as specified in Article 8.8 (kips)

$M_u$  = factored flexural moment (kip-in.)

$M_r$  = factored flexural resistance calculated as specified in Article 8.6 (kip-in.)

$F_{cE}$  = Euler buckling stress as defined in Eq. 8.8.2-4

$A_g$  = gross cross-sectional area

## 8.11—BRACING REQUIREMENTS

### 8.11.1—General

Where bracing is required, it shall prevent both lateral and rotational deformation.

### C8.11.1

In detailing of the diaphragms, the potential for shrinkage and expansion of the beam and the diaphragm should be considered. Rigidly connected steel angle framing may cause splitting of the beam and diaphragm as the wood attempts to swell and shrink under the effects of cyclic moisture.

### 8.11.2—Sawn Wood Beams

### C8.11.2

Beams shall be transversely braced to prevent lateral displacement and rotation of the beams and to transmit lateral forces to the bearings. Transverse bracing shall be provided at the supports for all span lengths and at intermediate locations for spans longer than 20.0 ft. The spacing of intermediate bracing shall be based on lateral stability and load transfer requirements but shall not exceed 25.0 ft. The depth of transverse bracing shall not be less than three-fourths the depth of the stringers or girders.

Transverse bracing should consist of solid wood blocking or fabricated steel shapes. Wood blocking shall be bolted to stringers with steel angles or suspended in steel saddles that are nailed to the blocks and stringer sides. Blocking shall be positively connected to the beams.

Transverse bracing at supports may be placed within a distance from the center of bearing equal to the stringer or girder depth.

The effectiveness of the transverse bracing directly affects the long-term durability of the system. The bracing facilitates erection, improves load distribution, and reduces relative movements of the stringers and girders, thereby reducing deck deformations. Excessive deformation can lead to mechanical deterioration of the system.

Bracing should be accurately framed to provide full bearing against stringer sides. Wood cross-frames or blocking that are toe-nailed to stringers have been found to be ineffective and should not be used.

**8.11.3—Glued Laminated Timber Girders**

Transverse bracing should consist of fabricated steel shapes or solid wood diaphragms.

Girders shall be attached to supports with steel shoes or angles that are bolted through the girder and into or through the support.

**8.11.4—Bracing of Trusses**

Wood trusses shall be provided with a rigid system of lateral bracing in the plane of the loaded chord. Lateral bracing in the plane of the unloaded chord and rigid portal and sway bracing shall be provided in all trusses having sufficient headroom. Outrigger bracing connected to extensions of the floorbeams shall be used for bracing through-trusses having insufficient headroom for a top chord lateral bracing system.

**8.12—CAMBER REQUIREMENTS****8.12.1—Glued Laminated Timber Girders**

Glued laminated timber girders shall be cambered a minimum of two times the dead load deflection at the service limit state.

**8.12.2—Trusses**

Trusses shall be cambered to sufficiently offset the deflection due to dead load, shrinkage, and creep.

**8.12.3—Stress Laminated Timber Deck Bridge**

Deck bridges shall be cambered for three times the dead load deflection at the service limit state.

**8.13—CONNECTION DESIGN**

The design of timber connections using mechanical fasteners including, wood screws, nails, bolts, lag screws, drift bolts, drift pins, shear plates, split rings, and timber rivets shall be in accordance with the 2005 *NDS*<sup>®</sup>.

**8.14—REFERENCES**

**C8.11.3**

Bracing should be placed tight against the girders and perpendicular to the longitudinal girder axis.

**C8.11.4**

Bracing is used to provide resistance to lateral forces, to hold the trusses plumb and true, and to hold compression elements in line.

**C8.12.1**

The initial camber offsets the effects of dead load deflection and long-term creep deflection.

**C8.12.2**

Camber should be determined by considering both elastic deformations due to applied loads and inelastic deformations such as those caused by joint slippage, creep of the timber components, or shrinkage due to moisture changes in the wood components.

## SECTION 9

### DECKS AND DECK SYSTEMS

#### 9.1—SCOPE

This Section contains provisions for the analysis and design of bridge decks and deck systems of concrete, metal, and wood or combinations thereof subjected to gravity loads.

For monolithic concrete bridge decks satisfying specific conditions, an empirical design, requiring no analysis, is permitted.

Continuity in the deck and its supporting components is encouraged.

Composite action between the deck and its supporting components is required where technically feasible.

#### 9.2—DEFINITIONS

*Appurtenance*—Curbs, parapets, railings, barriers, dividers, and sign and lighting posts attached to the deck.

*Arching Action*—A structural phenomenon in which wheel loads are transmitted primarily by compressive struts formed in the slab.

*Band*—A strip of laminated wood deck within which the pattern of butt joints is not repeated.

*Bolster*—A spacer between a metal deck and a beam.

*Bulkhead*—A steel element attached to the side of stress laminated timber decks to distribute the prestressing force and reduce the tendency to crush the wood.

*Cellular Deck*—A concrete deck with void-ratio in excess of 40 percent.

*Clear Span*—The face-to-face distance between supporting components.

*Closed Rib*—A rib in an orthotropic deck consisting of a plate forming a trough, welded to the deck plate along both sides of the rib.

*Closure Joint*—A cast-in-place concrete fill between precast components to provide continuity.

*Compatibility*—The equality of deformation at the interface of elements and/or components joined together.

*Component*—A structural element or combination of elements requiring individual design consideration.

*Composite Action*—A condition in which two or more elements or components are made to act together by preventing relative movement at their interface.

*Continuity*—In decks, both structural continuity and the ability to prevent water penetration without the assistance of nonstructural elements.

*Core Depth*—The distance between the top of top reinforcement and the bottom of bottom reinforcement in a concrete slab.

*Deck*—A component, with or without wearing surface, that supports wheel loads directly and is supported by other components.

*Deck Joint*—A complete or partial interruption of the deck to accommodate relative movement between portions of a structure.

#### C9.1

Implicit in this Section is a design philosophy that prefers jointless, continuous bridge decks and deck systems to improve the weather and corrosion-resisting effects of the whole bridge, reduce inspection efforts and maintenance costs, and increase structural effectiveness and redundancy.

*Deck System*—A superstructure, in which the deck is integral with its supporting components, or in which the effects or deformation of supporting components on the behavior of the deck is significant.

*Design Span*—For decks, the center-to-center distance between the adjacent supporting components, taken in the primary direction.

*Effective Length*—The span length used in the empirical design of concrete slabs defined in Article 9.7.2.3.

*Elastic*—A structural response in which stress is directly proportional to strain and no deformation remains upon removal of loading.

*Equilibrium*—A state where the sum of forces parallel to any axis and the sum of moments about any axis in space are 0.0.

*Equivalent Strip*—An artificial linear element, isolated from a deck for the purpose of analysis, in which extreme force effects calculated for a line of wheel loads, transverse or longitudinal, will approximate those actually taking place in the deck.

*Extreme*—Maximum or minimum.

*Flexural Continuity*—The ability to transmit moment and rotation between components or within a component.

*Floorbeam*—The traditional name for a cross-beam.

*Footprint*—The specified contact area between wheel and roadway surface.

*Frame Action*—Transverse continuity between the deck and the webs of cellular cross-section or between the deck and primary components in large bridges.

*Glued Laminated Deck Panel*—A deck panel made from wood laminations connected by adhesives.

*Governing Position*—The location and orientation of a transient load to cause extreme force effects.

*Inelastic*—The structural response in which stress is not directly proportional to strain and deformation may remain upon removal of loading.

*Interface*—The location where two elements and/or components are in contact.

*Internal Composite Action*—The interaction between a deck and a structural overlay.

*Isotropic Plate*—A plate having essentially identical structural properties in the two principal directions.

*Isotropic Reinforcement*—Two identical layers of reinforcement, perpendicular to and in touch with each other.

*Lateral*—Any horizontal or close to horizontal direction.

*Laminated Deck*—A deck consisting of a series of laminated wood elements that are tightly abutted along their edges to form a continuous surface.

*Local Analysis*—An in-depth study of strains and stresses in or among components using force effects obtained from global analysis.

*Net Depth*—The depth of concrete, excluding the concrete placed in the corrugations of a metal formwork.

*Open Grid Floor*—A metal grid floor not filled or covered with concrete.

*Open Rib*—A rib in an orthotropic deck consisting of a single plate or rolled section welded to the deck plate.

*Orthotropic*—A plate having significantly different structural properties in the two principal directions.

*Overfill*—The concrete above the top of the steel grid of filled or partially filled steel grid deck systems.

*Partial Composite Action*—A condition in which two or more elements or components are made to act together by decreasing, but not eliminating, relative movement at their interface, or where the connecting elements are too flexible to fully develop the deck in composite action.

*Primary Direction*—In isotropic decks: direction of the shorter span; in orthotropic decks: direction of the main load-carrying elements.

*Secondary Direction*—The direction normal to the primary direction.

*Segmental Construction*—A method of building a bridge utilizing match-cast, prefabricated, or cast-in-place concrete segments joined together by longitudinal post-tensioning.

*Shear Connector*—A mechanical device that prevents relative movements both normal and parallel to an interface.

*Shear Continuity*—A condition where shear and displacement are transmitted between components or within a component.

*Shear Key*—A preformed hollow in the side of a precast component filled with grout or a system of match-cast depressions and protrusions in the face of segments that is intended to provide shear continuity between components.

*Skew Angle*—The angle between the axis of support relative to a line normal to the longitudinal axis of the bridge, i.e., a zero-degree skew denotes a rectangular bridge.

*Spacing*—Center-to-center distance of elements or components, such as reinforcing bars, girders, bearings, etc.

*Stay-in-Place Formwork*—Permanent metal or precast concrete forms that remain in place after construction is finished.

*Stiffener Beam*—An unsupported beam attached to the underside of a wood deck to enhance lateral continuity.

*Stress Range*—The algebraic difference between extreme stresses.

*Structural Overlay*—An overlay bonded to the deck that consists of concretes other than asphaltic concretes.

*Tandem*—Two closely spaced and mechanically interconnected axles of equal weight.

*Tie-Down*—A mechanical device that prevents relative movement normal to an interface.

*Void*—An internal discontinuity of the deck by which its self-weight is reduced.

*Voided Deck*—Concrete deck in which the area of the voids does not constitute more than 40 percent of the gross area.

*Wheel*—One tire or a pair of tires at one end of an axle.

*Wheel Load*—One-half of a specified design axle load.

*Wearing Surface*—An overlay or sacrificial layer of the structural deck to protect the structural deck against wear, road salts, and environmental effects. The overlay may include waterproofing.

*Yield Line*—A plastic hinge line.

*Yield Line Analysis*—A method of determining the load-carrying capacity of a component on the basis of the formation of a mechanism.

*Yield Line Method*—A method of analysis in which a number of possible yield line patterns of concrete slabs are examined in order to determine minimum load-carrying capacity.

### 9.3—NOTATION

$A_B$	= effective bearing area of anchorage bulkhead (in. <sup>2</sup> ) (9.9.5.6.3)
$A_s$	= area of steel bar or strand (in. <sup>2</sup> ) (9.9.5.6.3)
$a$	= larger of the spacing of the rib webs (in.) (9.8.3.7.2)
$c$	= depth of the bottom cutout to accommodate a rib in an orthotropic deck (in.) (9.8.3.7.4)
$d$	= effective depth: distance between the outside compressive fiber and the center of gravity of the tensile reinforcement (in.) (C9.7.2.5)
$e$	= clear spacing between closed ribs in orthotropic steel decks (in.) (9.8.3.7.4)
$F$	= nominal bearing resistance of wood across the grain (ksi) (9.9.5.6.3)
$f_r$	= the out-of-plane flexural stresses in rib webs (ksi) (C9.8.3.7.2)
$h$	= depth of deck (in.) (9.9.5.6.3)
$h'$	= length of the inclined portion of the rib web (in.) (9.8.3.7.2)
$k$	= factor representing a distribution of bending moment along a rib (C9.8.3.7.2)
$L$	= span length from center-to-center of supports (9.5.2)
$P_{BU}$	= factored compressive resistance of the wood under the bulkhead (kip) (9.9.5.6.3)
$P_{pt}$	= prestressing force per prestressing element (kip) (9.9.5.6.3)
$q$	= load intensity (ksi) (C9.8.3.7.2)
$R_{sw}$	= steel-wood ratio (9.9.5.6.3)
$S$	= effective span length (ft) (9.7.3.2)
$s$	= spacing of prestressing bars (in.) (9.9.5.6.3)
$t$	= thickness of slab or plate (in.) (9.8.3.7.1)
$t_{d, eff}$	= effective depth of deck plate, including the stiffening effect of surfacing (in.) (9.8.3.7.2)
$t_r$	= thickness of rib web (in.) (9.8.3.7.2)
$\phi$	= resistance factor (9.9.5.6.3)

### 9.4—GENERAL DESIGN REQUIREMENTS

#### 9.4.1—Interface Action

Decks other than wood and open grid floors shall be made composite with their supporting components, unless there are compelling reasons to the contrary. Noncomposite decks shall be connected to their supporting components to prevent vertical separation.

Shear connectors and other connections between decks, other than open grid floors and wood decks, and their supporting members shall be designed for force effects calculated on the basis of full composite action, whether or not that composite action is considered in proportioning the primary members. The details for transmitting shear across the interface to metal supporting components shall satisfy the applicable provisions of Article 6.6 or Article 7.6.

Force effects between the deck and appurtenances or other components shall be accommodated.

#### 9.4.2—Deck Drainage

With the exception of unfilled steel grid decks, cross and longitudinal slopes of the deck surface shall be provided as specified in Article 2.6.6.

Structural effects of drainage openings shall be considered in the design of decks.

#### C9.4.1

Composite action is recommended to enhance the stiffness and economy of structures.

Some decks without shear connectors have historically demonstrated a degree of composite action due to chemical bond and/or friction that cannot be accounted for in structural design.

It is difficult to design and detail a tie-down device that does not attract shear forces due to transient loads, temperature changes, and fluctuation in moisture content. These forces may loosen and/or break such devices, and cause fatigue damage in other parts of the floor system and its connections to main members, and to floorbeams in particular.

### 9.4.3—Concrete Appurtenances

Unless otherwise specified by the Owner, concrete curbs, parapets, barriers, and dividers should be made structurally continuous. Consideration of their structural contribution to the deck should be limited in accordance with the provisions of Article 9.5.1.

### 9.4.4—Edge Supports

Unless the deck is designed to support wheel loads in extreme positions with respect to its edges, edge supports shall be provided. Nonintegral edge beams shall conform to the provisions of Article 9.7.1.4.

### 9.4.5—Stay-in-Place Formwork for Overhangs

Stay-in-place formwork, other than that in filled steel decks, shall not be used in the overhang of concrete decks.

## 9.5—LIMIT STATES

### 9.5.1—General

The structural contribution of a concrete appurtenance to the deck may be considered for service and fatigue but not for strength or extreme event limit states.

For other than the deck overhang, where the conditions specified in Article 9.7.2 are met, a concrete deck may be assumed to satisfy service, fatigue, and fracture and strength limit state requirements and need not meet the other provisions of Article 9.5.

### 9.5.2—Service Limit States

At service limit states, decks and deck systems shall be analyzed as fully elastic structures and shall be designed and detailed to satisfy the provisions of Sections 5, 6, 7, and 8.

The effects of excessive deck deformation, including deflection, shall be considered for metal grid decks and other lightweight metal and concrete bridge decks. For these deck systems, the deflection caused by live load plus dynamic load allowance shall not exceed the following criteria:

- $L/800$  for decks with no pedestrian traffic,
- $L/1000$  for decks with limited pedestrian traffic, and
- $L/1200$  for decks with significant pedestrian traffic

where:

$L$  = span length from center-to-center of supports.

### C9.4.3

Experience indicates that the interruption of concrete appurtenances at locations other than deck joints does not serve the intended purpose of stress relief. Large cracks, only a foot or so away from open joints, have been observed in concrete parapets. The structural participation of these components is usually but not always beneficial. One possible negative aspect of continuity is increased cracking in the appurtenance.

### C9.4.4

If the deck joint hardware is integrated with the deck, it may be utilized as a structural element of the edge beam.

### C9.5.1

Exclusion of contribution of an appurtenance at strength limit state is a safety measure in that advantage is not taken of a component that may be damaged, disconnected, or destroyed by a collision.

Article 9.7.2.2 states that the empirical design method does not apply to overhangs.

### C9.5.2

Deck deformation refers to local dishing at wheel loads, not to overall superstructure deformation.

The primary objective of curtailing excessive deck deformation is to prevent breakup and loss of the wearing surface. No overall limit can be specified because such limit is a function of the composition of the wearing surface and the adhesion between the deck and the wearing surface. The limits should be established by testing.

Substantial work has been done relating accelerations to user comfort. Acceleration is a function of the fundamental frequency of vibration of the deck on a particular span, and the magnitude of dynamic deflection due to live load. Dynamic deflections are typically 15 percent to 20 percent of static deflections. Analysis shows that static deflections serve well as a proxy for acceleration levels for deck systems.

### **9.5.3—Fatigue and Fracture Limit State**

Fatigue need not be investigated for:

- Concrete decks, and
- Wood decks as listed in Article 9.9.

Metal grid, filled grid, partially filled grid and unfilled grid decks composite with reinforced concrete slabs shall comply with the provisions of Article 4.6.2.1.8 and Article 6.5.3.

Steel grid and steel orthotropic decks shall comply with the provisions of Article 6.5.3. Aluminum decks shall comply with the provisions of Article 7.6.

Concrete decks, other than those in multigirder application, shall be investigated for the fatigue limit states as specified in Article 5.5.3.

### **9.5.4—Strength Limit States**

At strength limit states, decks and deck systems may be analyzed as either elastic or inelastic structures and shall be designed and detailed to satisfy the provisions of Sections 5, 6, 7, and 8.

### **9.5.5—Extreme Event Limit States**

Decks shall be designed for force effects transmitted by traffic and combination railings using loads, analysis procedures, and limit states specified in Section 13. Acceptance testing, complying with Section 13, may be used to satisfy this requirement.

## **9.6—ANALYSIS**

### **9.6.1—Methods of Analysis**

Approximate elastic methods of analysis specified in Article 4.6.2.1, refined methods specified in Article 4.6.3.2, or the empirical design of concrete slabs specified in Article 9.7 may be used for various limit states as permitted in Article 9.5.

### **9.6.2—Loading**

Loads, load positions, tire contact area, and load combinations shall be in accordance with the provisions of Section 3.

### **C9.5.3**

The provisions that do not require fatigue investigation of certain types of decks are based exclusively on observed performance and laboratory testing.

A series of 35 pulsating load fatigue tests of model slabs indicate that the fatigue limit for the slabs designed by the conventional AASHTO moment methods was approximately three times the service level. Decks based on the isotropic reinforcement method specified in Article 9.7.2 had fatigue limits of approximately twice the service level (deV Batchelor et al., 1978).

### **C9.5.4**

These Specifications do not permit an unlimited application of inelastic methods of analysis due to the lack of adequate background research. There are, however, well-established inelastic plate analyses whose use is allowed.

### **C9.6.1**

Analytical methods presented herein should not be construed as excluding other analytical approaches, provided that they are approved by the Owner.

## 9.7—CONCRETE DECK SLABS

### 9.7.1—General

#### 9.7.1.1—Minimum Depth and Cover

Unless approved by the Owner, the depth of a concrete deck, excluding any provision for grinding, grooving, and sacrificial surface, should not be less than 7.0 in.

Minimum cover shall be in accordance with the provisions of Article 5.12.3.

#### C9.7.1.1

For slabs of depth less than 1/20 of the design span, consideration should be given to prestressing in the direction of that span in order to control cracking.

Construction tolerances become a concern for thin decks.

Minimum cover requirements are based on traditional concrete mixes and on the absence of protective coating on either the concrete or the steel inside. A combination of special mix design, protective coatings, dry or moderate climate, and the absence of corrosion chemicals may justify a reduction of these requirements provided that the Owner approves.

#### 9.7.1.2—Composite Action

Shear connectors shall be designed in accordance with the provisions of Section 5 for concrete beams and Sections 6 and 7 for metal beams.

#### C9.7.1.2

Some research efforts have dealt with wood beams composite with concrete decks and steel beams with stressed wood decks, but progress is not advanced to a point which permits codification.

#### 9.7.1.3—Skewed Decks

If the skew angle of the deck does not exceed 25 degrees, the primary reinforcement may be placed in the direction of the skew; otherwise, it shall be placed perpendicular to the main supporting components.

#### C9.7.1.3

The intent of this provision is to prevent extensive cracking of the deck, which may result from the absence of appreciable reinforcement acting in the direction of principal flexural stresses due to a heavily skewed reinforcement, as shown in Figure C9.7.1.3-1. The somewhat arbitrary 25-degree limit could affect the area of steel as much as ten percent. This was not taken into account because the analysis procedure and the use of bending moment as a basis of design were not believed to be sufficiently accurate to warrant such an adjustment. Owners interested in making this refinement should also consider one of the refined methods of analysis identified in Article 4.6.3.2.

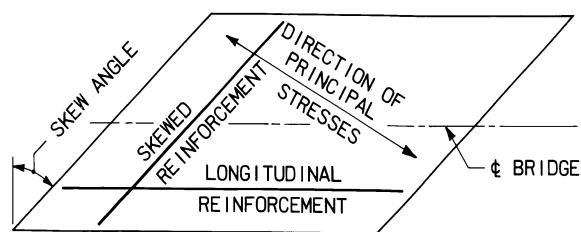

Figure C9.7.1.3-1—Reinforcement Layout

#### **9.7.1.4—Edge Support**

Unless otherwise specified, at lines of discontinuity, the edge of the deck shall either be strengthened or be supported by a beam or other line component. The beam or component shall be integrated in or made composite with the deck. The edge beams may be designed as beams whose width may be taken as the effective width of the deck specified in Article 4.6.2.1.4.

Where the primary direction of the deck is transverse, and/or the deck is composite with a structurally continuous concrete barrier, no additional edge beam need be provided.

#### **9.7.1.5—Design of Cantilever Slabs**

The overhanging portion of the deck shall be designed for railing impact loads and in accordance with the provisions of Article 3.6.1.3.4.

Punching shear effects at the outside toe of a railing post or barrier due to vehicle collision loads shall be investigated.

#### **C9.7.1.5**

An acceptable method of analyzing deck overhangs for railing impact loads is presented in the appendix to Section 13.

Any combination of increasing the depth of the slab, employing special reinforcement extending the slab width beyond the railing, and enlarging base plates under railing posts may be utilized to prevent failure due to punching shear.

### **9.7.2—Empirical Design**

#### **9.7.2.1—General**

The provisions of Article 9.7.2 relate exclusively to the empirical design process for concrete deck slabs supported by longitudinal components and shall not be applied to any other Article in this Section, unless specifically permitted.

#### **C9.7.2.1**

Extensive research into the behavior of concrete deck slabs discovered that the primary structural action by which these slabs resist concentrated wheel loads is not flexure, as traditionally believed, but a complex internal membrane stress state referred to as internal arching. This action is made possible by the cracking of the concrete in the positive moment region of the design slab and the resulting upward shift of the neutral axis in that portion of the slab. The action is sustained by in-plane membrane forces that develop as a result of lateral confinement provided by the surrounding concrete slab, rigid appurtenances, and supporting components acting compositely with the slab.

The arching creates what can best be described as an internal compressive dome, the failure of which usually occurs as a result of overstraining around the perimeter of the wheel footprint. The resulting failure mode is that of punching shear, although the inclination of the fracture surface is much less than 45 degrees due to the presence of large in-plane compressive forces associated with arching. The arching action, however, cannot resist the full wheel load. There remains a small flexural component for which the specified minimum amount of isotropic reinforcement is more than adequate. The steel has a dual purpose: it provides for both local flexural resistance and global confinement required to develop arching effects (Fang, 1985; Holowka et al., 1980).

All available test data indicate that the factor of safety of a deck designed by the flexural method specified in the 16th edition of the AASHTO Standard Specifications, working stress design, is at least 10.0. Tests indicate a comparable factor of safety of about 8.0 for an empirical design. Therefore, even the empirical design possesses an extraordinary reserve strength.

The design of reinforced concrete decks using the concept of internal arching action within the limits specified herein has been verified by extensive nonlinear finite element analysis (Hewitt and deV Batchelor, 1975; Fang et al. 1990). These analyses are accepted in lieu of project-specific design calculation as a preapproved basis of design.

Slabs with the minimum specified reinforcement have demonstrated nearly complete insensitivity to differential displacement among their supports.

The additional longitudinal reinforcement provided for the slab in the negative moment region of continuous beams and girder-type bridges beyond that required for isotropic reinforcement according to the provisions of Article 9.7.2.5 need not be matched in the perpendicular direction. Theoretically, this portion of the deck will be orthotropically reinforced, but this does not weaken the deck.

The longitudinal bars of the isotropic reinforcement may participate in resisting negative moments at an internal support in continuous structures.

#### **9.7.2.2—Application**

Empirical design of reinforced concrete decks may be used if the conditions set forth in Article 9.7.2.4 are satisfied.

The provisions of this Article shall not be applied to overhangs.

The overhang should be designed for:

- Wheel loads for decks with discontinuous railings and barriers using the equivalent strip method,
- Equivalent line load for decks with continuous barriers specified in Article 3.6.1.3.4, and
- Collision loads using a failure mechanism as specified in Article A13.2.

#### **9.7.2.3—Effective Length**

For the purpose of the empirical design method, the effective length of slab shall be taken as:

- For slabs monolithic with walls or beams: the face-to-face distance, and
- For slabs supported on steel or concrete girders: the distance between flange tips, plus the flange overhang, taken as the distance from the extreme flange tip to the face of the web, disregarding any fillets.

#### **C9.7.2.2**

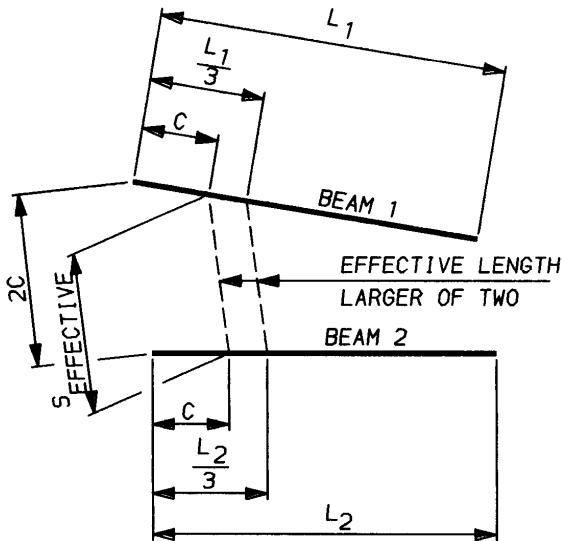

Although current tests indicated that arching action may exist in the cantilevered overhang of the slab, the available evidence is not sufficient to formulate code provisions for it (Hays et al., 1989).

As indicated in Article 9.5.5, acceptance testing complying with Section 13 may be used to satisfy design requirements for deck overhangs.

#### **C9.7.2.3**

Physical tests and analytical investigations indicate that the most important parameter concerning the resistance of concrete slabs to wheel loads is the ratio between the effective length and the depth of the slab.

In case of nonuniform spacing of supporting components, the effective length,  $S_{\text{effective}}$ , shall be taken as the larger of the deck lengths at the two locations shown in Figure 9.7.2.3-1.

**Figure 9.7.2.3-1—Effective Length for Nonuniform Spacing of Beams**

#### 9.7.2.4—Design Conditions

For the purpose of this Article, the design depth of the slab shall exclude the loss that is expected to occur as a result of grinding, grooving, or wear.

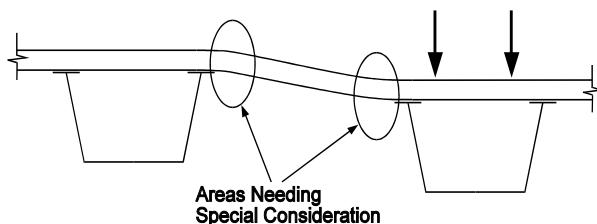

The empirical design may be used only if the following conditions are satisfied:

- Cross-frames or diaphragms are used throughout the cross-section at lines of support;
- For cross-section involving torsionally stiff units, such as individual separated box beams, either intermediate diaphragms between the boxes are provided at a spacing not to exceed 25.0 ft, or the need for supplemental reinforcement over the webs to accommodate transverse bending between the box units is investigated and reinforcement is provided if necessary;
- The supporting components are made of steel and/or concrete;
- The deck is fully cast-in-place and water cured;
- The deck is of uniform depth, except for haunches at girder flanges and other local thickening;
- The ratio of effective length to design depth does not exceed 18.0 and is not less than 6.0;

#### C9.7.2.4

Intermediate cross-frames are not needed in order to use the empirical deck design method for cross-sections involving torsionally weak open shapes, such as T- or I-shaped girders.

Use of separated, torsionally stiff beams without intermediate diaphragms can give rise to the situation, shown in Figure C9.7.2.4-1, in which there is a relative displacement between beams and in which the beams do not rotate sufficiently to relieve the moment over the webs. This moment may or may not require more reinforcing than is provided by the empirical deck design.

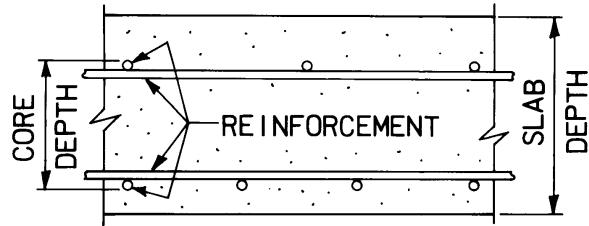

**Figure C9.7.2.4-1—Schematic of Effect of Relative Displacements in Torsionally Stiff Cross-Section**

All the tests carried out so far were restricted to specimens of uniform depth. Slabs supported by wood beams are not qualified for the empirical design due to the lack of experimental evidence regarding adequate lateral shear transfer between the slab and the relatively soft timber beams.

- Core depth of the slab is not less than 4.0 in.;
- The effective length, as specified in Article 9.7.2.3, does not exceed 13.5 ft;
- The minimum depth of the slab is not less than 7.0 in., excluding a sacrificial wearing surface where applicable;
- There is an overhang beyond the centerline of the outside girder of at least 5.0 times the depth of the slab; this condition is satisfied if the overhang is at least 3.0 times the depth of the slab and a structurally continuous concrete barrier is made composite with the overhang;

No experience exists for effective lengths exceeding 13.5 ft. The 7.0-in. depth is considered an absolute minimum with 2.0-in. cover on top and 1.0-in. cover on the bottom, providing for a reinforced core of 4.0 in., as indicated in Figure C9.7.2.4-2.

**Figure C9.7.2.4-2—Core of a Concrete Slab**

The provisions of the *Ontario Highway Bridge Design Code* (1991), based on model test results, do not permit length-to-depth ratios in excess of 15.0. The larger value of 18.0 is based on recent experiments (Hays et al., 1989).

The intention of the overhang provision is to ensure confinement of the slab between the first and the second beam.

The 4.0-ksi limit is based on the fact that none of the tests included concrete with less than 4.0-ksi strength at 28 days. Many jurisdictions specify 4.5-ksi concrete for ensuring reduced permeability of the deck. On the other hand, tests indicate that resistance is not sensitive to the compressive strength, and 3.5 ksi may be accepted with the approval of the Owner.

- The specified 28-day strength of the deck concrete is not less than 4.0 ksi; and
- The deck is made composite with the supporting structural components.

For the purpose of this Article, a minimum of two shear connectors at 24.0-in. centers shall be provided in the negative moment region of continuous steel superstructures. The provisions of Article 6.10.1.1 shall also be satisfied. For concrete girders, the use of stirrups extending into the deck shall be taken as sufficient to satisfy this requirement.

### 9.7.2.5—Reinforcement Requirements

Four layers of isotropic reinforcement shall be provided in empirically designed slabs. Reinforcement shall be located as close to the outside surfaces as permitted by cover requirements. Reinforcement shall be provided in each face of the slab with the outermost layers placed in the direction of the effective length. The minimum amount of reinforcement shall be 0.27 in.<sup>2</sup>/ft of steel for each bottom layer and 0.18 in.<sup>2</sup>/ft of steel for each top layer. Spacing of steel shall not exceed 18.0 in. Reinforcing steel shall be Grade 60 or better. All reinforcement shall be straight bars, except that hooks may be provided where required.

Both lap splices and mechanical splices shall be allowed. Mechanical splices shall be tested and approved to conform to the limits for slip in Article 5.11.5.2.2, Mechanical Couplers, and for fatigue in Article 5.5.3.4, Welded or Mechanical Splices of Reinforcement. Sleeve wedge-type couplers shall not be permitted on coated reinforcing.

### C9.7.2.5

Prototype tests indicated that 0.2 percent reinforcement in each of four layers based on the effective depth  $d$  satisfies strength requirements. However, the conservative value of 0.3 percent of the gross area, which corresponds to about 0.27 in.<sup>2</sup>/ft in a 7.5-in. slab, is specified for better crack control in the positive moment area. Field measurements show very low stresses in negative moment steel; this is reflected by the 0.18-in.<sup>2</sup>/ft requirement, which is about 0.2 percent reinforcement steel. The additional intent of this low amount of steel is to prevent spalling of the deck due to corrosion of the bars or wires.

Welded splices are not permitted due to fatigue considerations. Tested and preapproved mechanical splices may be permitted when lapping of reinforcing is not possible or desirable, as often occurs in staged construction and widenings. Sleeve wedge-type couplers will not be permitted on coated reinforcing due to stripping of the coating.

If the skew exceeds 25 degrees, the specified reinforcement in both directions shall be doubled in the end zones of the deck. Each end zone shall be taken as a longitudinal distance equal to the effective length of the slab specified in Article 9.7.2.3.

#### **9.7.2.6—Deck with Stay-in-Place Formwork**

For decks made with corrugated metal formwork, the design depth of the slab shall be assumed to be the minimum concrete depth.

Stay-in-place concrete formwork shall not be permitted in conjunction with empirical design of concrete slabs.

The intent of this provision is crack control. Beam slab bridges with a skew exceeding 25 degrees have shown a tendency to develop torsional cracks due to differential deflections in the end zone (OHBDC, 1991). The extent of cracking is usually limited to a width that approximates the effective length.

#### **C9.7.2.6**

Concrete in the troughs of the corrugated metal deck is ignored due to lack of evidence that it consistently contributes to the strength of the deck. Reinforcement should not be placed directly on corrugated metal formwork.

The empirical design is based on a radial confinement around the wheel load, which may be weakened by the inherent discontinuity of the bottom reinforcement at the boundaries between formwork panels. Limited tests carried out on flexurally designed slabs with stay-in-place concrete formwork indicate a punching shear failure mode, but somewhat less resistance than that provided by fully cast-in-place slabs. The reason for this decrease is that the discontinuity between the panels intercepts, and thus prevents, the undisturbed formation of the frustum of a cone where punching shear occurs (Buth et al., 1992).

### **9.7.3—Traditional Design**

#### **9.7.3.1—General**

The provisions of this Article shall apply to concrete slabs that have four layers of reinforcement, two in each direction, and that comply with Article 9.7.1.1.

#### **9.7.3.2—Distribution Reinforcement**

Reinforcement shall be placed in the secondary direction in the bottom of slabs as a percentage of the primary reinforcement for positive moment as follows:

- For primary reinforcement parallel to traffic:

$$100/\sqrt{S} \leq 50 \text{ percent}$$

- For primary reinforcement perpendicular to traffic:

$$220/\sqrt{S} \leq 67 \text{ percent}$$

where:

$S$  = the effective span length taken as equal to the effective length specified in Article 9.7.2.3 (ft)

#### **C9.7.3.1**

The traditional design is based on flexure. The live load force effect in the slab may be determined using the approximate methods of Article 4.6.2.1 or the refined methods of Article 4.6.3.2.

## 9.7.4—Stay-in-Place Formwork

### 9.7.4.1—General

Stay-in-place formwork shall be designed to be elastic under construction loads. The construction load shall not be taken to be less than the weight of the form and the concrete slab plus 0.050 ksf.

Flexural stresses due to unfactored construction loads shall not exceed:

- 75 percent of the yield strength of steel, or
- 65 percent of the 28-day compressive strength for concrete in compression or the modulus of rupture in tension for prestressed concrete form panels.

The elastic deformation caused by the dead load of the forms, plastic concrete, and reinforcement shall not exceed:

- For form span lengths of 10.0 ft or less, the form span length divided by 180 but not exceeding 0.50 in.; or
- For form span lengths greater than 10.0 ft, the form span length divided by 240 but not exceeding 0.75 in.

### 9.7.4.2—Steel Formwork

Panels shall be specified to be tied together mechanically at their common edges and fastened to their support. No welding of the steel formwork to the supporting components shall be permitted, unless otherwise shown in the contract documents.

Steel formwork shall not be considered to be composite with a concrete slab.

### C9.7.4.1

The intent of this Article is to prevent excessive sagging of the formwork during construction, which would result in an unanticipated increase in the weight of the concrete slab.

Deflection limits are specified to ensure adequate cover for reinforcing steel and to account for all dead load in the design.

### C9.7.4.2

For steel stay-in-place formwork, it has been common to provide an allowance for the weight of the form and additional concrete, with the provision added to the contract documents that if the allowance is exceeded by the Contractor's choice, the Contractor is responsible for showing that the effects on the rest of the bridge are acceptable or providing additional strengthening as needed at no cost to the Owner. The customary allowance has been 0.015 ksf, but this should be reviewed if form spans exceed about 10.0 ft.

### 9.7.4.3—Concrete Formwork

#### 9.7.4.3.1—Depth

The depth of stay-in-place concrete should neither exceed 55 percent of the depth of the finished deck slab nor be less than 3.5 in.

#### C9.7.4.3.1

Thousands of bridges have successfully been built with a depth ratio of 43 percent or somewhat higher; 55 percent is believed to be a practical limit, beyond which cracking of the cast-in-place concrete at the panel interface may be expected.

#### 9.7.4.3.2—*Reinforcement*

Concrete formwork panels may be prestressed in the direction of the design span.

If the precast formwork is prestressed, the strands may be considered as primary reinforcement in the deck slab.

Transfer and development lengths of the strands shall be investigated for conditions during construction and in service.

Prestressing strands and/or reinforcing bars in the precast panel need not be extended into the cast-in-place concrete above the beams.

If used, bottom distribution reinforcement may be placed directly on the top of the panels. Splices in the top primary reinforcement in deck slab shall not be located over the panel joints.

The concrete cover below the strands should not be less than 0.75 in.

#### 9.7.4.3.3—*Creep and Shrinkage Control*

The age of the panel concrete at the time of placing the cast-in-place concrete shall be such that the difference between the combined shrinkage and creep of the precast panel and the shrinkage of the cast-in-place concrete is minimized.

The upper surface of the panels shall be specified to be roughened in such a manner as to ensure composite action with the cast-in-place concrete.

#### 9.7.4.3.4—*Bedding of Panels*

The ends of the formwork panels shall be supported on a continuous mortar bed or shall be supported during construction in such a manner that the cast-in-place concrete flows into the space between the panel and the supporting component to form a concrete bedding.

#### C9.7.4.3.2

The transfer and development lengths for epoxy-coated strands with alkali-resistant hard particles embedded in the coating may be less than that for uncoated strands. Where epoxy-coated strands are used, this value should be determined by testing.

Tests indicate no difference between constructions with and without reinforcement extended into the cast-in-place concrete over the beams (Bieschke and Klingner, 1982). The absence of extended reinforcement, however, may affect transverse load distribution due to a lack of positive moment continuity over the beams or may result in reflective cracking at the ends of the panel. In addition to transverse cracking, which usually occurs at the panel joints due to creep and shrinkage, the latter may appear unseemly and/or make the construction of this type of deck questionable where deicing salts are used.

#### C9.7.4.3.3

The objective of this Article is to minimize interface shear stresses between the precast panel and the cast-in-place concrete and to promote good bond. Normally, no bonding agents and/or mechanical connectors are needed for composite action.

#### C9.7.4.3.4

Setting screws, bituminous fiber boards, neoprene glands, etc., may be appropriate as temporary supports. In the past, some jurisdictions have had bad experience where prestressed concrete panels were supported only by flexible materials. Creep due to prestress had apparently pulled the panel ends away from cast-in-place concrete. Load was transferred to the flexible panel supports, which compressed, resulting in excessive reflective cracking in the cast-in-place concrete.

### 9.7.5—Precast Deck Slabs on Girders

#### 9.7.5.1—General

Both reinforced and prestressed precast concrete slab panels may be used. The depth of the slab, excluding any provision for grinding, grooving, and sacrificial surface, shall not be less than 7.0 in.

### **9.7.5.2—Transversely Joined Precast Decks**

Flexurally discontinuous decks made from precast panels and joined together by shear keys may be used. The design of the shear key and the grout used in the key shall be approved by the Owner. The provisions of Article 9.7.4.3.4 may be applicable for the design of bedding.

### **9.7.5.3—Longitudinally Post-Tensioned Precast Decks**

The precast components may be placed on beams and joined together by longitudinal post-tensioning. The minimum average effective prestress shall not be less than 0.25 ksi.

The transverse joint between the components and the block-outs at the coupling of post-tensioning ducts shall be specified to be filled with a nonshrink grout having a minimum compressive strength of 5.0 ksi at 24 hours.

Block-outs shall be provided in the slab around the shear connectors and shall be filled with the same grout upon completion of post-tensioning.

### **C9.7.5.2**

The shear keys tend to crack due to wheel loads, warping, and environmental effects, leading to leaking of the keys and decreased shear transfer. The relative movement between adjacent panels tends to crack the overlay, if present. Therefore, this construction is not recommended for the regions where the deck may be exposed to salts.

### **C9.7.5.3**

Decks made flexurally continuous by longitudinal post-tensioning are the more preferred solution because they behave monolithically and are expected to require less maintenance on the long-term basis.

The post-tensioning ducts should be located at the center of the slab cross-section. Block-outs should be provided in the joints to permit the splicing of post-tensioning ducts.

Panels should be placed on the girders without mortar or adhesives to permit their movement relative to the girders during prestressing. Panels can be placed directly on the girders or located with the help of shims of inorganic material or other leveling devices. If the panels are not laid directly on the beams, the space therein should be grouted at the same time as the shear connector block-outs.

A variety of shear key formations has been used in the past. Recent prototype tests indicate that a "V" joint may be the easiest to form and to fill.

## **9.7.6—Deck Slabs in Segmental Construction**

### **9.7.6.1—General**

The provisions of this Article shall apply to the top slabs of post-tensioned girders whose cross-sections consist of single or multicell boxes. The slab shall be analyzed in accordance with the provisions of Article 4.6.2.1.6.

### **9.7.6.2—Joints in Decks**

Joints in the decks of precast segmental bridges may be dry joints, epoxied match-cast surfaces, or cast-in-place concrete.

Dry joints should be used only in regions where deicing salts are not applied.

The strength of cast-in-place concrete joints shall not be less than that of the precast concrete. The width of the concrete joint shall permit the development of reinforcement in the joint or coupling of ducts if used, but in no case shall it be less than 12.0 in.

### **C9.7.6.2**

Dry joints in the deck, with or without a nonstructural sealant, have been observed to permit percolation of water due to shrinkage as well as creep and temperature-induced warping of segments. Both epoxied match-cast and cast-in-place concrete joints permitted herein should produce water-tight joints. The 12.0-in. cast-in-place closure joint is believed to provide a better riding profile if the deck is not overlaid.

A combination joint in which only the deck part of a match-cast joint is epoxied should be avoided.

## 9.8—METAL DECKS

### 9.8.1—General

Metal decks shall be designed to satisfy the requirements of Sections 6 and 7. The tire contact area shall be determined as specified in Article 3.6.1.2.5.

### 9.8.2—Metal Grid Decks

#### 9.8.2.1—General

Grid deck shall be composed of main elements that span between beams, stringers, or cross-beams and secondary members that interconnect and span between the main elements. The main and secondary elements may form a rectangular or diagonal pattern and shall be securely joined together. All intersections of elements in open grid floors, partially filled grid decks, and unfilled grid decks composite with reinforced concrete slabs shall be welded.

Force effects may be determined using one of the following methods:

- The approximate methods specified in Article 4.6.2.1, as applicable;
- Orthotropic plate theory;
- Equivalent grillage; or
- Design aids provided by the manufacturers, if the performance of the deck is documented and supported by sufficient technical evidence.

One of the accepted approximate methods is based on transformed cross-section area. Mechanical shear transfer devices, including indentations, embossment, sand coating of surface, and other appropriate means may be used to enhance the composite action between elements of the grid and the concrete fill.

If a filled or partially filled grid deck, or an unfilled grid deck composite with reinforced concrete slab is considered to be composite with its supporting members for the purpose of designing those members, the effective width of slab in composite section shall be as specified in Article 4.6.2.6.1.

#### C9.8.2.1

Research has shown that welds between elements in partially filled grids “may be very important to the survival of the cross bar” (Gangarao et al., 1992).

Laboratory tests have shown that section properties of filled and partially filled grids, computed by the transformed area method, are conservative (Gangarao et al., 1992). Tests have also demonstrated that a monolithic concrete overpour may be considered fully effective in determining section properties.

Filled and partially filled grid decks and unfilled grid decks composite with reinforced concrete slabs have better potential for composite action with the supporting components due to their considerable in-plane rigidity.

In computing section properties, omit any effect of concrete in tension (i.e., below the neutral axis in positive bending, and above the neutral axis in negative bending).

The modular ratios may be applied to the composite action of concrete fill with grid deck in flexure and to the composite action between the deck and its supporting beams.

Field tests of systems consisting of unfilled grid decks composite with reinforced concrete slabs and stringers or floorbeams demonstrate significant levels of composite action, with the effective width being at least 12.0 times the overall thickness of the deck, including the grid portion and the structural reinforced concrete slab.

### 9.8.2.2—Open Grid Floors

Open grid floors shall be connected to the supporting components by welding or by mechanically fastening at each main element. Where welding is used to make this connection, a single-sided 3.0-in. long weld or a 1.5-in. weld on each side of the main element may be used.

Unless evidence is provided to the contrary, welding within open grid floors should be considered as a Category E detail, and the provisions of Article 6.6 shall apply.

Ends and edges of open grid floors that may be exposed to vehicular traffic shall be supported by closure bars or other effective means.

### 9.8.2.3—Filled and Partially Filled Grid Decks

#### 9.8.2.3.1—General

These decks shall consist of a metal grid or other metal structural system filled either completely or partially with concrete.

The provisions of Article 9.8.2.1 shall apply to filled and partially filled grid decks.

Where possible, a 1.75-in. thick structural overfill should be provided.

Filled and partially filled grids shall be attached to supporting components by welding or shear studs to transfer shear between the two surfaces.

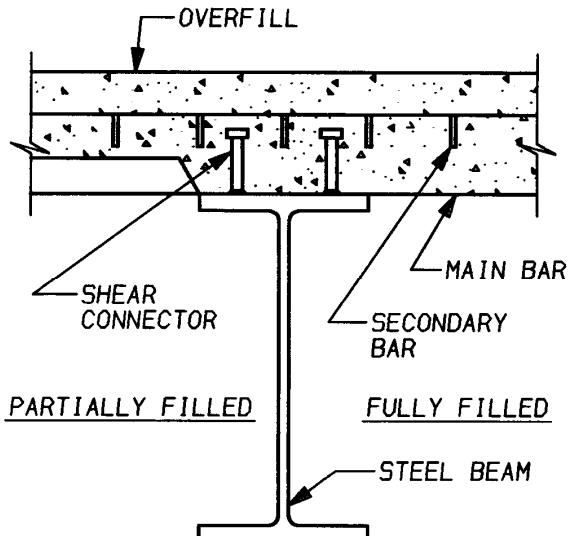

#### C9.8.2.2

Long-term experience indicates that even where there is an apparently insignificant degree of composite action between the deck and its supporting components, high stresses may develop at their interface, resulting in local failures and separation of the deck. Therefore, the requirement to connect at each intersection of a main bar, as indicated, applies even to open grid floors.

#### C9.8.2.3.1

Full-scale tests on systems consisting of partially filled grid decks and stringers demonstrated significant levels of composite action, with the effective width being at least 12.0 times the depth of the deck. Under load, the deck strain readings across the width of the deck were nearly uniform, with extremely small slip recorded at the deck-stringer interface.

In order to activate the deck in composite action, large shear forces need be resisted at the interface. A preferred method of shear transfer is by welded studs encased in a concrete haunch, similar to that illustrated in Figure C9.8.2.3.1-1.

**Figure C9.8.2.3.1-1—An Acceptable Shear Connection of Partially and Fully Filled Grid Decks to Beams**

### 9.8.2.3.2—Design Requirements

Design of filled and partially filled grid decks shall be in accordance with the provisions of Article 9.8.2.1 and Article 4.6.2.1.8.

The concrete portion of filled and partially filled grid decks shall be in accordance with the general provisions of Section 5 relating to long-term durability and integrity.

For cast-in-place applications, weight of concrete fill shall be assumed to be carried solely by the metal portion of the deck. The transient loads and superimposed permanent loads may be assumed to be supported by the grid bars and concrete fill acting compositely. A structural overfill may be considered as part of the composite structural deck. Where a structural overfill is provided, the design depth of the deck shall be reduced by a provision for loss that is expected as a result of grinding, grooving, or wear of the concrete.

### 9.8.2.3.3—Fatigue and Fracture Limit State

The internal connection between the elements of the steel grid in a fully or partially filled grid deck shall be investigated for fatigue.

Unless evidence is provided to the contrary, tack welds attaching horizontal form pans to metal grids shall be considered Category E' details.

### C9.8.2.3.2

The presence of a composite structural overlay improves both the structural performance and riding quality of the deck.

### C9.8.2.3.3

The fatigue category to be used for fatigue investigation should be determined by appropriate laboratory testing in positive and negative bending. The fatigue category for welds and punchouts shall not be taken as better than Category C, which has been shown by testing to be appropriate for most details of grid decks constructed with concrete.

The small fillet welds used in the fabrication of grid decks are generally less than 1.5 in. long, but are not considered “tack welds.” In grid decks, “tack welds” refers only to small welds used to attach sheet metal pans that serve only as forms for concrete poured onto or into the grid.

Where possible, form pans should be attached by means other than tack welding.

### 9.8.2.4—Unfilled Grid Decks Composite with Reinforced Concrete Slabs

#### 9.8.2.4.1—General

An unfilled grid deck composite with reinforced concrete slab consists of a reinforced concrete slab that is cast on top of and is composite with an unfilled steel grid. Composite action between the concrete slab and the grid deck shall be ensured by providing shear connectors or other means capable of resisting horizontal and vertical components of interface shears.

Composite action between the grid deck and the supporting components should be ensured by mechanical shear connectors.

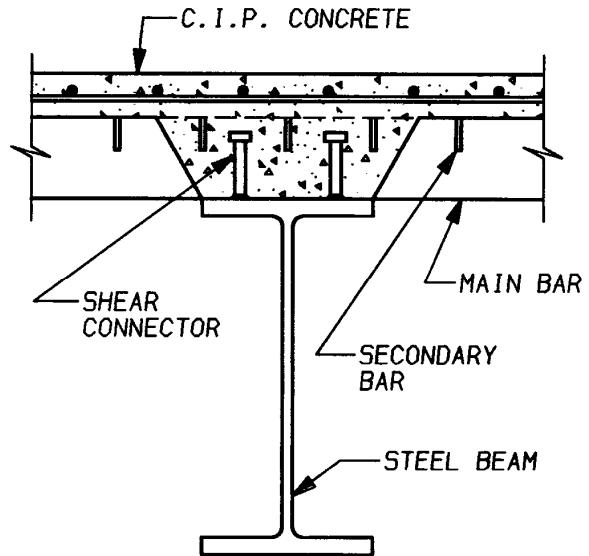

Unless otherwise specified, provisions of Article 9.8.2.1 shall apply.

Discontinuities and cold joints in such decks should be kept to a minimum.

### C9.8.2.4.1

This bridge deck combines the attributes of a concrete deck and a steel grid deck.

An acceptable way of providing composite action between the deck and the supporting components is shown in Figure C9.8.2.4.1-1.

**Figure C9.8.2.4.1-1—An Acceptable Shear Connection of Unfilled Grid Decks Composite with Reinforced Concrete Slabs to Beams**

#### 9.8.2.4.2—Design

Design of unfilled grid decks composite with reinforced concrete slabs shall be in accordance with the provisions of Article 9.8.2.1 and Article 4.6.2.1.8. The design depth of the deck shall be reduced by a provision for loss that is expected as a result of grinding, grooving, or wear of the concrete.

The reinforced concrete portion of unfilled grid decks composite with reinforced concrete slabs shall be in accordance with the general provisions of Section 5 relating to long-term durability and integrity.

In the concrete slab, one layer of reinforcement in each principal direction may be used.

For cast-in-place applications, weight of concrete slab shall be assumed to be carried solely by the grid portion of the deck. The transient loads and superimposed permanent loads may be assumed to be supported by the composite section.

The interface between the concrete slab and the metal system shall satisfy the provisions of Article 6.10.10. Acceptable methods of shear connection shall include tertiary bars to which 0.5-in. diameter rebar or round studs have been welded, or the punching of holes at least 0.75 in. in size in the top portion of the main bars of the grid which are embedded in the reinforced concrete slab by a minimum of 1.0 in.

#### 9.8.2.4.3—Fatigue Limit State

The internal connection between the elements of the steel grid in unfilled grid decks composite with reinforced concrete slabs shall be investigated for fatigue.

#### C9.8.2.4.2

For the purpose of design, the deck can be subdivided into intersecting sets of composite concrete/steel beams.

#### C9.8.2.4.3

The fatigue category to be used for fatigue investigation should be determined by appropriate laboratory testing in positive and negative bending. The fatigue category for welds and punchouts shall not be

Unless evidence is provided to the contrary, tack welds attaching horizontal form pans to metal grids shall be considered Category E' details.

The composite reinforced concrete slab shall be included in the calculation of stress range.

better than Category C, which has been shown by testing to be appropriate for most details of grid decks constructed with concrete.

The small fillet welds used in the fabrication of grid decks are generally less than 1.5 in. long, but are not considered "tack welds." In grid decks, "tack welds" refers only to small welds used to attach sheet metal pans that serve only as forms for concrete poured onto or into the grid.

Where possible, form pans should be attached by means other than tack welding.

### **9.8.3—Orthotropic Steel Decks**

#### **9.8.3.1—General**

Orthotropic steel decks shall consist of a deck plate stiffened and supported by longitudinal ribs and transverse floorbeams. The deck plate shall act as a common flange of the ribs, the floorbeams, and the main longitudinal components of the bridge.

In rehabilitation, if the orthotropic deck is supported by existing floorbeams, the connection between the deck and the floorbeam should be designed for full composite action, even if the effect of composite action is neglected in the design of floorbeams. Where practical, connections suitable to develop composite action between the deck and the main longitudinal components should be provided.

#### **9.8.3.2—Wheel Load Distribution**

A 45-degree distribution of the tire pressure may be assumed to occur in all directions from the surface contact area to the middle of the deck plate. The tire footprint shall be as specified in Article 3.6.1.2.5.

#### **9.8.3.3—Wearing Surface**

The wearing surface should be regarded as an integral part of the total orthotropic deck system and shall be specified to be bonded to the top of the deck plate.

The contribution of a wearing surface to the stiffness of the members of an orthotropic deck may be considered if structural and bonding properties are satisfactorily demonstrated over the temperature range of -20° to +120°F. If the contribution of the wearing surface to stiffness is considered in the design, the required engineering properties of the wearing surface shall be indicated in the contract documents.

Force effects in the wearing surface and at the interface with the deck plate shall be investigated with consideration of engineering properties of the wearing surface at anticipated extreme service temperatures.

The long-term composite action between deck plate and wearing surface shall be documented by both static and cyclic load tests.

#### **C9.8.3.1**

The intent of this Article is to ensure the structural integrity of the deck and its structural participation with the cross-beams and the primary longitudinal components, as appropriate. Any structural arrangement in which the orthotropic deck is made to act independently from the main components is undesirable.

#### **C9.8.3.2**

The 45-degree distribution is the traditional, conservative assumption.

#### **C9.8.3.3**

Wearing surfaces acting compositely with the deck plate may reduce deformations and stresses in orthotropic decks.

The deck stiffening effect of the wearing surface is dependent upon its thickness, the elastic modulus which is dependent on temperature and the load application, i.e., static or dynamic, and bond characteristics.

The combination of temperature and live load effects has resulted in debonding of some wearing surfaces in the field, which should be regarded as failure of the wearing surface. The Designer should consider past experience in selection of a wearing surface and in determination of its long-term contribution to the structural system.

Wearing surface cracking is related to stresses exceeding tensile strength of surfacing material. Flexural stresses in surfacing may be reduced by limiting local deck flexibility, as indicated in Article 2.5.2.6.2. Safety against surfacing cracking may be best assured by using surfacing materials with semiplastic properties or with low elastic modulus not subject to much variation with temperature.

For the purpose of designing the wearing surface and its adhesion to the deck plate, the wearing surface shall be assumed to be composite with the deck plate, regardless of whether the deck plate is designed on that basis.

The wearing surface plays an important role in improving skid resistance, distributing wheel loads, and protecting the deck against corrosion and abuse.

Selection or design of a wearing surface should include evaluation of the following functional requirements:

- Sufficient ductility and strength to accommodate expansion, contraction, and imposed deformation without cracking or debonding;
- Sufficient fatigue strength to withstand flexural stresses due to composite action of the wearing surface with the deck plate resulting from local flexure;
- Sufficient durability to resist rutting, shoving, and wearing;
- Imperviousness to water and motor vehicle fuels and oils;
- Resistance to deterioration from deicing salts; and
- Resistance to aging and deterioration due to solar radiation.

#### **9.8.3.4—Refined Analysis**

Force effects in orthotropic decks may be determined by elastic methods of analysis, such as equivalent grillage, finite strip, or finite element methods, as specified in Section 4.

#### **9.8.3.5—Approximate Analysis**

##### *9.8.3.5.1—Effective Width*

The effective width of deck plate acting with a rib should be determined as specified in Article 4.6.2.6.4.

##### *9.8.3.5.2—Decks with Open Ribs*

The rib may be analyzed as a continuous beam supported by the floorbeams.

For rib spans not exceeding 15.0 ft, the load on one rib due to wheel loads may be determined as the reaction of transversely continuous deck plate supported by rigid ribs. For rib spans greater than 15.0 ft, the effect of rib flexibility on the lateral distribution of wheel loads may be determined by elastic analysis.

For rib spans smaller than 10.0 ft or for decks with shallow floorbeams, the flexibility of the floorbeams shall be considered in calculating force effects in the ribs.

Local stresses at rib/floorbeam intersections needed for fatigue investigation shall be obtained by detailed analysis.

##### *C9.8.3.5.2*

Approximate analysis of both open rib and closed rib decks is based on the Pelikan-Esslinger method presented in Wolchuk (1963) and Troitsky (1987). This method gives conservative values of global force effects in the orthotropic deck supported on longitudinal edge girders. Load distribution of adjacent transversely located wheel loads on decks with closed ribs is discussed in Wolchuk (1964).

#### 9.8.3.5.3—Decks with Closed Ribs

For the global analysis of decks with closed ribs, the semiempirical Pelikan-Esslinger method may be used. Local stresses at rib/floorbeam intersections subject to load-induced fatigue shall be determined by detailed analysis. The load effects on a closed rib with a span not greater than 20.0 ft may be calculated from wheel loads placed over one rib only, without regard for the effects of the adjacent transversely located wheel loads.

For longer rib spans appropriate corrections of load effects on ribs shall be calculated.

#### 9.8.3.6—Design

##### 9.8.3.6.1—Superposition of Local and Global Effects

In calculating extreme force effects in the deck, the combination of local and global effects should be determined as specified in Article 6.14.3.

##### C9.8.3.6.1

The orthotropic deck is part of the global structural system, and, therefore, participates in distributing global stresses. These stresses may be additive to those generated in the deck locally. The axles of the design truck or the design tandem is used for the design of decks, whereas the rest of the bridge is proportioned for combinations of the design truck, the design tandem, and the design lane load. The governing positions of the same load for local and global effects could be quite different. Therefore, the Designer should analyze the bridge for both load regimes separately, apply the appropriate dynamic load allowance factor, and use the one that governs.

##### 9.8.3.6.2—Limit States

Orthotropic decks shall be designed to meet the requirements of Section 6 at all applicable limit states, unless otherwise specified herein.

At the service limit state, the deck shall satisfy the requirements as specified in Article 2.5.2.6.

At the strength limit state for the combination of local and global force effects, the provisions of Article 6.14.3 shall apply.

The effects of compressive instability of the orthotropic deck shall be investigated at strength limit states. If instability does not control, the resistance of orthotropic plate deck shall be based on the attainment of yield strength at any point in the cross-section.

For the fatigue limit state, the provisions of Article 6.6.1.2 shall apply for load-induced fatigue.

##### C9.8.3.6.2

Tests indicate a large degree of redundancy and load redistribution between first yield and failure of the deck. The large reduction in combined force effects is a reflection of this performance.

The deck, because it acts as part of the global structural system, is exposed to in-plane axial tension and/or compression. Consequently, buckling should be investigated.

Components and supporting elements of orthotropic steel decks, along with their connections, should be designed for infinite life using the Fatigue I load combination. Since most components of a bridge deck are subject to individual cycles from each passing axle, the number of applied cycles will generally exceed the number of cycles associated with the finite-life limits of most orthotropic deck details that are used. Connor and Fisher (2006) discuss a consistent approach that is recommended for calculating the stress range for fatigue design of welded rib-to-web connections in steel orthotropic bridge decks. For details on the diaphragm or web of orthotropic steel decks at the connection of the diaphragms and/or

The deck plate/rib wall junction of decks with closed ribs is considered to be subject to distortion-induced fatigue rules of Article 6.6.1.3.3. Fatigue strength of this detail may be considered satisfactory if requirements for geometric proportions and welding details stipulated in Article 9.8.3.7 are satisfied.

Application of less stringent fatigue design rules may be considered, with Owner's approval, for interior traffic lanes of multilane decks subjected to infrequent truck traffic.

### 9.8.3.7—Detailing Requirements

#### 9.8.3.7.1—Minimum Plate Thickness

The deck plate thickness,  $t$ , shall not be less than 0.5625 in. or four percent of the larger spacing of rib webs.

#### 9.8.3.7.2—Closed Ribs

The thickness of closed ribs shall not be less than 0.1875 in.

Cross-sectional dimensions of an orthotropic steel deck shall satisfy:

$$\frac{t_r a^3}{t_{d,eff}^3 h'} < 400 \quad (9.8.3.7.2-1)$$

where:

$t_r$  = thickness of the rib web (in.)

$t_{d,eff}$  = effective thickness of the deck plate, with consideration of the stiffening effect of the surfacing, as specified in Article 9.8.3.3 (in.)

$a$  = larger of the spacing of the rib webs (in.)

$h'$  = length of the inclined portion of the rib web (in.)

bulkheads to the longitudinal ribs, research suggests that calculated stress ranges at these details due to the Fatigue I load combination be multiplied by an additional factor of 1.5 (Connor, 2002).

Experience has shown that fatigue damage on orthotropic decks occurs mainly at the ribs under the truck wheel paths in the exterior lanes.

#### C9.8.3.7.1

Although analysis may indicate that deck plates less than 0.5625 in. thick could be satisfactory, experience shows that a minimum thickness of 0.5625 in. is advisable both from construction and long-term performance points of view.

#### C9.8.3.7.2

Fatigue tests indicate that local out-of-plane flexural stress in the rib web at the junction with the deck plate should be minimized. One way to achieve this is to limit the stress in the rib web caused by the rotation of the rib-deck plate junction by making the rib web relatively slender compared with the deck plate. Eq. C9.8.3.7.2-1 is based on parameter studies of out-of-plane flexural stresses in rib webs.

Eq. 9.8.3.7.2-1 is a simplified representation of Eq. C9.8.3.7.2-1, which is written for the out-of-plane flexural stress in the rib web in terms of the cross-sectional dimensions of the orthotropic steel deck.

$$f_r = k \frac{qa^2}{8} \frac{6}{t_r^2} \frac{\frac{t_r^3}{h'}}{\frac{t_{d,eff}^3}{a} + \frac{t_{d,eff}^3}{a} + \frac{t_r^3}{h'}} \quad (C9.8.3.7.2-1)$$

where:

$k$  = factor representing a distribution of bending moment along a rib

$q$  = load intensity (ksf)

The interiors of closed ribs shall be sealed:

- By continuous welds at the rib-to-deck plate interface,
- At welded rib splices, and
- At the diaphragms at the ends of the ribs.

Eighty percent partial penetration welds between the webs of a closed rib and the deck plate should be permitted.

The interior of closed ribs cannot be inspected and/or repaired. It is, therefore, essential to hermetically seal them against the ingress of moisture and air. The use of sealed ribs justifies the minimum plate thickness specified.

Partial penetration welds are generally used for connecting closed ribs with thickness greater than 0.25 in. to deck plates. Such welds, which require careful choice of automatic welding processes and a tight fit, are less susceptible to fatigue failure than full penetration groove welds requiring backup bars.

#### *9.8.3.7.3—Unauthorized Welding to Orthotropic Decks*

Welding of attachments, utility supports, lifting lugs, or shear connectors to the deck plate or ribs shall not be permitted.

#### *C9.8.3.7.3*

Experience shows that welding attachments to the deck plate or the ribs may result in fatigue cracks.

#### *9.8.3.7.4—Deck and Rib Details*

Deck and rib splices shall either be welded or mechanically fastened by high-strength bolts using details as shown in Figure 9.8.3.7.4-1. Details whose fatigue resistance has been established through testing are also acceptable as permitted by the Owner. Ribs shall be run continuously through cutouts in the webs of floorbeams, as shown in Figure 9.8.3.7.4-1. The following fabrication details shall be required by the contract documents where identified in Figure 9.8.3.7.4-1:

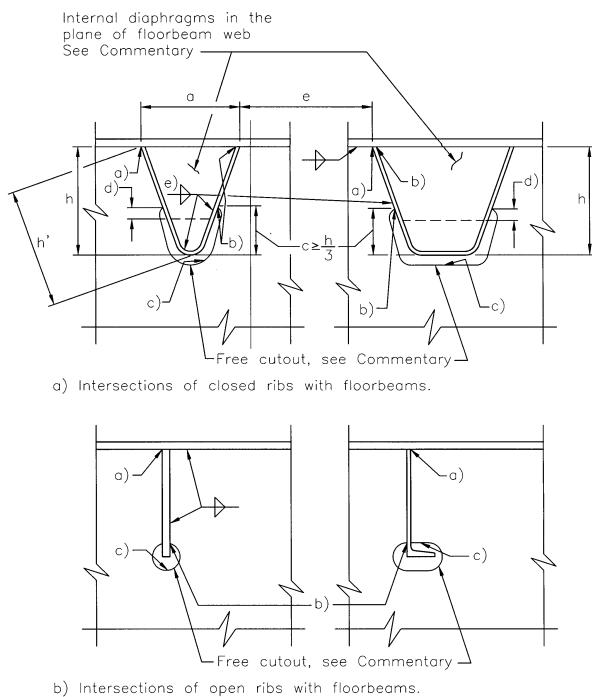

- a) No snipes (cutouts) in floorbeam web
- b) Welds to be wrapped around
- c) Grind smooth
- d) 1.0 in. minimum if internal diaphragm not extended to the bottom of the rib (see commentary)
- e) Combined fillet-groove welds may have to be used in cases where the required size of fillet welds to satisfy the fatigue resistance requirements would be excessive, if used alone.

#### *C9.8.3.7.4*

Closed ribs may be trapezoidal, U-shaped or V-shaped, the latter are most efficient.

The floorbeam web cutouts at the intersections with the ribs may be with or without an additional free cutout at the bottom of the ribs. The former detail is generally preferable since it minimizes the rib restraint against rotation in its plane and associated stresses in the welds and in the floorbeam web.

If the bottom cutout depth  $c$  is small, the rotation of the rib is restrained and considerable out-of-plane stresses are introduced in the floorbeam web when the floorbeam is shallow. Local secondary stresses are also introduced in the rib walls by the interaction forces between the floorbeam webs and the rib walls and by secondary effects due to the small depth of cutout  $c$  (Wolchuk and Ostapenko, 1992). The secondary stresses due to rib-floorbeam interaction can be eliminated if diaphragms are placed inside of the rib in the plane of the floorbeam web. The designer may have the option of either terminating the diaphragm below the top of the free cutout, in which case the diaphragm should extend at least 1.0 in. below the top of the free cutout and must have a fatigue resistant welded connection to the rib wall, or extending the diaphragm to the bottom of the rib and welding all around. Extending the diaphragm to the underside of the deck plate may significantly alleviate local stresses in the deck plate, see commentary regarding Table 6.6.1.2.3-2, Case (12).

**Figure 9.8.3.7.4-1—Detailing Requirements for Orthotropic Decks**

#### 9.8.4—Orthotropic Aluminum Decks

##### 9.8.4.1—General

Orthotropic aluminum decks shall consist of a deck plate stiffened and supported by rib extrusions. The ribs may be parallel or perpendicular to the direction of traffic.

The provisions of Article 9.8.3.2 through Article 9.8.3.3 shall apply, except that the wearing surface shall not be regarded as an integral part of the orthotropic deck for analysis and design of the deck or rib.

When an aluminum orthotropic deck is supported by components of another material, the differences in thermal expansion of the two materials and the potential for accelerated corrosion due to dissimilar metals shall be considered.

The structural interaction of an aluminum orthotropic deck with the existing structure shall be investigated.

##### 9.8.4.2—Approximate Analysis

In lieu of more precise information, the effective width of deck plate acting with a rib shall not exceed the rib spacing or one-third of the span.

The flexibility of the supports shall be considered in determining the longitudinal moments in continuous decks.

In determining the transverse moments, the effects of the torsional rigidity of the ribs shall be included when the ribs are torsionally stiff and may be disregarded if the ribs are torsionally flexible.

For the analysis of decks with closed ribs, the provisions of Article 9.8.3.5.3 may be applied.

If the floorbeam web is deep and flexible, or where additional depth of the cutout would unduly reduce the shear strength of the floorbeam, welding all around the rib periphery may be appropriate (*ECSC Report on Fatigue*, 1995; Wolchuk, 1999).

Fatigue tests suggest that open snipes in the floorbeam webs at the junctions of the rib walls with the deck plate may cause cracks in the rib walls. Therefore, a tight-fitting snipe and a continuous weld between the floorbeam web and the deck and rib wall plates appear to be preferable.

Orthotropic deck failures caused by improper details are discussed elsewhere (Wolchuk, 1991).

Open ribs may be flat bars, angles, tees or bulb bars. Open-rib decks are less efficient, but have better fatigue strength.

##### C9.8.4.1

Only one application of ribs placed perpendicular to traffic was known as of 1997. Therefore, little or no experience of in-service fatigue behavior exists, and complete investigation of load-induced and distortion-induced fatigue should be required for this application.

##### C9.8.4.2

The transverse moments should be calculated in two stages: those due to the direct loading of the deck plate, assuming nondeflecting ribs, and those due to the transverse shear transfer resulting from the rib displacements. Stresses from these moments are then combined.

### **9.8.4.3—Limit States**

Orthotropic decks shall be designed to meet the requirements of Section 7 at all applicable limit states.

At the service limit state, the deck shall satisfy the requirement of Article 2.5.2.6.

The longitudinal ribs, including an effective width of deck plate, shall be investigated for stability as individual beam-columns assumed as simply supported at transverse beams.

At the fatigue limit state, the deck shall satisfy the provisions of Article 7.6.

Regardless of whether the stress range is tensile, compressive, or reversal, maximum stress range shall be investigated for:

- Transverse direction at the rib-to-plate connection;
- Longitudinal direction;
- All bolted, welded end, and edge details; and
- Transverse direction at the rib-to-plate connection when the adjacent rib is loaded.

### **9.8.5—Corrugated Metal Decks**

#### **9.8.5.1—General**

Corrugated metal decks should be used only on secondary and rural roads.

Corrugated metal decks shall consist of corrugated metal pans filled with bituminous asphalt or another approved surfacing material. The metal pans shall be positively fastened to the supporting components.

#### **9.8.5.2—Distribution of Wheel Loads**

A 45-degree distribution of the tire load from the contact area to the neutral axis of the corrugated metal pans may be assumed.

#### **9.8.5.3—Composite Action**

For contribution of the fill to composite action with the deck plate, the provisions of Article 9.8.3.3 shall apply.

Composite action of the corrugated metal deck pan with the supporting components may be considered only if the interface connections are designed for full composite action, and the deck is shown to resist the compressive forces associated with the composite action.

### **C9.8.4.3**

This condition has been shown to control the design under certain geometrical conditions.

The maximum stress range is used for design because significant tensile residual stresses exist adjacent to most weldments, and gross compressive stresses may result in a net tensile stress range.

See Menzemer et al. (1987) for additional discussion.

#### **C9.8.5.1**

The intent of fastening the corrugated metal pans to the supporting components is to ensure the stability of both under transient loads.

#### **C9.8.5.2**

The 45-degree distribution is a traditional approach for most nonmetallic structural materials.

#### **C9.8.5.3**

Due to the sensitivity of the plate to temperature, corrosion, and structural instability, composite action should be utilized only if physical evidence is sufficient to prove that its functionality can be counted on for the specified design life.

## 9.9—WOOD DECKS AND DECK SYSTEMS

### 9.9.1—Scope

This Article shall apply to the design of wood decks supported by beams, stringers, or floorbeams or used as a deck system.

### 9.9.2—General

The provisions of Section 8 shall apply.

Materials used in wood decks and their preservative treatment shall meet the requirements of Sections 2, 5, 6, and 8.

The nominal thickness of plank decks shall not be less than 4.0 in. for roadways and 2.0 in. for sidewalks. The nominal thickness of wood decks other than plank decks shall not be less than 6.0 in.

### C9.9.1

This Article applies to wood decks and deck systems that are currently being designed and built in the United States and that have demonstrated acceptable performance. The supporting components may be metal, concrete, or wood.

### C9.9.2

In laminated decks, large deviations in the thickness or extensive warping of the laminations may be detrimental regarding both strength and long-term performance. Although rough or full sawn material can be more economical than planed, the variations in dimensions can be quite large. If appropriate dimensional tolerances are not likely to be obtained, dressing of the components should be recommended.

### 9.9.3—Design Requirements

#### 9.9.3.1—Load Distribution

Force effects may be determined by using one of the following methods:

- The approximate method specified in Article 4.6.2.1,
- Orthotropic plate theory, or
- Equivalent grillage model.

If the spacing of the supporting components is less than either 36.0 in. or 6.0 times the nominal depth of the deck, the deck system, including the supporting components, shall be modeled as an orthotropic plate or an equivalent grid.

In stress laminated decks, satisfying the butt stagger requirements specified in Article 9.9.5.3, rigidity may be determined without deduction for the butt joints.

#### C9.9.3.1

In wood decks with closely spaced supporting components, the assumption of infinitely rigid supports upon which approximate methods of analysis are based, is not valid. Two-dimensional methods of analysis are, therefore, recommended to obtain force effects with reasonable accuracy.

#### 9.9.3.2—Shear Design

Shear effects may be neglected in the design of stress laminated decks.

In longitudinal decks, maximum shear shall be computed in accordance with the provisions of Article 8.7.

In transverse decks, maximum shear shall be computed at a distance from the support equal to the depth of the deck.

For both longitudinal and transverse decks, the tire footprint shall be located adjacent to, and on the span side of, the point of the span where maximum force effect is sought.

#### C9.9.3.2

Shear problems in laminated wood decks are rare, as the inherent load sharing benefits of the multiple member system are believed to be quite significant. The probability of simultaneous occurrence of potentially weak shear zones in adjacent laminates is low. Therefore, a multiple member shear failure, which would be necessary to propagate shear splits in any one lamination, would be difficult to achieve.

With little test data available, no changes to the shear design for spike laminated decks is being introduced.

### **9.9.3.3—Deformation**

At the service limit state, wood decks shall satisfy the requirements as specified in Article 2.5.2.6.

### **9.9.3.4—Thermal Expansion**

The coefficient of thermal expansion of wood parallel to its fibers shall be taken as 0.000002 per °F.

Thermal effects may be neglected in plank decks and spike laminated decks.

For stress laminated and glued laminated panel decks made continuous over more than 400 ft, relative movements due to thermal expansion with respect to substructures and abutments shall be investigated.

### **9.9.3.5—Wearing Surfaces**

Wood decks shall be provided with a wearing surface conforming to the provisions of Article 9.9.8.

### **9.9.3.6—Skewed Decks**

Where the skew of the deck is less than 25 degrees, transverse laminations may be placed on the skew angle. Otherwise, the transverse laminations shall be placed normal to the supporting components, and the free ends of the laminations at the ends of the deck shall be supported by a diagonal beam or other suitable means.

## **9.9.4—Glued Laminated Decks**

### **9.9.4.1—General**

Glued laminated timber panel decks shall consist of a series of panels, prefabricated with water-resistant adhesives, that are tightly abutted along their edges.

Transverse deck panels shall be continuous across the bridge width.

If the span in the primary direction exceeds 8.0 ft, the panels shall be interconnected with stiffener beams as specified in Article 9.9.4.3.

### **9.9.4.2—Deck Tie-Downs**

Where panels are attached to wood supports, the tie-downs shall consist of metal brackets that are bolted through the deck and attached to the sides of the supporting component. Lag screws or deformed shank spikes may be used to tie panels down to wood support.

Where panels are attached to steel beams, they shall be tied down with metal clips that extend over the beam flange and that are bolted through the deck.

### **C9.9.3.4**

Generally, thermal expansion has not presented problems in wood deck systems. Except for the stress laminated deck and tightly placed glued laminated panels, most wood decks inherently contain gaps at the butt joints that can absorb thermal movements.

### **C9.9.3.5**

Experience has shown that unprotected wood deck surfaces are vulnerable to wear and abrasion and/or may become slippery when wet.

### **C9.9.3.6**

With transverse decks, placement of the laminations on the skew is the easiest and most practical method for small skew angles, and cutting the ends of the laminations on the skew provides a continuous straight edge.

In longitudinal decks, except for stress laminated wood, any skew angle can generally be accommodated by offsetting each adjacent lamination on the skew.

### **C9.9.4.1**

In glued laminated decks built to date, transverse deck panels have been 3.0 to 6.0 ft wide, and longitudinal deck panels have been 3.5 to 4.5 ft wide. The design provisions are considered applicable only to the range of panel sizes given herein.

These design provisions are based upon development work carried out at the USDA Forest Products Laboratory in the late 1970s.

This form of deck is appropriate only for roads having low to medium volumes of commercial vehicles.

### **C9.9.4.2**

The methods of tie-down specified herein are based upon current practices that have proven to be adequate. Use of other methods require approval by Owner.

### 9.9.4.3—Interconnected Decks

#### 9.9.4.3.1—Panels Parallel to Traffic

Interconnection of panels shall be made with transverse stiffener beams attached to the underside of the deck. The distance between stiffener beams shall not exceed 8.0 ft, and the rigidity,  $EI$ , of each stiffener beam shall not be less than 80,000 kip-in.<sup>2</sup>. The beams shall be attached to each deck panel near the panel edges and at intervals not exceeding 15.0 in.

#### 9.9.4.3.2—Panels Perpendicular to Traffic

Interconnection of panels may be made with mechanical fasteners, splines, dowels, or stiffener beams. Where used, the stiffener beams should be continuous over the full length of the span and should be secured through the deck within 6.0 in. of the edges of each panel and as required between edges.

When panels are interconnected with stiffener beams, the beams shall be placed longitudinally along the centerspan of each deck span. Provisions of Article 9.9.4.3.1 shall apply for the design of the stiffener beams.

The live load bending moment per unit width shall be determined in accordance with the provisions of Article 4.6.2.1.3.

### 9.9.4.4—Noninterconnected Decks

Decks not interconnected at their edges shall only be employed on secondary, rural roads. No transfer of force effects at the panel edges shall be assumed in the analysis.

#### C9.9.4.3.1

Although the transverse stiffener beam ensures interpanel shear transfer of loads, some relative deflection will take place. Under frequent heavy loads, this relative deflection will cause reflective cracking of bituminous wearing surfaces.

#### C9.9.4.3.2

The doweling of the deck system is intended to prevent relative displacement of the glued laminated deck panels. A design procedure for dowels can be found in Ritter (1990). With proper prefabrication and construction, this doweled system has proven to be effective in preventing relative displacement between panels. However, in practice, problems with hole alignment and the necessity for field modifications may reduce their efficiency.

Using one longitudinal stiffener beam in each space between girders has proven to be both a practical and effective method of reducing relative displacements between transverse panels.

### C9.9.4.4

The noninterconnected panel deck will likely cause reflective cracking in the wearing surface at the butt joints, even under relatively low levels of loading. It is appropriate only for roads having low volumes of commercial vehicles in order to avoid the extensive maintenance that the wearing surface may require.

### 9.9.5—Stress Laminated Decks

#### 9.9.5.1—General

Stress laminated decks shall consist of a series of wood laminations that are placed edgewise and post-tensioned together, normal to the direction of the lamination.

Stress laminated decks shall not be used where the skew exceeds 45 degrees.

The contract documents shall require that the material be subjected to expansion baths to remove excess oils.

#### C9.9.5.1

The majority of decks of this type include laminations which are 2.0 to 3.0 in. in thickness.

The increased load distribution and load sharing qualities of this deck, coupled with its improved durability under the effects of repeated heavy vehicles, make it the best choice among the several wood decks for high volume road application (Csagoly and Taylor, 1979; Sexsmith et al., 1979).

The structural performance of these decks relies on friction, due to transverse prestress, between the surfaces of the laminations to transfer force effects. Unlike spiked or bolted connections in wood, the friction-based performance of stress laminated decks does not deteriorate with time under the action of repeated heavy loads.

Experience seems to indicate that the use of waterborne preservatives can negatively affect the performance of stress laminated decks. Wood treated with waterborne preservatives responds rapidly to the short-term changes in moisture conditions to which bridges are subjected frequently in most areas of North America. The attendant dimensional changes in the wood can result in substantial changes in the prestressing forces. Wood treated with oil-borne preservatives does not respond so readily to short-term changes in moisture conditions.

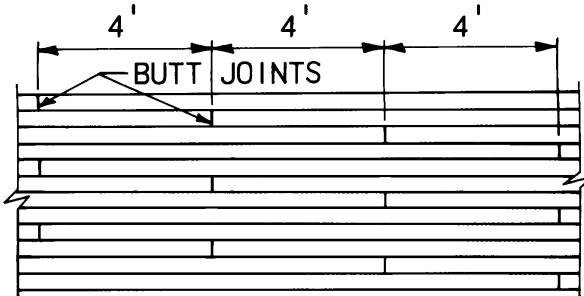

The preservative treatment for wood to be used in stress laminated decks should be kept to the minimum specified in the standards given in Article 8.4.3. Excessive oils in the wood may be expelled after the deck is stressed and can contribute to higher prestress losses over a short period after construction.

#### 9.9.5.2—Nailing

Each lamination shall be specified to be fastened to the preceding one by common or spiral nails at intervals not exceeding 4.0 ft. The nails shall be driven alternately near the top and bottom edges of the laminations. One nail shall be located near both the top and bottom at butt joints. The nails should be of sufficient length to pass through two laminations.

#### 9.9.5.3—Staggered Butt Joints

Where butt joints are used, not more than one butt joint shall occur in any four adjacent laminations within a 4.0 ft distance, as shown in Figure 9.9.5.3-1.

**Figure 9.9.5.3-1—Minimum Spacing of Lines of Butt Joints**

#### 9.9.5.4—Holes in Laminations

The diameter of holes in laminations for the prestressing unit shall not be greater than 20 percent of the lamination depth. Spacing of the holes along the laminations shall be neither less than 15.0 times the hole diameter nor less than 2.5 times the depth of the laminate.

Only drilled holes shall be permitted.

#### C9.9.5.2

Nailing is only a temporary construction convenience in stress laminated decks, and it should be kept as close to minimum requirements as possible. Excessive nailing may inhibit the build up of elastic strains during transverse stressing, which could subsequently contribute to decreasing its effectiveness.

#### C9.9.5.3

Butt joint requirements are extreme values and are intended to allow for lamination lengths that are less than the deck length. Uniformly reducing or eliminating the occurrence of butt joints and/or distributing butt joints will improve performance.

The implication of this provision is that laminations shorter than 16.0 ft cannot be used. If laminations longer than 16.0 ft are used, the spacing of butt joint is one-quarter of the length.

#### C9.9.5.4

These empirical limitations are intended to minimize the negative effects of hole size and spacing on the performance of the deck.

Punched holes can seriously affect the performance of the laminates by breaking the wood fibers in the vicinity of the holes.

### 9.9.5.5—Deck Tie-Downs

Decks shall be tied down at every support, and the spacing of the tie-downs along each support shall not exceed 3.0 ft. Each tie-down shall consist of a minimum of two 0.75-in. diameter bolts for decks up to and including 12.0 in. deep and two 1.0-in. diameter bolts for decks more than 12.0 in. deep.

### 9.9.5.6—Stressing

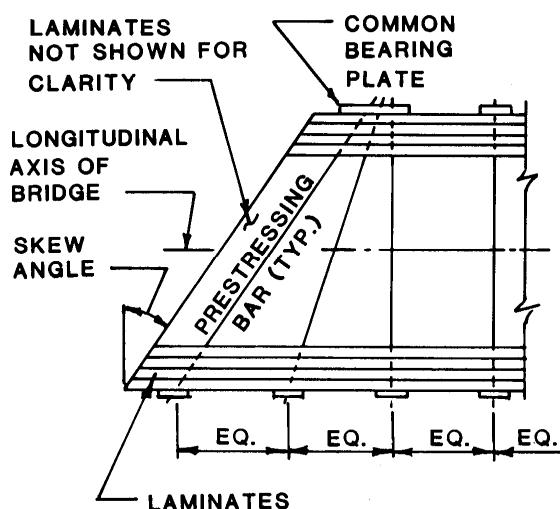

#### 9.9.5.6.1—Prestressing System

New stressed wood decks shall be designed using internal prestressing. External prestressing may be used to rehabilitate existing nail laminated decks and shall utilize continuous steel bulkheads.

In stress laminated decks, with skew angles less than 25 degrees, stressing bars may be parallel to the skew. For skew angles between 25 degrees and 45 degrees, the bars should be placed perpendicular to the laminations, and in the end zones, the transverse prestressing bars should be fanned in plan as shown in Figure 9.9.5.6.1-1 or arranged in a step pattern as shown in Figure 9.9.5.6.1-2.

Dimensional changes in the deck due to prestressing shall be considered in the design.

Anchorage hardware for the prestressing rods should be arranged in one of the three ways shown in Figure 9.9.5.6.1-3.

**Figure 9.9.5.6.1-1—Fanned Layout of Prestressing Bars in End Zones of Skewed Decks—Illustrative Only**

### C9.9.5.5

The stress laminated deck requires a more effective tie-down than toe-nailing or drift pins. It has a tendency to develop curvature perpendicular to the laminates when transversely stressed. Tie-downs using bolts or lag screws ensure proper contact of the deck with the supporting members.

#### C9.9.5.6.1

External and internal prestressing systems are shown in Figure 9.9.5.6.1-3. The internal system provides better protection to the prestressing element and lessens restriction to the application of wearing surfaces.

Generally, it is not necessary to secure timber decks to the supports until all the transverse stressing has been completed. There is the potential for extensive deformation when a deck is stressed over a very long length due to unintentional eccentricity of prestressing. It is recommended that restraints during stressing be provided when the width of the deck, perpendicular to the laminations, exceeds 50.0 times the depth of the deck for longitudinal decks and 40.0 times the depth of the deck for transverse decks. These restraints should not inhibit the lateral movement of the deck over its width during the stressing procedure.

Potential concentration of bearing stresses and sliding of the common bearing plate should be considered in conjunction with the fanned arrangement of prestressing elements shown in Figure 9.9.5.6.1-1.

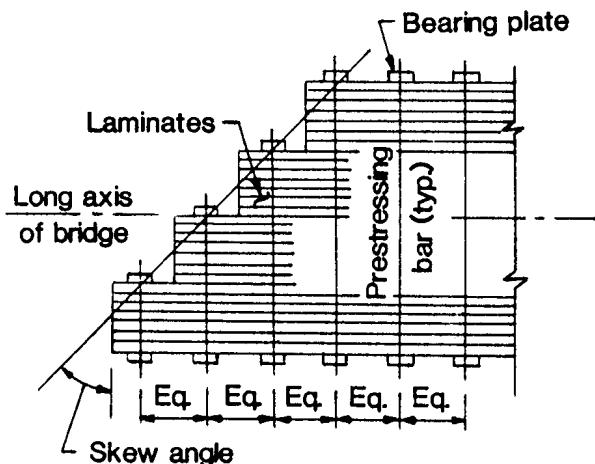

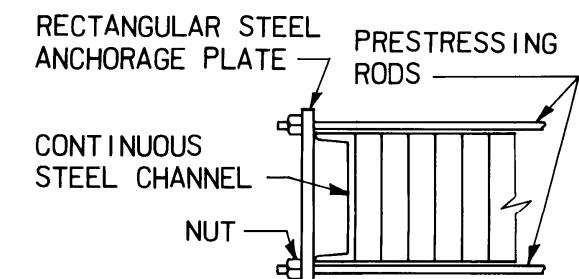

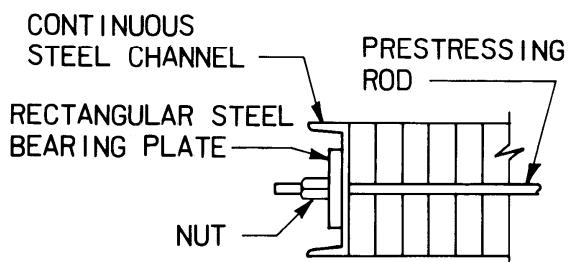

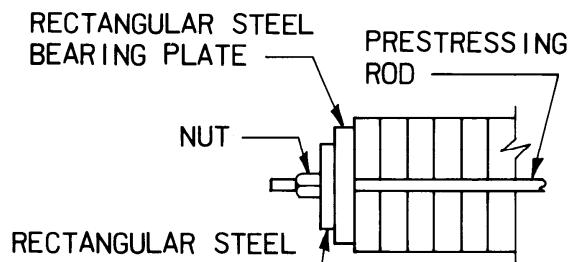

Figure 9.9.5.6.1-2—Staggered Layout of Prestressing Bars in End Zones of Skewed Decks—Illustrative Only

A. EXTERNAL CHANNEL BULKHEAD ANCHORAGE CONFIGURATION.

B. CHANNEL BULKHEAD ANCHORAGE CONFIGURATION.

C. BEARING PLATE ANCHORAGE CONFIGURATION.

Figure 9.9.5.6.1-3—Types of Prestressing Configurations

The isolated steel bearing plates should be used only on hardwood decks, or, where a minimum of two hardwood laminations are provided, on the outside edges of the deck.

#### 9.9.5.6.2—Prestressing Materials

Prestressing materials shall comply with the provisions of Article 5.4.

#### 9.9.5.6.3—Design Requirements

The steel-wood ratio,  $R_{sw}$ , shall satisfy:

$$R_{sw} = \frac{A_s}{sh} \leq 0.0016 \quad (9.9.5.6.3-1)$$

where:

$s$  = spacing of the prestressing elements (in.)

$h$  = depth of deck (in.)

$A_s$  = area of steel bar or strand ( $\text{in.}^2$ )

The prestressing force per prestressing element (kip) shall be determined as:

$$P_{pt} = 0.1hs \quad (9.9.5.6.3-2)$$

The effective bearing area,  $A_B$ , on the wood directly under the anchorage bulkhead due to prestress shall be determined by considering the relative stiffness of the wood deck and the steel bulkhead. The bulkhead shall satisfy:

$$P_{BU} = \phi FA_B \geq P_{pt} \quad (9.9.5.6.3-3)$$

where:

$P_{BU}$  = factored compressive resistance of the wood under the bulkhead (kip)

$\phi$  = resistance factor for compression perpendicular to grain as specified in Article 8.5.2.2

$F$  = as specified in Table 9.9.5.6.3-1

Continuous steel bulkheads or hardwood laminations are required because they improve field performance. Isolated steel bearing plates on softwood decks have caused crushing of the wood, substantially increased stress losses and resulted in poor aesthetics.

#### C9.9.5.6.2

All prestressed wood decks built to date have utilized high-strength bars as the stressing elements. Theoretically, any prestressing system that can be adequately protected against corrosion is acceptable.

#### C9.9.5.6.3

The limitation on the steel-wood area ratio is intended to decrease prestress losses due to relaxation caused by wood and steel creep as well as deck dimensional changes due to variations in wood moisture content. Prestress losses are very sensitive to this ratio, and most existing structures have values less than 0.0016. A small area ratio of 0.0012 to 0.0014, coupled with an initial moisture content of less than 19 percent and proper preservative treatment, will ensure the highest long-term prestress levels in the deck.

The average compressive design stress represents the uniform pressure that is achieved away from the anchorage bulkhead. Limitation on compressive stress at maximum prestress minimizes permanent deformation in the wood. Increasing the initial compressive stress beyond these levels does not significantly increase the final compressive stress after all losses have occurred.

Eq. 9.9.5.6.3-2 is based on a uniform compressive stress of 0.1 ksi between the laminations due to prestressing. For structural analysis, a net compressive stress of 0.04 ksi, after losses, may be assumed.

Relaxation of the prestressing system is time-dependent, and the extensive research work, along with the experience obtained on the numerous field structures, have shown that it is necessary to restress the system after the initial stressing to offset long-term relaxation effects. The optimum stressing sequence is as follows:

- Stress to full design level at time of construction,
- Restress to full design level not less than one week after the initial stressing, and
- Restress to full design level not less than four weeks after the second stressing.

After the first restressing, increasing the time period to the second restressing improves long-term stress retention. Subsequent restressings will further decrease the effects of long-term creep losses and improve stress retention.

**Table 9.9.5.6.3-1—*F* Values for Prestressed Wood Decks**

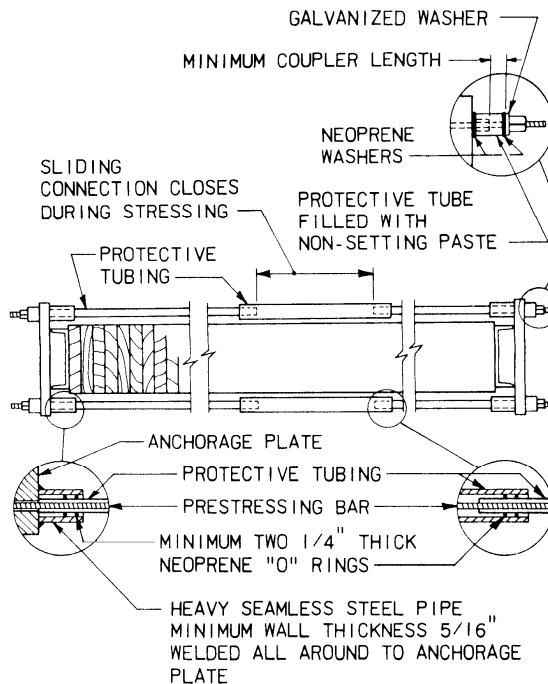

Species	<i>F</i> (ksi)
Douglas Fir Larch	0.425
Hemlock Fir	0.275
Spruce-Pine Fir	0.275
Eastern Softwoods	0.225
Mixed Southern Pine	0.375
Southern Pine	0.375
Spruce-Pine Fir-South	0.225
Northern Red Oak	0.600
Red Maple	0.400
Red Oak	0.550
Yellow Poplar	0.275

**9.9.5.6.4—Corrosion Protection**

Elements of the prestressing system shall be protected by encapsulation and/or surface coatings. The protective tubing shall be capable of adjusting at least ten percent of its length during stressing without damage.

**C9.9.5.6.4**

Elements of a suitable protection system are shown in Figure C9.9.5.6.4-1.

**Figure C9.9.5.6.4-1—Elements of Corrosion Protection****9.9.5.6.5—Railings**

Railings shall not be attached directly either to any prestressing element or to bulkhead systems. The deck shall not be penetrated within 6.0 in. of a prestressing element.

**C9.9.5.6.5**

Curb and rail attachment directly to any component of the stressing system increases the risk of failure in the event of vehicle impact.

## 9.9.6—Spike Laminated Decks

### 9.9.6.1—General

Spike laminated decks shall consist of a series of lumber laminations that are placed edgewise between supports and spiked together on their wide face with deformed spikes of sufficient length to fully penetrate four laminations. The spikes shall be placed in lead holes that are bored through pairs of laminations at each end and at intervals not greater than 12.0 in. in an alternating pattern near the top and bottom of the laminations, as shown in Figure 9.9.6.1-1.

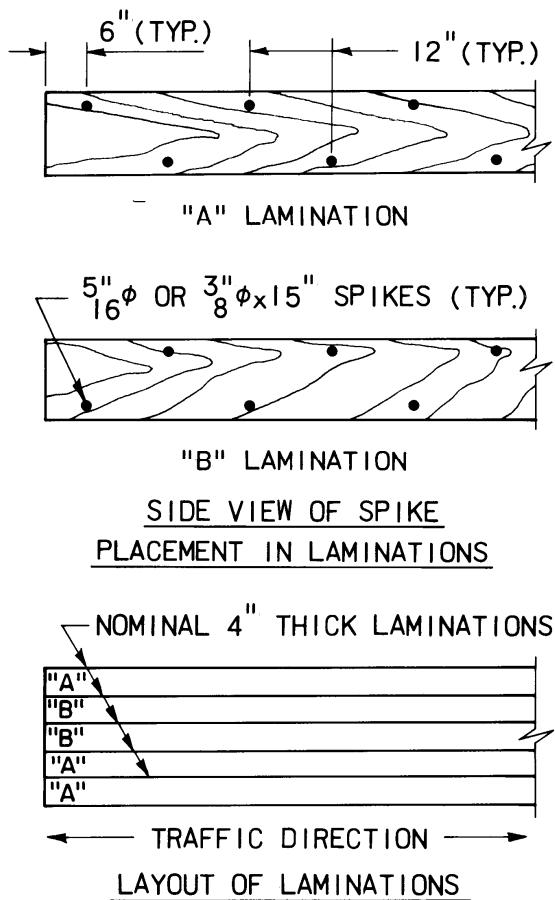

Laminations shall not be butt spliced within their unsupported length.

### C9.9.6.1

The use of spike laminated decks should be limited to secondary roads with low truck volumes, i.e., *ADTT* significantly less than 100 trucks per day.

The majority of decks of this type have used laminations of 3.0 to 4.0 in. in thickness. The laminates are either assembled on site or are prefabricated into panels in preparation for such assembly.

The specified design details for lamination arrangement and spiking are based upon current practice. It is important that the spike lead holes provide a tight fit to ensure proper load transfer between laminations and to minimize mechanical movements.

**Figure 9.9.6.1-1—Spike Layout for Spike Laminated Decks**

### 9.9.6.2—Deck Tie-Downs

Deck tie-downs shall be as specified in Article 9.9.4.2.

### 9.9.6.3—Panel Decks

The distribution widths for interconnected spike laminated panels may be assumed to be the same as those for continuous decks, as specified in Section 4.

The panels may be interconnected with mechanical fasteners, splines, dowels, or stiffener beams to transfer shear between the panels. If stiffener beams are used, the provisions of Article 9.9.4.3 shall apply.

### C9.9.6.3

The use of noninterconnected decks should be limited to secondary and rural roads.

It is important to provide an effective interconnection between panels to ensure proper load transfer. Stiffener beams, comparable to those specified for glued laminated timber panels, are recommended. Use of an adequate stiffener beam enables the spike laminated deck to approach the serviceability of glue laminated panel construction.

With time, the deck may begin to delaminate in the vicinity of the edge-to-edge panel joints. The load distribution provisions given for the noninterconnected panels are intended for use in the evaluation of existing noninterconnected panel decks and interconnected panel decks in which the interconnection is no longer effective.

### 9.9.7—Plank Decks

#### 9.9.7.1—General

Wood plank decks shall consist of a series of lumber planks placed flatwise on supports. Butt joints shall be placed over supports and shall be staggered a minimum of 3.0 ft for adjacent planks.

#### C9.9.7.1

This type of deck has been used on low volume roads with little or no heavy vehicles, and it is usually economical. However, these decks provide no protection against moisture to the supporting members; they will not readily accept and/or retain a bituminous wearing surface and usually require continuous maintenance if used by heavy vehicles.

These decks should be limited to roads that carry little or no heavy vehicles or where the running surface is constantly monitored and maintained.

#### 9.9.7.2—Deck Tie-Downs

On wood beams, each plank shall be nailed to each support with two nails of minimum length equal to twice the plank thickness.

On steel beams, planks shall be bolted to the beams or nailed to wood nailing strips. The strips should be at least 4.0 in. thick, and their width should exceed that of the beam flange. The strips should be secured with A 307 bolts at least 0.625 in. in diameter and placed through the flanges, spaced not more than 4.0 ft apart and no more than 1.5 ft from the ends of the strips.

### 9.9.8—Wearing Surfaces for Wood Decks

#### 9.9.8.1—General

Wearing surfaces shall be of continuous nature and no nails, except in wood planks, shall be used to fasten them to the deck.

#### C9.9.8.1

Bituminous wearing surfaces are recommended for wood decks.

The surface of wood deck should be free of surface oils to encourage adhesion and prevent bleeding of the preservative treatment through the wearing surface. Excessive bleeding of the treatment can seriously reduce the adhesion. The plans and specifications should clearly state that the deck material be treated using the empty cell process, followed by an expansion bath or steaming.

### 9.9.8.2—Plant Mix Asphalt

An approved tack coat shall be applied to wood decks prior to the application of an asphalt wearing surface. The tack coat may be omitted when a geotextile fabric is used, subject to the recommendations of the manufacturer.

When possible, a positive connection between the wood deck and the wearing surface shall be provided. This connection may be provided mechanically or with a geotextile fabric.

The asphalt should have a minimum compacted depth of 2.0 in. Where cross slope is not provided by the wood deck, a minimum of one percent shall be provided by the wearing surface.

### 9.9.8.3—Chip Seal

When a chip seal wearing surface is used on wood decks, a minimum of two layers should be provided.

### C9.9.8.2

The application of a tack coat greatly improves the adhesion of asphalt wearing surfaces.

Due to the smooth surface of individual laminations and glued laminated decks, it is beneficial to provide a positive connection in order to ensure proper performance. The use of asphalt impregnated geotextile fabric, when installed properly, has proven to be effective.

Asphalt wearing surfaces on stress laminated wood decks have proven to perform well with only a tack coat and no reinforcement between the deck and the asphalt.

### C9.9.8.3

Laminated decks may have offset laminations creating irregularities on the surface, and it is necessary to provide an adequate depth of wearing surface to provide proper protection to the wood deck. Chip seal wearing surfaces have a good record as applied to stress laminated decks due to their behavior approaching that of solid slabs.

## SECTION 10

# FOUNDATIONS

### 10.1—SCOPE

Provisions of this Section shall apply for the design of spread footings, driven piles, drilled shaft, and micropile foundations.

The probabilistic LRFD basis of these Specifications, which produces an interrelated combination of load, load factor resistance, resistance factor, and statistical reliability, shall be considered when selecting procedures for calculating resistance other than that specified herein. Other methods, especially when locally recognized and considered suitable for regional conditions, may be used if resistance factors are developed in a manner that is consistent with the development of the resistance factors for the method(s) provided in these Specifications, and are approved by the Owner.

### 10.2—DEFINITIONS

*Battered Pile*—A pile or micropile installed at an angle inclined to the vertical to provide higher resistance to lateral loads.

*Bearing Pile*—A pile or micropile whose purpose is to carry axial load through friction or point bearing.

*Bent*—A type of pier comprised of multiple columns or piles supporting a single cap and in some cases connected with bracing.

*Bent Cap*—A flexural substructure element supported by columns or piles that receives loads from the superstructure.

*Bond Length*—The length of a micropile that is bonded to the ground and which is conceptually used to transfer the applied axial loads to the surrounding soil or rock. Also known as the load transfer length.

*Casing*—Steel pipe introduced during the drilling process to temporarily stabilize the drill hole. Depending on the details of micropile construction and composition, this casing may be fully extracted during or after grouting, or may remain partially or completely in place as part of the final micropile pile configuration.

*Centralizer*—A device to centrally locate the core steel within a borehole.

*Column Bent*—A type of bent that uses two or more columns to support a cap. Columns may be drilled shafts or other independent units supported by individual footings or a combined footing; and may employ bracing or struts for lateral support above ground level.

*Combination Point Bearing and Friction Pile*—Pile that derives its capacity from contributions of both point bearing developed at the pile tip and resistance mobilized along the embedded shaft.

*Combined Footing*—A footing that supports more than one column.

*Core Steel*—Reinforcing bars or pipes used to strengthen or stiffen a micropile, excluding any left-in casing.

*CPT*—Cone Penetration Test.

*CU*—Consolidated Undrained.

*Deep Foundation*—A foundation that derives its support by transferring loads to soil or rock at some depth below the structure by end bearing, adhesion or friction, or both.

*DMT*—Flat Plate Dilatometer Test.

### C10.1

The development of the resistance factors provided in this Section are summarized in Allen (2005), with additional details provided in Appendix A of Barker et al. (1991), in Paikowsky et al. (2004), in Allen (2005), and in D'Appolonia (2006).

The specification of methods of analysis and calculation of resistance for foundations herein is not intended to imply that field verification and/or reaction to conditions actually encountered in the field are no longer needed. These traditional features of foundation design and construction are still practical considerations when designing in accordance with these Specifications.

**Drilled Shaft**—A deep foundation unit, wholly or partly embedded in the ground, constructed by placing fresh concrete in a drilled hole with or without steel reinforcement. Drilled shafts derive their capacity from the surrounding soil and/or from the soil or rock strata below its tip. Drilled shafts are also commonly referred to as caissons, drilled caissons, bored piles, or drilled piers.

**Effective Stress**—The net stress across points of contact of soil particles, generally considered as equivalent to the total stress minus the pore water pressure.

**ER**—Hammer efficiency expressed as percent of theoretical free fall energy delivered by the hammer system actually used in a Standard Penetration Test.

**Free (Unbonded) Length**—The designed length of a micropile that is not bonded to the surrounding ground or grout.

**Friction Pile**—A pile whose support capacity is derived principally from soil resistance mobilized along the side of the embedded pile.

**Geomechanics Rock Mass Rating System**—Rating system developed to characterize the engineering behavior of rock masses (Bieniawski, 1984).

**Geotechnical Bond Strength**—The nominal grout-to-ground bond strength.

**IGM**—Intermediate Geomaterial, a material that is transitional between soil and rock in terms of strength and compressibility, such as residual soils, glacial tills, or very weak rock.

**Isolated Footing**—Individual support for the various parts of a substructure unit; the foundation is called a footing foundation.

**Length of Foundation**—Maximum plan dimension of a foundation element.

**Load Test**—Incremental loading of a foundation element, recording the total movement at each increment.

**Micropile**—A small-diameter drilled and grouted non-displacement pile (normally less than 12 in.) that is typically reinforced.

**OCR**—Over Consolidation Ratio, the ratio of the preconsolidation pressure to the current vertical effective stress.

**Pile**—A slender deep foundation unit, wholly or partly embedded in the ground, that is installed by driving, drilling, auguring, jetting, or otherwise and that derives its capacity from the surrounding soil and/or from the soil or rock strata below its tip.

**Pile Bent**—A type of bent using pile units, driven or placed, as the column members supporting a cap.

**Pile Cap**—A flexural substructure element located above or below the finished ground line that receives loads from substructure columns and is supported by shafts or piles.

**Pile Shoe**—A metal piece fixed to the penetration end of a pile to protect it from damage during driving and to facilitate penetration through very dense material.

**Piping**—Progressive erosion of soil by seeping water that produces an open pipe through the soil through which water flows in an uncontrolled and dangerous manner.

**Plunge Length**—The length of casing inserted into the bond zone to effect a transition between the upper cased portion to the lower uncased portion of a micropile.

**Plunging**—A mode of behavior observed in some pile load tests, wherein the settlement of the pile continues to increase with no increase in load.

**PMT**—Pressuremeter Test.

**Point-Bearing Pile**—A pile whose support capacity is derived principally from the resistance of the foundation material on which the pile tip bears.

*Post Grouting*—The injection of additional grout into the load bond length of a micropile after the primary grout has set. Also known as regROUTing or secondary grouting.

*Primary Grout*—Portland cement-based grout that is injected into a micropile hole, prior to or after the installation of the reinforcement to provide the load transfer to the surrounding ground along the micropile and afford a degree of corrosion protection for a micropile loaded in compression.

*Reinforcement*—The steel component of a micropile which accepts and/or resists applied loadings.

*RMR*—Rock Mass Rating.

*RQD*—Rock Quality Designation.

*Shallow Foundation*—A foundation that derives its support by transferring load directly to the soil or rock at shallow depth.

*Slickensides*—Polished and grooved surfaces in clayey soils or rocks resulting from shearing displacements along planes.

*SPT*—Standard Penetration Test.

*Total Stress*—Total pressure exerted in any direction by both soil and water.

*UU*—Unconsolidated Undrained.

*VST*—Vane Shear Test (performed in the field).

*Width of Foundation*—Minimum plan dimension of a foundation element.

### 10.3—NOTATION

$A$	= steel pile cross-sectional area ( $\text{ft}^2$ ) (10.7.3.8.2)
$A_b$	= cross-sectional area of steel reinforcing bar ( $\text{in.}^2$ ) (10.9.3.10.2a)
$A_c$	= cross-sectional area of steel casing ( $\text{in.}^2$ ) (10.9.3.10.2a)
$A_{ct}$	= cross-sectional area of steel casing considering reduction for threads ( $\text{in.}^2$ ) (10.9.3.10.3a)
$A_g$	= cross-sectional area of grout within micropile ( $\text{in.}^2$ ) (10.9.3.10.3a)
$A_p$	= area of pile or micropile tip or base of drilled shaft ( $\text{ft}^2$ ) (10.7.3.8.6a) (10.8.3.5) (10.9.3.5.1)
$A_s$	= surface area of pile shaft; area of grout to ground bond surface of micropile through bond length ( $\text{ft}^2$ ) (10.7.3.8.6a) (10.9.3.5.1)
$A_u$	= uplift area of a belled drilled shaft ( $\text{ft}^2$ ) (10.8.3.7.2)
$A'$	= effective footing area for determination of elastic settlement of footing subjected to eccentric loads ( $\text{ft}^2$ ) (10.6.2.4.2)
$a_{si}$	= pile perimeter at the point considered (ft) (10.7.3.8.6g)
$B$	= footing width; pile group width; pile diameter (ft) (10.6.1.3) (10.7.2.3.2) (10.7.2.4)
$B'$	= effective footing width (ft) (10.6.1.3)
$C_a$	= secondary compression index, void ratio definition (dim) (10.4.6.3)
$C_{a\varepsilon}$	= secondary compression index, strain definition (dim) (10.6.2.4.3)
$C_c$	= compression index, void ratio definition (dim) (10.4.6.3)
$C_{c\varepsilon}$	= compression index, strain definition (dim) (10.6.2.4.3)
$C_F$	= correction factor for $K_\delta$ when $\delta$ is not equal to $\phi_f$ (dim) (10.7.3.8.6f)
$C_N$	= overburden stress correction factor for N (dim) (10.4.6.2.4)
$C_r$	= recompression index, void ratio definition (dim) (10.4.6.3)
$C_{re}$	= recompression index, strain definition (dim) (10.6.2.4.3)
$C_{wg}, C_{wy}$	= correction factors for groundwater effect (dim) (10.6.3.1.2a)
$C'$	= bearing capacity index (dim) (10.6.2.4.2)
$c$	= cohesion of soil taken as undrained shear strength (ksf) (10.6.3.1.2a)
$c_v$	= coefficient of consolidation ( $\text{ft}^2/\text{yr}$ ) (10.4.6.3)
$c_1$	= undrained shear strength of the top layer of soil as depicted in Figure 10.6.3.1.2e-1 (ksf) (10.6.3.1.2e)
$c_2$	= undrained shear strength of the lower layer of soil as depicted in Figure 10.6.3.1.2e-1 (ksf) (10.6.3.1.2e)
$c'_1$	= drained shear strength of the top layer of soil (ksf) (10.6.3.1.2f)
$c^*$	= reduced effective stress soil cohesion for punching shear (ksf) (10.6.3.1.2b)

$c'$	= effective stress cohesion intercept (ksf) (10.4.6.2.3)
$c'_i$	= instantaneous cohesion at a discrete value of normal stress (ksf) (C10.4.6.4)
$D$	= depth of pile embedment; pile width or diameter; diameter of drilled shaft (ft) (10.7.2.3) (10.7.3.8.6g) (10.8.3.5.1c)
$DD$	= downdrag load per pile (kips) (C10.7.3.7)
$D'$	= effective depth of pile or micropile group (ft) (10.7.2.3.2) (10.9.2.3.2)
$D_b$	= depth of embedment of pile into a bearing stratum (ft) (10.7.2.3.2)
$D_{est}$	= estimated pile length needed to obtain desired nominal resistance per pile (ft) (C10.7.3.7)
$D_f$	= foundation embedment depth taken from ground surface to bottom of footing (ft) (10.6.3.1.2a)
$D_i$	= pile width or diameter at the point considered (ft) (10.7.3.8.6g)
$D_p$	= diameter of the bell on a belled drilled shaft (ft) (10.8.3.7.2)
$D_r$	= relative density (percent) (C10.6.3.1.2b)
$D_w$	= depth to water surface taken from the ground surface (ft) (10.6.3.1.2a)
$d_b$	= grouted bond zone diameter (ft) (10.9.3.5.2)
$d_q$	= correction factor to account for the shearing resistance along the failure surface passing through cohesionless material above the bearing elevation (dim) (10.6.3.1.2a)
$E$	= modulus of elasticity of pile material (ksi) (10.7.3.8.2)
$E_d$	= developed hammer energy (ft-lb) (10.7.3.8.5)
$E_i$	= modulus of elasticity of intact rock (ksi) (10.4.6.5)
$E_m$	= rock mass modulus (ksi) (10.4.6.5)
$E_p$	= modulus of elasticity of pile (ksi) (10.7.3.13.4)
$ER$	= hammer efficiency expressed as percent of theoretical free fall energy delivered by the hammer system actually used (dim) (10.4.6.2.4)
$E_s$	= soil (Young's) modulus (ksi) (C10.4.6.3)
$e$	= void ratio (dim) (10.6.2.4.3)
$e_B$	= eccentricity of load parallel to the width of the footing (ft) (10.6.1.3)
$e_L$	= eccentricity of load parallel to the length of the footing (ft) (10.6.1.3)
$e_o$	= void ratio at initial vertical effective stress (dim) (10.6.2.4.3)
$F_{CO}$	= base resistance of wood in compression parallel to the grain (ksi) (10.7.8)
$f'_c$	= 28-day compressive strength of concrete or grout, unless another age is specified (ksi) (10.6.2.6.2) (10.9.3.10.2a)
$f_{pe}$	= effective stress in the prestressing steel after losses (ksi) (10.7.8)
$f_s$	= approximate constant sleeve friction resistance measured from a CPT at depths below $8D$ (ksf) (C10.7.3.8.6g)
$f_{si}$	= unit local sleeve friction resistance from CPT at the point considered (ksf) (10.7.3.8.6g)
$f_y$	= specified minimum yield strength of steel (ksi) (10.7.8) (10.9.3.10.2a)
$H$	= horizontal component of inclined loads (kips) (10.6.3.1.2a)
$H_c$	= height of compressible soil layer (ft) (10.6.2.4.2)
$H_{crit}$	= minimum distance below a spread footing to a second separate layer of soil with different properties that will affect shear strength of the foundation (ft) (10.6.3.1.2d)
$H_d$	= length of longest drainage path in compressible soil layer (ft) (10.6.2.4.3)
$H_s$	= height of sloping ground mass (ft) (10.6.3.1.2c)
$H_{s2}$	= distance from bottom of footing to top of the second soil layer (ft) (10.6.3.1.2e)
$h_i$	= length interval at the point considered (ft) (10.7.3.8.6g)
$I$	= influence factor of the effective group embedment (dim) (10.7.2.3.2)
$I_p$	= influence coefficient to account for rigidity and dimensions of footing (dim) (10.6.2.4.4)
$I_w$	= weak axis moment of inertia for a pile ( $\text{ft}^4$ ) (10.7.3.13.4)
$i_c, i_q, i_\gamma$	= load inclination factors (dim) (10.6.3.1.2a)
$j$	= damping constant (dim) (10.7.3.8.3)
$K_c$	= correction factor for side friction in clay (dim) (10.7.3.8.6g)
$K_s$	= correction factor for side friction in sand (dim) (10.7.3.8.6g)
$K_\delta$	= coefficient of lateral earth pressure at midpoint of soil layer under consideration (dim) (10.7.3.8.6f)
$L$	= length of foundation; pile length (ft) (10.6.1.3) (10.7.3.8.2)
$L_b$	= micropile bonded length (ft) (10.9.3.5.2)
$L_i$	= depth to middle of length interval at the point considered (ft) (10.7.3.8.6g)
$L_p$	= micropile casing plunge length (ft) (10.9.3.10.4)
$L'$	= effective footing length (ft) (10.6.1.3)
$LL$	= liquid limit of soil (percent) (10.4.6.3)
$N$	= uncorrected Standard Penetration Test (SPT) blow count (blows/ft) (10.4.6.2.4)

\*\*\*\*\*

$\bar{N}_1$	= average corrected SPT blow count along pile side (blows/ft) (10.7.3.8.6g)
$N_1$	= SPT blow count corrected for overburden pressure $\sigma'_v$ (blows/ft) (10.4.6.2.4)
$N_{160}$	= SPT blow count corrected for both overburden and hammer efficiency effects (blows/ft) (10.4.6.2.4) (10.7.2.3.2)
$N_b$	= number of hammer blows for 1 in. of pile permanent set (blows/in.) (10.7.3.8.5)
$N_c$	= cohesion term (undrained loading) bearing capacity factor (dim) (10.6.3.1.2a)
$N_{cm}, N_{q_m}$	
$N_{qm}$	= modified bearing capacity factors (dim) (10.6.3.1.2a)
$N_{cq}$	= modified bearing capacity factor (dim) (10.6.3.1.2e)
$N_m$	= modified bearing capacity factor (dim) (10.6.3.1.2e)
$N_s$	= slope stability factor (dim) (10.6.3.1.2c)
$N_q$	= surcharge (embedment) term (drained or undrained loading) bearing capacity factor (dim) (10.6.3.1.2a)
$N_u$	= uplift adhesion factor for bell (dim) (10.8.3.7.2)
$N'$	= alternate notation for $N_1$ (blows/ft) (10.6.2.4.2)
$N'_{q_p}$	= pile bearing capacity factor from Figure 10.7.3.8.6f-8 (dim) (10.7.3.8.6f)
$N_\gamma$	= unit weight (footing width) term (drained loading) bearing capacity factor (dim) (10.6.3.1.2a)
$N_1$	= number of intervals between the ground surface and a point $8D$ below the ground surface (dim) (10.7.3.8.6g)
$N_2$	= number of intervals between $8D$ below the ground surface and the tip of the pile (dim) (10.7.3.8.6g)
$N_{60}$	= SPT blow count corrected for hammer efficiency (blows/ft) (10.4.6.2.4)
$n$	= porosity (dim); number of soil layers within zone of stress influence of the footing (dim) (10.4.6.2.4) (10.6.2.4.2)
$n_h$	= rate of increase of soil modulus with depth (ksi/ft) (10.4.6.3)
$PL$	= plastic limit of soil (percent) (10.4.6.3)
$P_f$	= probability of failure (dim) (C10.5.5.2.1)
$P_m$	= $p$ -multiplier from Table 10.7.2.4-1 (dim) (10.7.2.4)
$P_t$	= factored axial load transferred to ground along micropile plunge length (kips) (10.9.3.10.4)
$P_u$	= factored axial load on uncased micropile segment adjusted for plunge length load transfer (10.9.3.10.4)
$p_a$	= atmospheric pressure (ksf) (Sea level value equivalent to 2.12 ksf or 1 atm or 14.7 psi) (10.8.3.5.1b)
$Q$	= load applied to top of footing, shaft, or micropile (kips); load test load (kips) (C10.6.3.1.2b) (10.7.3.8.2) (10.9.3.10.4)
$Q_f$	= load at failure during load test (kips) (10.7.3.8.2)
$Q_g$	= bearing capacity for block failure (kips) (C10.7.3.9)
$Q_p$	= factored load per pile, excluding downdrag load (kips) (C10.7.3.7)
$Q_{T1}$	= total load acting at the head of the drilled shaft (kips) (C10.8.3.5.4d)
$q$	= net foundation pressure applied at $2D_b/3$ ; this pressure is equal to applied load at top of the group divided by the area of the equivalent footing and does not include the weight of the piles or the soil between the piles (ksf) (10.7.2.3.2)
$q_c$	= static cone tip resistance (ksf) (C10.4.6.3)
$\bar{q}_c$	= average static cone tip resistance over a depth $B$ below the equivalent footing (ksf) (10.6.3.1.3)
$q_{c1}$	= average $q_c$ over a distance of $yD$ below the pile tip (path a-b-c) (ksf) (10.7.3.8.6g)
$q_{c2}$	= average $q_c$ over a distance of $8D$ above the pile tip (path c-e) (ksf) (10.7.3.8.6g)
$q_L$	= limiting unit tip resistance of a single pile from Figure 10.7.3.8.6f-9 (ksf) (10.7.3.8.6f)
$q_\ell$	= limiting tip resistance of a single pile (ksf) (10.7.3.8.6g)
$q_n$	= nominal bearing resistance (ksf) (10.6.3.1.1)
$q_o$	= applied vertical stress at base of loaded area (ksf) (10.6.2.4.2)
$q_p$	= nominal unit tip resistance of pile or micropile (ksf) (10.7.3.8.6a) (10.9.3.5.1)
$q_R$	= factored bearing resistance (ksf) (10.6.3.1.1)
$q_s$	= unit shear resistance (ksf); unit side resistance of pile or micropile (ksf) (10.6.3.4) (10.7.3.8.6a) (10.9.3.5.1)
$q_{bell}$	= nominal unit uplift resistance of a belled drilled shaft (ksf) (10.8.3.7.2)
$q_u$	= uniaxial compression strength of rock (ksf) (10.4.6.4)
$q_{ult}$	= nominal bearing resistance (ksf) (10.6.3.1.2e)
$q_1$	= nominal bearing resistance of footing supported in the upper layer of a two-layer system, assuming the upper layer is infinitely thick (ksf) (10.6.3.1.2d)
$q_2$	= nominal bearing resistance of a fictitious footing of the same size and shape as the actual footing but supported on surface of the second (lower) layer of a two-layer system (ksf) (10.6.3.1.2d)

$R_C$	= factored micropile structural axial compression resistance (kips) (10.9.3.10.2)
$R_{CC}$	= factored structural axial compression resistance of cased micropile segments (kips) (10.9.3.10.2a)
$R_{CU}$	= factored structural axial compression resistance of uncased micropile segments (kips) (10.9.3.10.2b)
$R_{ep}$	= nominal passive resistance of soil available throughout the design life of the structure (kips) (10.6.3.4)
$R_n$	= nominal resistance of footing, pile, shaft, or micropile (kips) (10.6.3.4)
$R_{ndr}$	= nominal pile driving resistance including downdrag (kips) (C10.7.3.3)
$R_{nstat}$	= nominal resistance of pile from static analysis method (kips) (C10.7.3.3)
$R_p$	= nominal pile or micropile tip resistance (kips) (10.7.3.8.6a) (10.9.3.5.1)
$R_R$	= factored nominal resistance of a footing, pile, micropile, or shaft (kips) (10.6.3.4) (10.9.3.5.1)
$R_s$	= pile side resistance (kips); nominal uplift resistance due to side resistance (kips); nominal micropile grout-to-ground bond resistance (kips) (10.7.3.8.6a) (10.7.3.10) (C10.9.3.5.1)
$R_{sbell}$	= nominal uplift resistance of a belled drilled shaft (kips) (10.8.3.5.2)
$R_{sdd}$	= skin friction which must be overcome during driving (kips) (C10.7.3.7)
$R_T$	= factored structural axial tension resistance (kips) (10.9.3.10.3)
$R_{TC}$	= factored structural axial tension resistance of cased micropile segments (kips) (10.9.3.10.3a)
$R_{TU}$	= factored structural axial tension resistance of uncased micropile segments (kips) (10.9.3.10.3b)
$R_{ug}$	= nominal uplift resistance of a pile group (kips) (10.7.3.11)
$R_\tau$	= nominal sliding resistance between the footing and the soil (kips) (10.6.3.4)
$r$	= radius of circular footing or $B/2$ for square footing (ft) (10.6.2.4.4)
$S_c$	= primary consolidation settlement (ft) (10.6.2.4.1)
$S_{c(1-D)}$	= single dimensional consolidation settlement (ft) (10.6.2.4.3)
$S_e$	= elastic settlement (ft) (10.6.2.4.1)
$S_s$	= secondary settlement (ft) (10.6.2.4.1)
$S_t$	= total settlement (ft) (10.6.2.4.1)
$S_u$	= undrained shear strength (ksf) (10.4.6.2.2)
$\overline{S}_u$	= average undrained shear strength along pile side (ksf) (10.7.3.9)
$s$	= pile permanent set (in.) (10.7.3.8.5)
$s, m$	= fractured rock mass parameters (10.4.6.4)
$s_c, s_q, s_\gamma$	= shape factors (dim) (10.6.3.1.2a)
$s_f$	= pile top movement during load test (in.) (10.7.3.8.2)
$T$	= time factor (dim) (10.6.2.4.3)
$t$	= time for a given percentage of one-dimensional consolidation settlement to occur (yr) (10.6.2.4.3)
$t_1, t_2$	= arbitrary time intervals for determination of secondary settlement, $S_s$ (yr) (10.6.2.4.3)
$U$	= percentage of consolidation (10.6.2.4.3)
$V$	= total vertical force applied by a footing (kips); pile displacement volume ( $\text{ft}^3/\text{ft}$ ) (10.6.3.1.2a) (10.7.3.8.6f)
$W_g$	= weight of block of soil, piles and pile cap (kips) (10.7.3.11)
$W_{T1}$	= vertical movement at the head of the drilled shaft (in.) (C10.8.3.5.4d)
$X$	= width or smallest dimension of pile group (ft) (10.7.3.9)
$Y$	= length of pile group (ft) (10.7.3.9)
$Z$	= total embedded pile length; penetration of shaft (ft) (10.7.3.8.6g)
$z$	= depth below ground surface (ft) (C10.4.6.3)
$\alpha$	= adhesion factor applied to $s_u$ (dim) (10.7.3.8.6b)
$\alpha_b$	= nominal micropile grout-to-ground bond stress (ksf) (10.9.3.5.2)
$\alpha_E$	= reduction factor to account for jointing in rock (dim) (10.8.3.5.4b)
$\alpha_t$	= coefficient from Figure 10.7.3.8.6f-7 (dim) (10.7.3.8.6f)
$\beta$	= reliability index; coefficient relating the vertical effective stress and the unit skin friction of a pile or drilled shaft (dim) (C10.5.5.2.1) (10.7.3.8.6c)
$\beta_m$	= punching index (dim) (10.6.3.1.2e)
$\beta_z$	= factor to account for footing shape and rigidity (dim) (10.6.2.4.2)
$\gamma$	= unit density of soil (kcf) (10.6.3.1.2a)
$\gamma_p$	= load factor for downdrag (C10.7.3.7)
$\Delta H_i$	= elastic settlement of layer $i$ (ft) (10.6.2.4.2)
$\delta$	= elastic deformation of pile (in.); friction angle between foundation and soil (degrees) (C10.7.3.8.2) (10.7.3.8.6f)
$\epsilon_v$	= vertical strain of over consolidated soil (in./in.) (10.6.2.4.3)

$\eta$	= shaft efficiency reduction factor for axial resistance of a drilled shaft or micropile group (dim) (10.7.3.9)
$\lambda$	= empirical coefficient relating the passive lateral earth pressure and the unit skin friction of a pile (dim) (10.7.3.8.6d)
$\mu_c$	= reduction factor for consolidation settlements to account for three-dimensional effects (dim) (10.6.2.4.3)
$\phi_f$	= angle of internal friction of drained soil (degrees) (10.4.6.2.4)
$\phi'_f$	= drained (long term) effective angle of internal friction of clays (degrees) (10.4.6.2.3)
$\phi'_i$	= instantaneous friction angle of the rock mass (degrees) (10.4.6.4)
$\phi'_1$	= effective stress angle of internal friction of the top layer of soil (degrees) (10.6.3.1.2f)
$\phi'_s$	= secant friction angle (degrees) (10.4.6.2.4)
$\phi^*$	= reduced effective stress soil friction angle for punching shear (degrees) (10.6.3.1.2b)
$\varphi$	= resistance factor (dim) (10.5.5.2.3)
$\varphi_b$	= resistance factor for bearing of shallow foundations (dim) (10.5.5.2.2)
$\varphi_{bl}$	= resistance factor for driven piles or shafts, block failure in clay (dim) (10.5.5.2.3)
$\varphi_C$	= structural resistance factor for micropiles in axial compression (dim) (10.9.3.10.2)
$\varphi_{CC}$	= structural resistance factor for cased micropiles segments in axial compression (dim) (10.9.3.10.2a)
$\varphi_{CU}$	= structural resistance factor for uncased micropiles segments in axial compression (dim) (10.9.3.10.2b)
$\varphi_{da}$	= resistance factor for driven piles, drivability analysis (dim) (10.5.5.2.3)
$\varphi_{dyn}$	= resistance factor for driven piles, dynamic analysis and static load test methods (dim) (10.5.5.2.3)
$\varphi_{ep}$	= resistance factor for passive soil resistance (dim) (10.5.5.2.2)
$\varphi_{load}$	= resistance factor for shafts, static load test (dim) (10.5.5.2.4)
$\varphi_{qp}$	= resistance factor for tip resistance (dim) (10.8.3.5) (10.9.3.5.1)
$\varphi_{qs}$	= resistance factor for shaft side resistance (dim) (10.8.3.5)
$\varphi_{stat}$	= resistance factor for driven piles or shafts, static analysis methods (dim) (10.5.5.2.3)
$\varphi_T$	= structural resistance factor for micropiles in axial tension (dim) (10.9.3.10.3)
$\varphi_{TC}$	= structural resistance factor for cased micropiles segments in axial tension (dim) (10.9.3.10.3a)
$\varphi_{TU}$	= structural resistance factor for uncased micropiles segments in axial tension (dim) (10.9.3.10.3b)
$\varphi_{ug}$	= resistance factor for group uplift (dim) (10.5.5.2.3)
$\varphi_{up}$	= resistance factor for uplift resistance of a single pile or drilled shaft (dim) (10.5.5.2.3)
$\varphi_{upload}$	= resistance factor for shafts, static uplift load test (dim) (10.5.5.2.4) (10.9.3.5.1)
$\varphi_\tau$	= resistance factor for sliding resistance between soil and footing (dim) (10.5.5.2.2)

## 10.4—SOIL AND ROCK PROPERTIES

### 10.4.1—Informational Needs

The expected project requirements shall be analyzed to determine the type and quantity of information to be developed during the geotechnical exploration. This analysis should consist of the following:

- Identify design and constructability requirements, e.g., provide grade separation, support loads from bridge superstructure, provide for dry excavation, and their effect on the geotechnical information needed.
- Identify performance criteria, e.g., limiting settlements, right of way restrictions, proximity of adjacent structures, and schedule constraints.
- Identify areas of geologic concern on the site and potential variability of local geology.
- Identify areas of hydrologic concern on the site, e.g., potential erosion or scour locations.

### C10.4.1

The first phase of an exploration and testing program requires that the Engineer understand the project requirements and the site conditions and/or restrictions. The ultimate goal of this phase is to identify geotechnical data needs for the project and potential methods available to assess these needs.

Geotechnical Engineering Circular #5—Evaluation of Soil and Rock Properties (Sabatini et al., 2002) provides a summary of information needs and testing considerations for various geotechnical applications.

- Develop likely sequence and phases of construction and their effect on the geotechnical information needed.
- Identify engineering analyses to be performed, e.g., bearing capacity, settlement, global stability.
- Identify engineering properties and parameters required for these analyses.
- Determine methods to obtain parameters and assess the validity of such methods for the material type and construction methods.
- Determine the number of tests/samples needed and appropriate locations for them.

#### 10.4.2—Subsurface Exploration

Subsurface explorations shall be performed to provide the information needed for the design and construction of foundations. The extent of exploration shall be based on variability in the subsurface conditions, structure type, and any project requirements that may affect the foundation design or construction. The exploration program should be extensive enough to reveal the nature and types of soil deposits and/or rock formations encountered, the engineering properties of the soils and/or rocks, the potential for liquefaction, and the groundwater conditions. The exploration program should be sufficient to identify and delineate problematic subsurface conditions such as karstic formations, mined out areas, swelling/collapsing soils, existing fill or waste areas, etc.

Borings should be sufficient in number and depth to establish a reliable longitudinal and transverse substrata profile at areas of concern such as at structure foundation locations and adjacent earthwork locations, and to investigate any adjacent geologic hazards that could affect the structure performance.

As a minimum, the subsurface exploration and testing program shall obtain information adequate to analyze foundation stability and settlement with respect to:

- Geological formation(s) present,
- Location and thickness of soil and rock units,
- Engineering properties of soil and rock units, such as unit weight, shear strength and compressibility,
- Groundwater conditions,
- Ground surface topography, and
- Local considerations, e.g., liquefiable, expansive or dispersive soil deposits, underground voids from solution weathering or mining activity, or slope instability potential.

#### C10.4.2

The performance of a subsurface exploration program is part of the process of obtaining information relevant for the design and construction of substructure elements. The elements of the process that should precede the actual exploration program include a search and review of published and unpublished information at and near the site, a visual site inspection, and design of the subsurface exploration program. Refer to Mayne et al. (2001) and Sabatini et al. (2002) for guidance regarding the planning and conduct of subsurface exploration programs.

The suggested minimum number and depth of borings are provided in Table 10.4.2-1. While engineering judgment will need to be applied by a licensed and experienced geotechnical professional to adapt the exploration program to the foundation types and depths needed and to the variability in the subsurface conditions observed, the intent of Table 10.4.2-1 regarding the minimum level of exploration needed should be carried out. The depth of borings indicated in Table 10.4.2-1 performed before or during design should take into account the potential for changes in the type, size and depth of the planned foundation elements.

This Table should be used only as a first step in estimating the number of borings for a particular design, as actual boring spacings will depend upon the project type and geologic environment. In areas underlain by heterogeneous soil deposits and/or rock formations, it will probably be necessary to drill more frequently and/or deeper than the minimum guidelines in Table 10.4.2-1 to capture variations in soil and/or rock type and to assess consistency across the site area. For situations where large diameter rock socketed shafts will be used or where drilled shafts are being installed in formations known to have large boulders, or voids such as in karstic or mined areas, it may be necessary to advance a boring at the location of each shaft. Even the best and most detailed subsurface exploration programs may not identify every important subsurface problem condition if conditions are highly variable. The goal of the subsurface exploration program, however, is to reduce the risk of such problems to an acceptable minimum.

Table 10.4.2-1 shall be used as a starting point for determining the locations of borings. The final exploration program should be adjusted based on the variability of the anticipated subsurface conditions as well as the variability observed during the exploration program. If conditions are determined to be variable, the exploration program should be increased relative to the requirements in Table 10.4.2-1 such that the objective of establishing a reliable longitudinal and transverse substrata profile is achieved. If conditions are observed to be homogeneous or otherwise are likely to have minimal impact on the foundation performance, and previous local geotechnical and construction experience has indicated that subsurface conditions are homogeneous or otherwise are likely to have minimal impact on the foundation performance, a reduced exploration program relative to what is specified in Table 10.4.2-1 may be considered.

If requested by the Owner or as required by law, boring and penetration test holes shall be plugged.

Laboratory and/or in-situ tests shall be performed to determine the strength, deformation, and permeability characteristics of soils and/or rocks and their suitability for the foundation proposed.

In a laterally homogeneous area, drilling or advancing a large number of borings may be redundant, since each sample tested would exhibit similar engineering properties. Furthermore, in areas where soil or rock conditions are known to be very favorable to the construction and performance of the foundation type likely to be used, e.g., footings on very dense soil, and groundwater is deep enough to not be a factor, obtaining fewer borings than provided in Table 10.4.2-1 may be justified. In all cases, it is necessary to understand how the design and construction of the geotechnical feature will be affected by the soil and/or rock mass conditions in order to optimize the exploration.

Borings may need to be plugged due to requirements by regulatory agencies having jurisdiction and/or to prevent water contamination and/or surface hazards.

Parameters derived from field tests, e.g., driven pile resistance based on cone penetrometer testing, may also be used directly in design calculations based on empirical relationships. These are sometimes found to be more reliable than analytical calculations, especially in familiar ground conditions for which the empirical relationships are well established.

**Table 10.4.2-1—Minimum Number of Exploration Points and Depth of Exploration (modified after Sabatini et al., 2002)**

Application	Minimum Number of Exploration Points and Location of Exploration Points	Minimum Depth of Exploration
Retaining Walls	A minimum of one exploration point for each retaining wall. For retaining walls more than 100 ft in length, exploration points spaced every 100 to 200 ft with locations alternating from in front of the wall to behind the wall. For anchored walls, additional exploration points in the anchorage zone spaced at 100 to 200 ft. For soil-nailed walls, additional exploration points at a distance of 1.0 to 1.5 times the height of the wall behind the wall spaced at 100 to 200 ft.	Investigate to a depth below bottom of wall at least to a depth where stress increase due to estimated foundation load is less than ten percent of the existing effective overburden stress at that depth and between one and two times the wall height. Exploration depth should be great enough to fully penetrate soft highly compressible soils, e.g., peat, organic silt, or soft fine grained soils, into competent material of suitable bearing capacity, e.g., stiff to hard cohesive soil, compact dense cohesionless soil, or bedrock.
Shallow Foundations	For substructure, e.g., piers or abutments, widths less than or equal to 100 ft, a minimum of one exploration point per substructure. For substructure widths greater than 100 ft, a minimum of two exploration points per substructure. Additional exploration points should be provided if erratic subsurface conditions are encountered.	<p>Depth of exploration should be:</p> <ul style="list-style-type: none"> <li>• great enough to fully penetrate unsuitable foundation soils, e.g., peat, organic silt, or soft fine grained soils, into competent material of suitable bearing resistance, e.g., stiff to hard cohesive soil, or compact to dense cohesionless soil or bedrock;</li> <li>• at least to a depth where stress increase due to estimated foundation load is less than ten percent of the existing effective overburden stress at that depth; and</li> <li>• if bedrock is encountered before the depth required by the second criterion above is achieved, exploration depth should be great enough to penetrate a minimum of 10 ft into the bedrock, but rock exploration should be sufficient to characterize compressibility of infill material of near-horizontal to horizontal discontinuities.</li> </ul> <p>Note that for highly variable bedrock conditions, or in areas where very large boulders are likely, more than 10 ft or rock core may be required to verify that adequate quality bedrock is present.</p>
Deep Foundations	For substructure, e.g., bridge piers or abutments, widths less than or equal to 100 ft, a minimum of one exploration point per substructure. For substructure widths greater than 100 ft, a minimum of two exploration points per substructure. Additional exploration points should be provided if erratic subsurface conditions are encountered, especially for the case of shafts socketed into bedrock.	<p>In soil, depth of exploration should extend below the anticipated pile or shaft tip elevation a minimum of 20 ft, or a minimum of two times the maximum pile group dimension, whichever is deeper. All borings should extend through unsuitable strata such as unconsolidated fill, peat, highly organic materials, soft fine-grained soils, and loose coarse-grained soils to reach hard or dense materials.</p> <p>For piles bearing on rock, a minimum of 10 ft of rock core shall be obtained at each exploration point location to verify that the boring has not terminated on a boulder.</p> <p>For shafts supported on or extending into rock, a minimum of 10 ft of rock core, or a length of rock core equal to at least three times the shaft diameter for isolated shafts or two times the maximum shaft group dimension, whichever is greater, shall be extended below the anticipated shaft tip elevation to determine the physical characteristics of rock within the zone of foundation influence.</p> <p>Note that for highly variable bedrock conditions, or in areas where very large boulders are likely, more than 10 ft or rock core may be required to verify that adequate quality bedrock is present.</p>

### 10.4.3—Laboratory Tests

#### 10.4.3.1—Soil Tests

Laboratory testing should be conducted to provide the basic data with which to classify soils and to measure their engineering properties.

When performed, laboratory tests shall be conducted in accordance with the AASHTO, ASTM, or Owner-supplied procedures applicable to the design properties needed.

#### C10.4.3.1

Laboratory tests of soils may be grouped broadly into two general classes:

- Classification or index tests. These may be performed on either disturbed or undisturbed samples.
- Quantitative or performance tests for permeability, compressibility and shear strength. These tests are generally performed on undisturbed samples, except for materials to be placed as controlled fill or materials that do not have a stable soil-structure, e.g., cohesionless materials. In these cases, tests should be performed on specimens prepared in the laboratory.

Detailed information regarding the types of tests needed for foundation design is provided in Geotechnical Engineering Circular #5—Evaluation of Soil and Rock Properties (Sabatini et al., 2002).

#### 10.4.3.2—Rock Tests

#### C10.4.3.2

If laboratory strength tests are conducted on intact rock samples for classification purposes, they should be considered as upper bound values. If laboratory compressibility tests are conducted, they should be considered as lower bound values. Additionally, laboratory tests should be used in conjunction with field tests and field characterization of the rock mass to give estimates of rock mass behavioral characteristics. When performed, laboratory tests shall be conducted in accordance with the ASTM or Owner-supplied procedures applicable to the design properties needed.

#### 10.4.4—In-Situ Tests

Rock samples small enough to be tested in the laboratory are usually not representative of the entire rock mass. Laboratory testing of rock is used primarily for classification of intact rock samples, and, if performed properly, serves a useful function in this regard.

Detailed information regarding the types of tests needed and their use for foundation design is provided in Geotechnical Engineering Circular #5—Evaluation of Soil and Rock Properties, April 2002 (Sabatini et al., 2002).

#### C10.4.4

Detailed information on in-situ testing of soils and rock and their application to geotechnical design can be found in Sabatini et al. (2002) and Wyllie (1999).

Correlations are in some cases specific to a geological formation. While this fact does not preclude the correlation from being useful in other geologic formations, the applicability of the correlation to those other formations should be evaluated.

For further discussion, see Article 10.4.6.

In-situ tests may be performed to obtain deformation and strength parameters of foundation soils or rock for the purposes of design and/or analysis. In-situ tests should be conducted in soils that do not lend themselves to undisturbed sampling as a means to estimate soil design parameters. When performed, in-situ tests shall be conducted in accordance with the appropriate ASTM or AASHTO standards.

Where in-situ test results are used to estimate design properties through correlations, such correlations should be well established through long-term widespread use or through detailed measurements that illustrate the accuracy of the correlation.

#### 10.4.5—Geophysical Tests

Geophysical testing should be used only in combination with information from direct methods of exploration, such as *SPT*, *CPT*, etc. to establish stratification of the subsurface materials, the profile of the top of bedrock and bedrock quality, depth to groundwater, limits of types of soil deposits, the presence of voids, anomalous deposits, buried pipes, and depths of existing foundations. Geophysical tests shall be selected and conducted in accordance with available ASTM standards. For those cases where ASTM standards are not available, other widely accepted detailed guidelines, such as Sabatini et al. (2002), AASHTO *Manual on Subsurface Investigations* (1988), Arman et al. (1997) and Campanella (1994), should be used.

#### C10.4.5

Geophysical testing offers some notable advantages and some disadvantages that should be considered before the technique is recommended for a specific application. The advantages are summarized as follows:

- Many geophysical tests are noninvasive and thus, offer, significant benefits in cases where conventional drilling, testing and sampling are difficult, e.g., deposits of gravel, talus deposits, or where potentially contaminated subsurface soils may occur.
- In general, geophysical testing covers a relatively large area, thus providing the opportunity to generally characterize large areas in order to optimize the locations and types of in-situ testing and sampling. Geophysical methods are particularly well suited to projects that have large longitudinal extent compared to lateral extent, e.g., new highway construction.
- Geophysical measurement assesses the characteristics of soil and rock at very small strains, typically on the order of 0.001 percent, thus providing information on truly elastic properties, which are used to evaluate service limit states.
- For the purpose of obtaining subsurface information, geophysical methods are relatively inexpensive when considering cost relative to the large areas over which information can be obtained.

Some of the disadvantages of geophysical methods include:

- Most methods work best for situations in which there is a large difference in stiffness or conductivity between adjacent subsurface units.
- It is difficult to develop good stratigraphic profiling if the general stratigraphy consists of hard material over soft material or resistive material over conductive material.
- Results are generally interpreted qualitatively and, therefore, only an experienced engineer or geologist familiar with the particular testing method can obtain useful results.
- Specialized equipment is required (compared to more conventional subsurface exploration tools).
- Since evaluation is performed at very low strains, or no strain at all, information regarding ultimate strength for evaluation of strength limit states is only obtained by correlation.

There are a number of different geophysical in-situ tests that can be used for stratigraphic information and determination of engineering properties. These methods can be combined with each other and/or combined with the in-situ tests presented in Article 10.4.4 to provide additional resolution and accuracy. [ASTM D6429](#), Standard Guide for Selecting Surface Geophysical Methods, provides additional guidance on selection of suitable methods.

## 10.4.6—Selection of Design Properties

### 10.4.6.1—General

Subsurface soil or rock properties shall be determined using one or more of the following methods:

- In-situ testing during the field exploration program, including consideration of any geophysical testing conducted,
- Laboratory testing, and
- Back analysis of design parameters based on site performance data.

Local experience, local geologic formation specific property correlations, and knowledge of local geology, in addition to broader based experience and relevant published data, should also be considered in the final selection of design parameters. If published correlations are used in combination with one of the methods listed above, the applicability of the correlation to the specific geologic formation shall be considered through the use of local experience, local test results, and/or long-term experience.

The focus of geotechnical design property assessment and final selection shall be on the individual geologic strata identified at the project site.

The design values selected for the parameters should be appropriate to the particular limit state and its correspondent calculation model under consideration.

The determination of design parameters for rock shall take into consideration that rock mass properties are generally controlled by the discontinuities within the rock mass and not the properties of the intact material. Therefore, engineering properties for rock should account for the properties of the intact pieces and for the properties of the rock mass as a whole, specifically considering the discontinuities within the rock mass. A combination of laboratory testing of small samples, empirical analysis, and field observations should be employed to determine the engineering properties of rock masses, with greater emphasis placed on visual observations and quantitative descriptions of the rock mass.

### C10.4.6.1

A geologic stratum is characterized as having the same geologic depositional history and stress history, and generally has similarities throughout the stratum in terms of density, source material, stress history, and hydrogeology. The properties of a given geologic stratum at a project site are likely to vary significantly from point to point within the stratum. In some cases, a measured property value may be closer in magnitude to the measured property value in an adjacent geologic stratum than to the measured properties at another point within the same stratum. However, soil and rock properties for design should not be averaged across multiple strata.

It should also be recognized that some properties, e.g., undrained shear strength in normally consolidated clays, may vary as a predictable function of a stratum dimension, e.g., depth below the top of the stratum. Where the property within the stratum varies in this manner, the design parameters should be developed taking this variation into account, which may result in multiple values of the property within the stratum as a function of a stratum dimension such as depth.

The observational method, or use of back analysis, to determine engineering properties of soil or rock is often used with slope failures, embankment settlement or excessive settlement of existing structures. With landslides or slope failures, the process generally starts with determining the geometry of the failure and then determining the soil/rock parameters or subsurface conditions that result from a combination of load and resistance factors that approach 1.0. Often the determination of the properties is aided by correlations with index tests or experience on other projects. For embankment settlement, a range of soil properties is generally determined based on laboratory performance testing on undisturbed samples. Monitoring of fill settlement and pore pressure in the soil during construction allows the soil properties and prediction of the rate of future settlement to be refined. For structures such as bridges that experience unacceptable settlement or retaining walls that have excessive deflection, the engineering properties of the soils can sometimes be determined if the magnitudes of the loads are known. As with slope stability analysis, the subsurface stratigraphy must be adequately known, including the history of the groundwater level at the site.

Local geologic formation-specific correlations may be used if well established by data comparing the prediction from the correlation to measured high quality laboratory performance data, or back-analysis from full scale performance of geotechnical elements affected by the geologic formation in question.

The Engineer should assess the variability of relevant data to determine if the observed variability is a result of inherent variability of subsurface materials and testing methods or if the variability is a result of significant variations across the site. Methods to compare soil parameter variability for a particular project to published values of variability based on database information of common soil parameters are presented in Sabatini (2002) and Duncan (2000). Where the variability is deemed to exceed the inherent variability of the material and testing methods, or where sufficient relevant data is not available to determine an average value and variability, the Engineer may perform a sensitivity analysis using average parameters and a parameter reduced by one standard deviation, i.e., "mean minus 1 sigma," or a lower bound value. By conducting analyses at these two potential values, an assessment is made of the sensitivity of the analysis results to a range of potential design values. If these analyses indicate that acceptable results are provided and that the analyses are not particularly sensitive to the selected parameters, the Engineer may be comfortable with concluding the analyses. If, on the other hand, the Engineer determines that the calculation results are marginal or that the results are sensitive to the selected parameter, additional data collection/review and parameter selection are warranted.

When evaluating service limit states, it is often appropriate to determine both upper and lower bound values from the relevant data, since the difference in displacement of substructure units is often more critical to overall performance than the actual value of the displacement for the individual substructure unit.

For strength limit states, average measured values of relevant laboratory test data and/or in-situ test data were used to calibrate the resistance factors provided in Article 10.5, at least for those resistance factors developed using reliability theory, rather than a lower bound value. It should be recognized that to be consistent with how the resistance factors presented in Article 10.5.5.2 were calibrated, i.e., to average property values, accounting for the typical variability in the property, average property values for a given geologic unit should be selected. However, depending on the availability of soil or rock property data and the variability of the geologic strata under consideration, it may not be possible to reliably estimate the average value of the properties needed for design. In such cases, the Engineer may have no choice but to use a more conservative selection of design parameters to mitigate the additional risks created by potential variability or the paucity of relevant data.

Note that for those resistance factors that were determined based on calibration by fitting to allowable stress design, this property selection issue is not relevant, and property selection should be based on past practice.

### 10.4.6.2—Soil Strength

#### 10.4.6.2.1—General

The selection of soil shear strength for design should consider, at a minimum, the following:

- the rate of construction loading relative to the hydraulic conductivity of the soil, i.e., drained or undrained strengths;
- the effect of applied load direction on the measured shear strengths during testing;
- the effect of expected levels of deformation for the geotechnical structure; and
- the effect of the construction sequence.

#### C10.4.6.2.1

Refer to Sabatini et al. (2002) for additional guidance on determining which soil strength parameters are appropriate for evaluating a particular soil type and loading condition. In general, where loading is rapid enough and/or the hydraulic conductivity of the soil is low enough such that excess pore pressure induced by the loading does not dissipate, undrained (total) stress parameters should be used. Where loading is slow enough and/or the hydraulic conductivity of the soil is great enough such that excess pore pressures induced by the applied load dissipate as the load is applied, drained (effective) soil parameters should be used. Drained (effective) soil parameters should also be used to evaluate long term conditions where excess pore pressures have been allowed to dissipate or where the designer has explicit knowledge of the expected magnitude and distribution of the excess pore pressure.

#### 10.4.6.2.2—Undrained Strength of Cohesive Soils

Where possible, laboratory consolidated undrained (CU) and unconsolidated undrained (UU) testing should be used to estimate the undrained shear strength,  $S_u$ , supplemented as needed with values determined from in-situ testing. Where collection of undisturbed samples for laboratory testing is difficult, values obtained from in-situ testing methods may be used. For relatively thick deposits of cohesive soil, profiles of  $S_u$  as a function of depth should be obtained so that the deposit stress history and properties can be ascertained.

#### C10.4.6.2.2

For design analyses of short-term conditions in normally to lightly overconsolidated cohesive soils, the undrained shear strength,  $S_u$ , is commonly evaluated. Since undrained strength is not a unique property, profiles of undrained strength developed using different testing methods will vary. Typical transportation project practice entails determination of  $S_u$  based on laboratory CU and UU testing and, for cases where undisturbed sampling is very difficult, field vane testing. Other in-situ methods can also be used to estimate the value of  $S_u$ .

Specific issues that should be considered when estimating the undrained shear strength are described below:

- Strength measurements from hand torvanes, pocket penetrometers, or unconfined compression tests should not be solely used to evaluate undrained shear strength for design analyses. Consolidated undrained (CU) triaxial tests and in-situ tests should be used.

- For relatively deep deposits of cohesive soil, e.g., approximately 20 ft depth or more, all available undrained strength data should be plotted with depth. The type of test used to evaluate each undrained strength value should be clearly identified. Known soil layering should be used so that trends in undrained strength data can be developed for each soil layer.
- Review data summaries for each laboratory strength test method. Moisture contents of specimens for strength testing should be compared to moisture contents of other samples at similar depths. Significant changes in moisture content will affect measured undrained strengths. Review boring logs, Atterberg limits, grain size, and unit weight measurements to confirm soil layering.
- CU tests on normally to slightly over consolidated samples that exhibit disturbance should contain at least one specimen consolidated to at least  $4\sigma'_p$  to permit extrapolation of the undrained shear strength at  $\sigma'_p$ .
- Undrained strengths from CU tests correspond to the effective consolidation pressure used in the test. This effective stress needs to be converted to the equivalent depth in the ground.
- A profile of  $\sigma'_p$  (or OCR) should be developed and used in evaluating undrained shear strength.
- Correlations for  $S_u$  based on in-situ test measurements should not be used for final design unless they have been calibrated to the specific soil profile under consideration. Correlations for  $S_u$  based on SPT tests should be avoided.

#### *10.4.6.2.3—Drained Strength of Cohesive Soils*

Long-term effective stress strength parameters,  $c'$  and  $\phi'_f$ , of clays should be evaluated by slow consolidated drained direct shear box tests, consolidated drained (CD) triaxial tests, or consolidated undrained (CU) triaxial tests with pore pressure measurements. In laboratory tests, the rate of shearing should be sufficiently slow to ensure substantially complete dissipation of excess pore pressure in the drained tests or, in undrained tests, complete equalization of pore pressure throughout the specimen.

#### *10.4.6.2.4—Drained Strength of Granular Soils*

The drained friction angle of granular deposits should be evaluated by correlation to the results of SPT testing, CPT testing, or other relevant in-situ tests. Laboratory shear strength tests on undisturbed samples, if feasible to obtain, or reconstituted disturbed samples, may also be used to determine the shear strength of granular soils.

#### *C10.4.6.2.3*

The selection of peak, fully softened, or residual strength for design analyses should be based on a review of the expected or tolerable displacements of the soil mass.

The use of a nonzero cohesion intercept ( $c'$ ) for long-term analyses in natural materials must be carefully assessed. With continuing displacements, it is likely that the cohesion intercept value will decrease to zero for long-term conditions, especially for highly plastic clays.

#### *C10.4.6.2.4*

Because obtaining undisturbed samples of granular deposits for laboratory testing is extremely difficult, the results of in-situ tests are commonly used to develop estimates of the drained friction angle,  $\phi_f$ . If reconstituted disturbed soil samples and laboratory tests are used to estimate the drained friction angle, the reconstituted samples should be compacted to the same

If *SPT N* values are used, unless otherwise specified for the design method or correlation being used, they shall be corrected for the effects of overburden pressure determined as:

$$N_1 = C_N N \quad (10.4.6.2.4-1)$$

$N_1$  = *SPT* blow count corrected for overburden pressure,  $\sigma'_v$  (blows/ft)

$$C_N = [0.77 \log_{10}(40/\sigma'_v)], \text{ and } C_N < 2.0$$

$\sigma'_v$  = vertical effective stress (ksf)

$N$  = uncorrected *SPT* blow count (blows/ft)

*SPT N* values should also be corrected for hammer efficiency, if applicable to the design method or correlation being used, determined as:

$$N_{60} = (ER / 60\%)N \quad (10.4.6.2.4-2)$$

where:

$N_{60}$  = *SPT* blow count corrected for hammer efficiency (blows/ft)

$ER$  = hammer efficiency expressed as percent of theoretical free fall energy delivered by the hammer system actually used

$N$  = uncorrected *SPT* blow count (blows/ft)

When *SPT* blow counts have been corrected for both overburden effects and hammer efficiency effects, the resulting corrected blow count shall be denoted as  $N_{160}$ , determined as:

$$N_{160} = C_N N_{60} \quad (10.4.6.2.4-3)$$

The drained friction angle of granular deposits should be determined based on the following correlation.

**Table 10.4.6.2.4-1—Correlation of *SPT N*<sub>160</sub> Values to Drained Friction Angle of Granular Soils (modified after Bowles, 1977)**

$N_{160}$	$\phi_f$
<4	25–30
4	27–32
10	30–35
30	35–40
50	38–43

relative density estimated from the available in-situ data. The test specimen should be large enough to allow the full grain size range of the soil to be included in the specimen. This may not always be possible, and if not possible, it should be recognized that the shear strength measured would likely be conservative.

A method using the results of *SPT* testing is presented. Other in-situ tests such as *CPT* and *DMT* may be used. For details on determination of  $\phi_f$  from these tests, refer to Sabatini et al. (2002).

The use of automatic trip hammers is increasing. In order to use correlations based on standard rope and cathead hammers, the *SPT N* values must be corrected to reflect the greater energy delivered to the sampler by these systems.

Hammer efficiency (ER) for specific hammer systems used in local practice may be used in lieu of the values provided. If used, specific hammer system efficiencies shall be developed in general accordance with [ASTM D4945](#) for dynamic analysis of driven piles or other accepted procedure.

The following values for ER may be assumed if hammer specific data are not available, e.g., from older boring logs:

ER = 60 percent for conventional drop hammer using rope and cathead

ER = 80 percent for automatic trip hammer

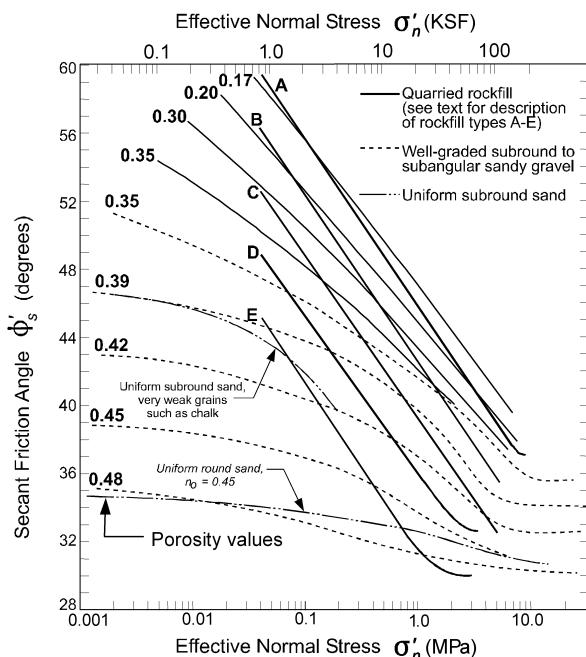

Corrections for rod length, hole size, and use of a liner may also be made if appropriate. In general, these are only significant in unusual cases or where there is significant variation from standard procedures. These corrections may be significant for evaluation of liquefaction. Information on these additional corrections may be found in Youd and Idriss (1997).

The  $N_{160}$ - $\phi_f$  correlation used is modified after Bowles (1977). The correlation of Peck, Hanson, and Thornburn (1974) falls within the ranges specified. Experience should be used to select specific values within the ranges. In general, finer materials or materials with significant silt-sized material will fall in the lower portion of the range. Coarser materials with less than five percent fines will fall in the upper portion of the ranges. The geologic history and angularity of the particles may also need to be considered when selecting a value for  $\phi_f$ .

Care should be exercised when using other correlations of *SPT* results to soil parameters. Some published correlations are based on corrected values

For gravels and rock fill materials where *SPT* testing is not reliable, Figure 10.4.6.2.4-1 should be used to estimate the drained friction angle.

Rock Fill Grade	Particle Unconfined Compressive Strength (ksf)
A	>4610
B	3460– 4610
C	2590– 3460
D	1730– 2590
E	≤1730

**Figure 10.4.6.2.4-1—Estimation of Drained Friction Angle of Gravels and Rock Fills (modified after Terzaghi, Peck, and Mesri, 1996)**

#### 10.4.6.3—Soil Deformation

Consolidation parameters  $C_c$ ,  $C_r$ ,  $C_a$  should be determined from the results of one-dimensional consolidation tests. To assess the potential variability in the settlement estimate, the average, upper and lower bound values obtained from testing should be considered.

( $N_{160}$ ) and some are based on uncorrected values ( $N$ ). The designer should ascertain the basis of the correlation and use either  $N_{160}$  or  $N$  as appropriate.

Care should also be exercised when using *SPT* blow counts to estimate soil shear strength if in soils with coarse gravel, cobbles, or boulders. Large gravels, cobbles, or boulders could cause the *SPT* blow counts to be unrealistically high.

The secant friction angle derived from the procedure to estimate the drained friction angle of gravels and rock fill materials depicted in Figure 10.4.6.2.4-1 is based on a straight line from the origin of a Mohr diagram to the intersection with the strength envelope at the effective normal stress. Thus the angle derived is applicable only to analysis of field conditions subject to similar normal stresses. See Terzaghi, Peck, and Mesri (1996) for additional details regarding this procedure.

#### C10.4.6.3

It is important to understand whether the values obtained are computed based on a void ratio definition or a strain definition. Computational methods vary for each definition.

For preliminary analyses or where accurate prediction of settlement is not critical, values obtained

Preconsolidation stress may be determined from one-dimensional consolidation tests and in-situ tests. Knowledge of the stress history of the soil should be used to supplement data from laboratory and/or in-situ tests, if available.

The coefficient of consolidation,  $c_v$ , should be determined from the results of one-dimensional consolidation tests. The variability in laboratory determination of  $c_v$  results should be considered in the final selection of the value of  $c_v$  to be used for design.

Where evaluation of elastic settlement is critical to the design of the foundation or selection of the foundation type, in-situ methods such as PMT or DMT for evaluating the modulus of the stratum should be used.

from correlations to index properties may be used. Refer to Sabatini et al. (2002) for discussion of the various correlations available. If correlations for prediction of settlement are used, their applicability to the specific geologic formation under consideration should be evaluated.

A profile of  $\sigma'_p$ , or  $OCR = \sigma'_p/\sigma_o'$ , with depth should be developed for the site for design applications where the stress history could have a significant impact on the design properties selected and the performance of the foundation. As with consolidation properties, an upper and lower bound profile should be developed based on laboratory tests and plotted with a profile based on particular in-situ test(s), if used. It is particularly important to accurately compute preconsolidation stress values for relatively shallow depths where in-situ effective stresses are low. An underestimation of the preconsolidation stress at shallow depths will result in overly conservative estimates of settlement for shallow soil layers.

Due to the numerous simplifying assumptions associated with conventional consolidation theory, on which the coefficient of consolidation is based, it is unlikely that even the best estimates of  $c_v$  from high-quality laboratory tests will result in predictions of time rate of settlement in the field that are significantly better than a prediction within one order of magnitude. In general, the in-situ value of  $c_v$  is larger than the value measured in the laboratory test. Therefore, a rational approach is to select average, upper, and lower bound values for the appropriate stress range of concern for the design application. These values should be compared to values obtained from previous work performed in the same soil deposit. Under the best-case conditions, these values should be compared to values computed from measurements of excess pore pressures or settlement rates during construction of other structures.

*CPTu* tests in which the pore pressure dissipation rate is measured may be used to estimate the field coefficient of consolidation.

For preliminary analyses or where accurate prediction of settlement is not critical, values obtained from correlations to index properties presented in Sabatini et al. (2002) may be used.

For preliminary design or for final design where the prediction of deformation is not critical to structure performance, i.e., the structure design can tolerate the potential inaccuracies inherent in the correlations. The elastic properties ( $E_s, v$ ) of a soil may be estimated from empirical relationships presented in Table C10.4.6.3-1.

The specific definition of  $E_s$  is not always consistent for the various correlations and methods of in-situ measurement. See Sabatini et al. (2002) for additional details regarding the definition and determination of  $E_s$ .

An alternative method of evaluating the equivalent elastic modulus using measured shear wave velocities is presented in Sabatini et al. (2002).

**Table C10.4.6.3-1—Elastic Constants of Various Soils  
(modified after U.S. Department of the Navy, 1982;  
Bowles, 1988)**

Soil Type	Typical Range of Young's Modulus Values, $E_s$ (ksi)	Poisson's Ratio, $\nu$ (dim)
Clay: Soft sensitive Medium stiff to stiff Very stiff	0.347–2.08 2.08–6.94 6.94–13.89	0.4–0.5 (undrained)
Loess	2.08–8.33	0.1–0.3
Silt	0.278–2.78	0.3–0.35
Fine Sand: Loose Medium dense Dense	1.11–1.67 1.67–2.78 2.78–4.17	0.25
Sand: Loose Medium dense Dense	1.39–4.17 4.17–6.94 6.94–11.11	0.20–0.36 0.30–0.40
Gravel: Loose Medium dense Dense	4.17–11.11 11.11–13.89 13.89–27.78	0.20–0.35 0.30–0.40
Estimating $E_s$ from SPT N Value		
Soil Type	$E_s$ (ksi)	
Silts, sandy silts, slightly cohesive mixtures	0.056 $N1_{60}$	
Clean fine to medium sands and slightly silty sands	0.097 $N1_{60}$	
Coarse sands and sands with little gravel	0.139 $N1_{60}$	
Sandy gravel and gravels	0.167 $N1_{60}$	
Estimating $E_s$ from $q_c$ (static cone resistance)		
Sandy soils	0.028 $q_c$	

The modulus of elasticity for normally consolidated granular soils tends to increase with depth. An alternative method of defining the soil modulus for granular soils is to assume that it increases linearly with depth starting at zero at the ground surface in accordance with the following equation:

$$E_s = nh \times z \quad (\text{C10.4.6.3-1})$$

where:

- $E_s$  = the soil modulus at depth  $z$  (ksi)  
 $n_h$  = rate of increase of soil modulus with depth as defined in Table C10.4.6.3-2 (ksi/ft)  
 $z$  = depth below the ground surface (ft)

**Table C10.4.6.3-2—Rate of Increase of Soil Modulus with Depth  $n_h$  (ksi/ft) for Sand**

Consistency	Dry or Moist	Submerged
Loose	0.417	0.208
Medium	1.11	0.556
Dense	2.78	1.39

The potential for soil swell that may result in uplift on deep foundations or heave of shallow foundations should be evaluated based on Table 10.4.6.3-1.

**Table 10.4.6.3-1—Method for Identifying Potentially Expansive Soils (Reese and O'Neill, 1988)**

Liquid Limit <i>LL</i> (%)	Plastic Limit <i>PL</i> (%)	Soil Suction (ksf)	Potential Swell (%)	Potential Swell Classification
>60	>35	>8	>1.5	High
50–60	25–35	3–8	0.5–1.5	Marginal
<50	<25	<3	<0.5	Low

#### 10.4.6.4—Rock Mass Strength

The strength of intact rock material should be determined using the results of unconfined compression tests on intact rock cores, splitting tensile tests on intact rock cores, or point load strength tests on intact specimens of rock.

The rock should be classified using the rock mass rating system (RMR) as described in Table 10.4.6.4-1. For each of the five parameters in the Table, the relative rating based on the ranges of values provided should be evaluated. The rock mass rating (RMR) should be determined as the sum of all five relative ratings. The RMR should be adjusted in accordance with the criteria in Table 10.4.6.4-2. The rock classification should be determined in accordance with Table 10.4.6.4-3.

#### C10.4.6.4

Because of the importance of the discontinuities in rock, and the fact that most rock is much more discontinuous than soil, emphasis is placed on visual assessment of the rock and the rock mass.

Other methods for assessing rock mass strength, including in-situ tests or other visual systems that have proven to yield accurate results may be used in lieu of the specified method.

**Table 10.4.6.4-1—Geomechanics Classification of Rock Masses**

Parameter			Ranges of Values					
1	Strength of intact rock material	Point load strength index	>175 ksf	85–175 ksf	45–85 ksf	20–45 ksf	For this low range, uniaxial compressive test is preferred	
		Uniaxial compressive strength	>4320 ksf	2160–4320 ksf	1080–2160 ksf	520–1080 ksf	215–520 ksf	70–215 ksf
	Relative Rating	15	12	7	4	2	1	0
2	Drill core quality RQD	90% to 100%	75% to 90%		50% to 75%	25% to 50%		<25%
	Relative Rating	20	17		13	8		3
3	Spacing of joints	>10 ft	3–10 ft		1–3 ft	2 in.–1 ft		<2 in.
	Relative Rating	30	25		20	10		5
4	Condition of joints		<ul style="list-style-type: none"> <li>• Very rough surfaces</li> <li>• Not continuous</li> <li>• No separation</li> <li>• Hard joint wall rock</li> </ul>	<ul style="list-style-type: none"> <li>• Slightly rough surfaces</li> <li>• Separation &lt;0.05 in.</li> <li>• Hard joint wall rock</li> </ul>	<ul style="list-style-type: none"> <li>• Slightly rough surfaces</li> <li>• Separation &lt;0.05 in.</li> <li>• Soft joint wall rock</li> </ul>	<ul style="list-style-type: none"> <li>• Slicken-sided surfaces or</li> <li>• Gouge &lt;0.2 in. thick or</li> <li>• Joints open &gt;0.2 in.</li> <li>• Continuous joints</li> </ul>	<ul style="list-style-type: none"> <li>• Soft gouge &gt;0.2 in. thick</li> <li>or</li> <li>• Joints open &gt;0.2 in.</li> <li>• Continuous joints</li> </ul>	
	Relative Rating		25	20		12	6	
	Groundwater conditions (use one of the three evaluation criteria as appropriate to the method of exploration)		None	<400 gal./hr.		400–2000 gal./hr.	>2000 gal./hr.

		General Conditions	Completely Dry	Moist only (interstitial water)		Water under moderate pressure	Severe water problems	
		Relative Rating	10	7		4	0	

**Table 10.4.6.4-2—Geomechanics Rating Adjustment for Joint Orientations**

Strike and Dip Orientations of Joints		Very Favorable	Favorable	Fair	Unfavorable	Very Unfavorable
Ratings	Tunnels	0	-2	-5	-10	-12
	Foundations	0	-2	-7	-15	-25
	Slopes	0	-5	-25	-50	-60

**Table 10.4.6.4-3—Geomechanics Rock Mass Classes Determined from Total Ratings**

RMR Rating	100–81	80–61	60–41	40–21	<20
Class No.	I	II	III	IV	V
Description	Very good rock	Good rock	Fair rock	Poor rock	Very poor rock

The shear strength of fractured rock masses should be evaluated using the Hoek and Brown criteria, in which the shear strength is represented as a curved envelope that is a function of the uniaxial compressive strength of the intact rock,  $q_u$ , and two dimensionless constants  $m$  and  $s$ . The values of  $m$  and  $s$  as defined in Table 10.4.6.4-4 should be used.

The shear strength of the rock mass should be determined as:

$$\tau = (\cot \phi'_i - \cos \phi'_i) m \frac{q_u}{8} \quad (10.4.6.4-1)$$

in which:

$$\phi'_i = \tan^{-1} \left\{ 4h \cos^2 \left[ 30 + 0.33 \sin^{-1} \left( h^{\frac{-3}{2}} \right) \right] - 1 \right\}^{-\frac{1}{2}}$$

$$h = 1 + \frac{16(m\sigma'_n + sq_u)}{(3m^2 q_u)}$$

where:

$\tau$  = the shear strength of the rock mass (ksf)

$\phi'_i$  = the instantaneous friction angle of the rock mass (degrees)

$q_u$  = average unconfined compressive strength of rock core (ksf)

$\sigma'_n$  = effective normal stress (ksf)

$m, s$  = constants from Table 10.4.6.4-4 (dim)

This method was developed by Hoek (1983) and Hoek and Brown (1988, 1997). Note that the instantaneous cohesion at a discrete value of normal stress can be taken as:

$$c_i = \tau - \sigma'_n \tan \phi'_i \quad (C10.4.6.4-1)$$

The instantaneous cohesion and instantaneous friction angle define a conventional linear Mohr envelope at the normal stress under consideration. For normal stresses significantly different than that used to compute the instantaneous values, the resulting shear strength will be unconservative. If there is considerable variation in the effective normal stress in the zone of concern, consideration should be given to subdividing the zone into areas where the normal stress is relative constant and assigning separate strength parameters to each zone. Alternatively, the methods of Hoek (1983) may be used to compute average values for the range of normal stresses expected.

**Table 10.4.6.4-4—Approximate Relationship between Rock-Mass Quality and Material Constants Used in Defining Nonlinear Strength (Hoek and Brown, 1988)**

Rock Quality	Constants	Rock Type				
		A	B	C	D	E
INTACT ROCK SAMPLES Laboratory size specimens free from discontinuities. CSIR rating: $RMR = 100$	$m$ $s$	7.00 1.00	10.00 1.00	15.00 1.00	17.00 1.00	25.00 1.00
VERY GOOD QUALITY ROCK MASS Tightly interlocking undisturbed rock with unweathered joints at 3–10 ft CSIR rating: $RMR = 85$	$m$ $s$	2.40 0.082	3.43 0.082	5.14 0.082	5.82 0.082	8.567 0.082
GOOD QUALITY ROCK MASS Fresh to slightly weathered rock, slightly disturbed with joints at 3–10 ft CSIR rating: $RMR = 65$	$m$ $s$	0.575 0.00293	0.821 0.00293	1.231 0.00293	1.395 0.00293	2.052 0.00293
FAIR QUALITY ROCK MASS Several sets of moderately weathered joints spaced at 1–3 ft CSIR rating: $RMR = 44$	$m$ $s$	0.128 0.00009	0.183 0.00009	0.275 0.00009	0.311 0.00009	0.458 0.00009
POOR QUALITY ROCK MASS Numerous weathered joints at 2 to 12 in.; some gouge. Clean compacted waste rock. CSIR rating: $RMR = 23$	$m$ $s$	0.029 $3 \times 10^{-6}$	0.041 $3 \times 10^{-6}$	0.061 $3 \times 10^{-6}$	0.069 $3 \times 10^{-6}$	0.102 $3 \times 10^{-6}$
VERY POOR QUALITY ROCK MASS Numerous heavily weathered joints spaced <2 in. with gouge. Waste rock with fines. CSIR rating: $RMR = 3$	$m$ $s$	0.007 $1 \times 10^{-7}$	0.010 $1 \times 10^{-7}$	0.015 $1 \times 10^{-7}$	0.017 $1 \times 10^{-7}$	0.025 $1 \times 10^{-7}$

Where it is necessary to evaluate the strength of a single discontinuity or set of discontinuities, the strength along the discontinuity should be determined as follows:

- For smooth discontinuities, the shear strength is represented by a friction angle of the parent rock material. To evaluate the friction angle of this type of discontinuity surface for design, direct shear tests on samples should be performed. Samples should be formed in the laboratory by cutting samples of intact core.
- For rough discontinuities the nonlinear criterion of Barton (1976) should be applied.

The range of typical friction angles provided in Table C10.4.6.4-1 may be used in evaluating measured values of friction angles for smooth joints.

**Table C10.4.6.4-1—Typical Ranges of Friction Angles for Smooth Joints in a Variety of Rock Types (modified after Barton, 1976; Jaeger and Cook, 1976)**

Rock Class	Friction Angle Range	Typical Rock Types
Low Friction	20–27°	Schists (high mica content), shale, marl
Medium Friction	27–34°	Sandstone, siltstone, chalk, gneiss, slate
High Friction	34–40°	Basalt, granite, limestone, conglomerate

Note: Values assume no infilling and little relative movement between joint faces.

When a major discontinuity with a significant thickness of infilling is to be investigated, the shear strength will be governed by the strength of the infilling material and the past and expected future displacement of the discontinuity. Refer to Sabatini et al. (2002) for detailed procedures to evaluate infilled discontinuities.

#### 10.4.6.5—Rock Mass Deformation

The elastic modulus of a rock mass ( $E_m$ ) shall be taken as the lesser of the intact modulus of a sample of rock core ( $E_i$ ) or the modulus determined from one of the following equations:

$$E_m = 145 \left( 10^{\frac{RMR-10}{40}} \right) \quad (10.4.6.5-1)$$

where:

$E_m$  = Elastic modulus of the rock mass (ksi)

$E_m \leq E_i$

$E_i$  = Elastic modulus of intact rock (ksi)

$RMR$  = Rock mass rating specified in Article 10.4.6.4.

or

$$E_m = \left( \frac{E_m}{E_i} \right) E_i \quad (10.4.6.5-2)$$

#### C10.4.6.5

Table 10.4.6.5-1 was developed by O'Neill and Reese (1999) based on a reanalysis of the data presented by Carter and Kulhawy (1988) for the purposes of estimating side resistance of shafts in rock.

Preliminary estimates of the elastic modulus of intact rock may be made from Table C10.4.6.5-1. Note that some of the rock types identified in the Table are not present in the U.S.

It is extremely important to use the elastic modulus of the rock mass for computation of displacements of rock materials under applied loads. Use of the intact modulus will result in unrealistic and unconservative estimates.

where:

$E_m$  = Elastic modulus of the rock mass (ksi)

$E_m/E_i$  = Reduction factor determined from Table 10.4.6.5-1 (dim)

$E_i$  = Elastic modulus of intact rock from tests (ksi)

For critical or large structures, determination of rock mass modulus ( $E_m$ ) using in-situ tests may be warranted. Refer to Sabatini et al. (2002) for descriptions of suitable in-situ tests.

**Table 10.4.6.5-1—Estimation of  $E_m$  Based on RQD (after O'Neill and Reese, 1999)**

RQD (percent)	$E_m/E_i$	
	Closed Joints	Open Joints
100	1.00	0.60
70	0.70	0.10
50	0.15	0.10
20	0.05	0.05

**Table C10.4.6.5-1—Summary of Elastic Moduli for Intact Rock (modified after Kulhawy, 1978)**

Rock Type	No. of Values	No. of Rock Types	Elastic Modulus, $E_i$ (ksi $\times 10^3$ )			Standard Deviation (ksi $\times 10^3$ )
			Maximum	Minimum	Mean	
Granite	26	26	14.5	0.93	7.64	3.55
Diorite	3	3	16.2	2.48	7.45	6.19
Gabbro	3	3	12.2	9.8	11.0	0.97
Diabase	7	7	15.1	10.0	12.8	1.78
Basalt	12	12	12.2	4.20	8.14	2.60
Quartzite	7	7	12.8	5.29	9.59	2.32
Marble	14	13	10.7	0.58	6.18	2.49
Gneiss	13	13	11.9	4.13	8.86	2.31
Slate	11	2	3.79	0.35	1.39	0.96
Schist	13	12	10.0	0.86	4.97	3.18
Phyllite	3	3	2.51	1.25	1.71	0.57
Sandstone	27	19	5.68	0.09	2.13	1.19
Siltstone	5	5	4.76	0.38	2.39	1.65
Shale	30	14	5.60	0.001	1.42	1.45
Limestone	30	30	13.0	0.65	5.7	3.73
Dolostone	17	16	11.4	0.83	4.22	3.44

Poisson's ratio for rock should be determined from tests on intact rock core.

Where tests on rock core are not practical, Poisson's ratio may be estimated from Table C10.4.6.5-2.

**Table C10.4.6.5-2—Summary of Poisson's Ratio for Intact Rock (modified after Kulhawy, 1978)**

Rock Type	No. of Values	No. of Rock Types	Poisson's Ratio, $\nu$			Standard Deviation
			Maximum	Minimum	Mean	
Granite	22	22	0.39	0.09	0.20	0.08
Gabbro	3	3	0.20	0.16	0.18	0.02
Diabase	6	6	0.38	0.20	0.29	0.06
Basalt	11	11	0.32	0.16	0.23	0.05
Quartzite	6	6	0.22	0.08	0.14	0.05
Marble	5	5	0.40	0.17	0.28	0.08
Gneiss	11	11	0.40	0.09	0.22	0.09

Limestone	19	19	0.33	0.12	0.23	0.06
Dolostone	5	5	0.35	0.14	0.29	0.08

**10.4.6.6—Erodibility of Rock**

Consideration should be given to the physical characteristics of the rock and the condition of the rock mass when determining a rock's susceptibility to erosion in the vicinity of bridge foundations. Physical characteristics that should be considered in the assessment of erodibility include cementing agents, mineralogy, joint spacing, and weathering.

**C10.4.6.6**

There is no consensus on how to determine erodibility of rock masses near bridge foundations. Refer to Richardson and Davis (2001) "Evaluating Scour at Bridges—Fourth Edition", Mayne et al. (2001), Appendix M for guidance on two proposed methods. The first method was proposed in an FHWA memorandum of July 1991 and consists of evaluating various rock index properties. The second method is documented in Smith (1994) "Preliminary Procedure to Evaluate Scour in Bedrock" which uses the erodibility index proposed by G. W. Annandale. The Engineer should consider the appropriateness of these two methods when determining the potential for a rock mass to scour.

**10.5—LIMIT STATES AND RESISTANCE FACTORS****10.5.1—General**

The limit states shall be as specified in Article 1.3.2; foundation-specific provisions are contained in this Section.

Foundations shall be proportioned so that the factored resistance is not less than the effects of the factored loads specified in Section 3.

**10.5.2—Service Limit States****10.5.2.1—General**

Foundation design at the service limit state shall include:

- Settlements,

**C10.5.2.1**

In bridges where the superstructure and substructure are not integrated, settlement corrections can be made by jacking and shimming bearings. Article 2.5.2.3 requires jacking provisions for these bridges.

- Horizontal movements,
- Overall stability, and
- Scour at the design flood.

Consideration of foundation movements shall be based upon structure tolerance to total and differential movements, rideability and economy. Foundation movements shall include all movement from settlement, horizontal movement, and rotation.

Bearing resistance estimated using the presumptive allowable bearing pressure for spread footings, if used, shall be applied only to address the service limit state.

The cost of limiting foundation movements should be compared with the cost of designing the superstructure so that it can tolerate larger movements or of correcting the consequences of movements through maintenance to determine minimum lifetime cost. The Owner may establish more stringent criteria.

The design flood for scour is defined in Article 2.6.4.4.2, and is specified in Article 3.7.5 as applicable at the service limit state.

Presumptive bearing pressures were developed for use with working stress design. These values may be used for preliminary sizing of foundations, but should generally not be used for final design. If used for final design, presumptive values are only applicable at service limit states.

### **10.5.2.2—Tolerable Movements and Movement Criteria**

Foundation movement criteria shall be consistent with the function and type of structure, anticipated service life, and consequences of unacceptable movements on structure performance. Foundation movement shall include vertical, horizontal, and rotational movements. The tolerable movement criteria shall be established by either empirical procedures or structural analyses, or by consideration of both.

Foundation settlement shall be investigated using all applicable loads in the Service I Load Combination specified in Table 3.4.1-1. Transient loads may be omitted from settlement analyses for foundations bearing on or in cohesive soil deposits that are subject to time-dependant consolidation settlements.

All applicable service limit state load combinations in Table 3.4.1-1 shall be used for evaluating horizontal movement and rotation of foundations.

### **C10.5.2.2**

Experience has shown that bridges can and often do accommodate more movement and/or rotation than traditionally allowed or anticipated in design. Creep, relaxation, and redistribution of force effects accommodate these movements. Some studies have been made to synthesize apparent response. These studies indicate that angular distortions between adjacent foundations greater than 0.008 rad. in simple spans and 0.004 rad. in continuous spans should not be permitted in settlement criteria (Moulton et al., 1985; DiMillio, 1982; Barker et al., 1991). Other angular distortion limits may be appropriate after consideration of:

- cost of mitigation through larger foundations, realignment or surcharge,
- rideability,
- aesthetics, and
- safety.

Rotation movements should be evaluated at the top of the substructure unit in plan location and at the deck elevation.

Tolerance of the superstructure to lateral movement will depend on bridge seat or joint widths, bearing type(s), structure type, and load distribution effects.

Horizontal movement criteria should be established at the top of the foundation based on the tolerance of the structure to lateral movement, with consideration of the column length and stiffness.

### **10.5.2.3—Overall Stability**

The evaluation of overall stability of earth slopes with or without a foundation unit shall be investigated at the service limit state as specified in Article 11.6.2.3.

#### **10.5.2.4—Abutment Transitions**

Vertical and horizontal movements caused by embankment loads behind bridge abutments shall be investigated.

#### **C10.5.2.4**

Settlement of foundation soils induced by embankment loads can result in excessive movements of substructure elements. Both short and long term settlement potential should be considered.

Settlement of improperly placed or compacted backfill behind abutments can cause poor rideability and a possibly dangerous bump at the end of the bridge. Guidance for proper detailing and material requirements for abutment backfill is provided in Cheney and Chassie (2000).

Lateral earth pressure behind and/or lateral squeeze below abutments can also contribute to lateral movement of abutments and should be investigated, if applicable.

#### **10.5.3—Strength Limit States**

##### **10.5.3.1—General**

Design of foundations at strength limit states shall include consideration of the nominal geotechnical and structural resistances of the foundation elements. Design at strength limit states shall not consider the deformations required to mobilize the nominal resistance, unless a definition of failure based on deformation is specified.

The design of all foundations at the strength limit state shall consider:

- Structural resistance and
- Loss of lateral and vertical support due to scour at the design flood event.

##### **10.5.3.2—Spread Footings**

The design of spread footings at the strength limit state shall also consider:

- Nominal bearing resistance,
- Overturning or excessive loss of contact,
- Sliding at the base of footing, and
- constructability.

#### **C10.5.3.1**

For the purpose of design at strength limit states, the nominal resistance is considered synonymous with the ultimate capacity of an element as previously defined under allowable stress design, i.e., AASHTO (2002).

For design of foundations such as piles or drilled shafts that may be based directly on static load tests, or correlation to static load tests, the definition of failure may include a deflection-limited criteria.

Structural resistance includes checks for axial, lateral and flexural resistance.

The design event for scour is defined in Section 2 and is specified in Article 3.7.5 as applicable at the strength limit state.

#### **C10.5.3.2**

The designer should consider whether special construction methods are required to bear a spread footing at the design depth. Consideration should be given to the potential need for shoring, cofferdams, seals, and/or dewatering. Basal stability of excavations should be evaluated, particularly if dewatering or cofferdams are required.

Effort should be made to identify the presence of expansive/collapsible soils in the vicinity of the footing. If present, the structural design of the footing should be modified to accommodate the potential impact to the performance of the structure, or the expansive/collapsible soils should be removed or otherwise remediated. Special conditions such as the presence of karstic formations or mines should also be evaluated, if present.

### 10.5.3.3—Driven Piles

The design of pile foundations at the strength limit state shall also consider:

- Axial compression resistance for single piles,
- Pile group compression resistance,
- Uplift resistance for single piles,
- Uplift resistance for pile groups,
- Pile punching failure into a weaker stratum below the bearing stratum,
- Single pile and pile group lateral resistance, and
- Constructability, including pile drivability.

### 10.5.3.4—Drilled Shafts

The design of drilled shaft foundations at the strength limit state shall also consider:

- Axial compression resistance for single drilled shafts,
- Shaft group compression resistance,
- Uplift resistance for single shafts,
- Uplift resistance for shaft groups,
- Single shaft and shaft group lateral resistance,
- Shaft punching failure into a weaker stratum below the bearing stratum, and
- Constructability, including method(s) of shaft construction.

### 10.5.3.5—Micropiles

The design of micropile foundations at the strength limit state shall also consider:

- Axial compression resistance for single micropile,
- Micropile group compression resistance,
- Uplift resistance for single micropile,
- Uplift resistance for micropile groups,
- Micropile group punching failure into a weaker stratum below the bearing stratum, and single micropile punching failure where tip resistance is considered,
- Single micropile and micropile group lateral resistance, and
- Constructability, including method(s) of micropile construction.

### C10.5.3.3

The commentary in Article C10.5.3.2 is applicable if a pile cap is needed.

For pile foundations, as part of the evaluation for the strength limit states identified herein, the effects of downdrag, soil setup or relaxation, and buoyancy due to groundwater should be evaluated.

### C10.5.3.4

See commentary in Articles C10.5.3.2 and C10.5.3.3.

The design of drilled shafts for each of these limit states should include the effects of the method of construction, including construction sequencing, whether the shaft will be excavated in the dry or if wet methods must be used, as well as the need for temporary or permanent casing to control caving ground conditions. The design assumptions regarding construction methods must carry through to the contract documents to provide assurance that the geotechnical and structural resistance used for design will be provided by the constructed product.

### C10.5.3.5

The commentary in Article C10.5.3.2 is applicable if a pile cap is needed.

The design of micropiles for each of these limit states should include the effects of the method of construction for the micropile type to be constructed. The design assumptions regarding construction methods must carry through to the contract documents to provide assurance that the geotechnical and structural resistance used for design will be provided by the constructed product.

## 10.5.4—Extreme Events Limit States

### 10.5.4.1—Extreme Events Design

Foundations shall be designed for extreme events as applicable.

### C10.5.4.1

Extreme events include the check flood for scour, vessel and vehicle collision, seismic loading, and other site-specific situations that the Engineer determines should be included. Appendix A10 gives additional guidance regarding seismic analysis and design.

### 10.5.4.2—Liquefaction Design Requirements

A liquefaction assessment shall be conducted for Seismic Zones 3 and 4 if both of the following conditions are present:

- *Ground Water Level*—The groundwater level anticipated at the site is within 50 ft of the existing ground surface or the final ground surface, whichever is lower.
- *Soil Characteristics*—Low plasticity silts and sands within the upper 75 ft are characterized by one of the following conditions: (1) the corrected standard penetration test (*SPT*) blow count,  $(N_1)_{60}$ , is less than or equal to 25 blows/ft in sand and nonplastic silt layers, (2) the corrected cone penetration test (*CPT*) tip resistance,  $q_{cN}$ , is less than or equal to 150 in sand, and nonplastic silt layers, (3) the normalized shear wave velocity,  $V_{sl}$ , is less than 660 fps, or (4) a geologic unit is present at the site that has been observed to liquefy in past earthquakes.

Where loose to very loose saturated sands are within the subsurface soil profile such that liquefaction of these soils could impact the stability of the structure, the potential for liquefaction in Seismic Zone 2 should also be considered.

For sites that require an assessment of liquefaction, the potential effects of liquefaction on soils and foundations shall be evaluated. The assessment shall consider the following effects of liquefaction:

- Loss in strength in the liquefied layer or layers,
- Liquefaction-induced ground settlement,
- Flow failures, lateral spreading, and slope instability.

For sites where liquefaction occurs around bridge foundations, bridges should be analyzed and designed in two configurations as follows:

- *Nonliquefied Configuration*—The structure should be analyzed and designed, assuming no liquefaction occurs, using the ground response spectrum appropriate for the site soil conditions in a nonliquefied state.

### C10.5.4.2

All of the following general conditions are necessary for liquefaction to occur:

- A sustained ground acceleration that is large enough and acting over a long enough period of time to develop excess pore-water pressure, thereby reducing effective stress and soil strength.
- Predominantly cohesionless soil that has the right gradation and composition. Liquefaction has occurred in soils ranging from low plasticity silts to gravels. Clean or silty sands and nonplastic silts are most susceptible to liquefaction.
- The state of the soil is characterized by a density that is low enough for the soil to exhibit contractive behavior when sheared undrained under the initial effective overburden stress.
- The presence of groundwater, resulting in a saturated or nearly saturated soil.

Methods used to assess the potential for liquefaction range from empirically-based design methods to complex numerical, effective stress methods that can model the time-dependent generation of pore-water pressure and its effect on soil strength and deformation. Furthermore, dynamic performance soil tests such as cyclic simple shear or cyclic triaxial tests can be used to assess liquefaction susceptibility and behavior to be used as input for liquefaction analysis and design.

The most common method of assessing liquefaction involves the use of empirical methods (e.g., Youd et al., 2001). These methods provide an estimate of liquefaction potential based on *SPT* blowcounts, *CPT* cone tip resistance, or shear wave velocity. This type of analysis should be conducted as a baseline evaluation, even when more rigorous methods are used.

Youd et al. (2001) summarizes the consensus of the profession up to year 2000 regarding the use of the simplified methods. Since the publication of this consensus paper, various other modifications to the consensus approach have been introduced, including those by Cetin et al. (2004), Moss et al. (2006), and Boulanger and Idriss (2006). These more recent methods account for additions to the database on liquefaction, as

- *Liquefied Configuration*—The structure as designed in nonliquefied configuration above should be reanalyzed assuming that the layer has liquefied and the liquefied soil provides the appropriate residual resistance for lateral and axial deep foundation response analyses consistent with liquefied soil conditions (i.e., modified  $P-y$  curves, modulus of subgrade reaction, or  $t-z$  curves). The design spectrum should be the same as that used in the nonliquefied configuration.

With the Owner's approval, or as required by the Owner, a site-specific response spectrum that accounts for the modifications in spectral content from the liquefying soil may be developed. Unless approved otherwise by the Owner, the reduced response spectrum resulting from the site-specific analyses shall not be less than two-thirds of the spectrum developed at the ground surface using the general procedure described in Article 3.10.4.1 modified by the site factors in Article 3.10.3.2.

The Designer should provide explicit detailing of plastic hinging zones for both cases mentioned above since it is likely that locations of plastic hinges for the liquefied configuration are different than locations of plastic hinges for the nonliquefied configuration. Design requirements including shear reinforcement should be met for the liquefied and nonliquefied configuration. Where liquefaction is identified, plastic hinging in the foundation may be permitted with the Owner's approval.

For those sites where liquefaction-related permanent lateral ground displacements (e.g., flow, lateral spreading, or slope instability) are determined to occur, the effects of lateral displacements on the bridge and retaining structures should be evaluated. These effects can include increased lateral pressure on bridge foundations and retaining walls.

The effects of liquefaction-related, permanent lateral ground displacements on bridge and retaining wall performance should be considered separate from the inertial evaluation of the bridge structures. However, if large magnitude earthquakes dominate the seismic hazards, the bridge response evaluation should consider the potential simultaneous occurrence of:

- Inertial response of the bridge, and loss in ground response from liquefaction around the bridge foundations, and
- Predicted amounts of permanent lateral displacement of the soil.

well as refinements in the interpretation of case history data. The newer methods potentially offer improved estimates of liquefaction potential and can be considered for use.

The simplified empirical methods are suited for use to a maximum depth of approximately 75 ft. This depth limit relates to the database upon which the original empirical method was developed. Most of the database was from observations of liquefaction at depths less than 50 to 60 ft. Extrapolation of the simplified method beyond 75 ft is therefore of uncertain validity. This limitation should not be interpreted as meaning liquefaction does not occur beyond 75 ft. Rather, different methods should be used for greater depths, including the use of site-specific ground motion response modeling in combination with liquefaction testing in the laboratory.

The magnitude for the design earthquake must be determined when conducting liquefaction assessments using the simplified empirical procedures. The earthquake magnitude used to assess liquefaction can be determined from earthquake deaggregation data for the site, available through the USGS national seismic hazard website <http://earthquake.usgs.gov/research/hazmaps/> based on the 975-yr return period (i.e., five percent in 50 yr within the USGS website). If a single or a few larger magnitude earthquakes dominate the deaggregation, the magnitude of the single dominant earthquake or the mean of the few dominant earthquakes in the deaggregation should be used.

Liquefaction is generally limited to granular soils, such as sands and non-plastic silts. Loose gravels also can liquefy if drainage is prevented such as might occur if a layer of clay or frozen soil is located over the gravel. Methods for eliminating sites based on soil type have been developed, as discussed by Youd et al., (2001), Bray and Sancio (2006), and Boulanger and Idriss (2006). These methods can be used to screen the potential for liquefaction in certain soil types. In the past soil screening with regard to silts was done using the Chinese criteria (Kramer, 1996). Recent studies (Bray and Sancio, 2006; Boulanger and Idriss, 2006) indicate that the Chinese criteria are unconservative, and therefore their use should be discontinued.

Two criteria for assessing liquefaction susceptibility of soils have been recently proposed as replacements to the Chinese criteria:

- Boulanger and Idriss (2006) recommend considering a soil to have clay-like behavior (i.e., not susceptible to liquefaction) if the plasticity index ( $PI$ )  $\geq 7$ .
- Bray and Sancio (2006) suggest that a soil with a  $PI < 12$  and a ratio of water content to liquid limit ( $wc/LL$ )  $> 0.85$  will be susceptible to liquefaction.

There is no current consensus on the preferred of the two criteria, and, therefore, either method may be used, unless the Owner has a specific preference.

If inelastic deformations are expected in the foundation due to liquefaction-induced effects, a quantitative assessment of such effects should be considered. Such assessment may follow the approach outlined for SDC D in the *AASHTO Guide Specifications for LRFD Seismic Bridge Design*.

To determine the location of soils that are adequately saturated for liquefaction to occur, the seasonally averaged groundwater elevation should be used. Groundwater fluctuations caused by tidal action or seasonal variations will cause the soil to be saturated only during a limited period of time, significantly reducing the risk that liquefaction could occur within the zone of fluctuation.

Liquefaction evaluation is required only for sites meeting requirements for Seismic Zones 3 and 4, provided that the soil is saturated and of a type that is susceptible to liquefaction. For loose to very loose sand sites (e.g.,  $(N_1)_{60} < 10$  bpf or  $q_{c1N} < 75$ ), a potential exists for liquefaction in Seismic Zone 2, if the acceleration coefficient,  $A_s$ , is 0.15 or higher. The potential for and consequences of liquefaction for these sites will depend on the dominant magnitude for the seismic hazard. As the magnitude decreases, the liquefaction resistance of the soil increases due to the limited number of earthquake loading cycles. Generally, if the magnitude is 6 or less, even in these very loose soils, either the potential for liquefaction is very low or the extent of liquefaction is very limited. Nevertheless, a liquefaction assessment should be made if loose to very loose sands are present to a sufficient extent to impact bridge stability and  $A_s$  is greater than or equal to 0.15. These loose to very loose sands are likely to be present in hydraulically placed fills and alluvial or estuarine deposits near rivers and waterfronts.

During liquefaction, pore-water pressure build-up occurs, resulting in loss of strength and then settlement as the excess pore-water pressures dissipate after the earthquake. The potential effects of strength loss and settlement include:

- *Slope Failure, Flow Failure, or Lateral Spreading*—The strength loss associated with pore-water pressure build-up can lead to slope instability. Generally, if the factor of safety against liquefaction is less than approximately 1.2 to 1.3, a potential for pore-water pressure build-up will occur, and the effects of this build-up should be assessed. If the soil liquefies, the stability is determined by the residual strength of the soil. The residual strength of liquefied soils can be determined using empirical methods developed by Seed and Harder (1990), Olson and Stark (2002), and others. Loss of lateral resistance can allow abutment soils to move laterally, resulting in bridge substructure distortion and unacceptable deformations and moments in the superstructure.
- *Reduced Foundation Bearing Resistance*—Liquefied strength is often a fraction of nonliquefied strength. This loss in strength can result in large displacements or bearing failure. For this reason, spread footing foundations are not recommended where liquefiable soils occur unless the spread footing is located below the maximum depth of liquefaction or soil improvement techniques are used to mitigate the effects of liquefaction.

- *Reduced Soil Stiffness and Loss of Lateral Support for Deep Foundations*—This loss in strength can change the lateral response characteristics of piles and shafts under lateral load.
- *Vertical Ground Settlement as Excess Pore-Water Pressures Induced by Liquefaction Dissipate, Resulting in Downdrag Loads on Deep Foundations*—If liquefaction-induced downdrag loads can occur, the downdrag loads should be assessed as specified in Article 3.11.8.

Most liquefaction-related damage to bridges during past earthquakes has been the result of lateral movement of the soil, causing severe column distortion and potential structure collapse. Therefore, a thorough analysis of the effects of lateral soil movement due to liquefaction on the structure is necessary. If there is potential for significant soil movement, the structure design should meet the requirements of Seismic Zone 4.

The effects of liquefaction will depend in large part on the amount of soil that liquefies and the location of the liquefied soil with respect to the foundation. On sloping ground, lateral flow, spreading, and slope instability can occur on relatively thin layers of liquefiable soils, whereas the effects of thin liquefied layer on the lateral response of piles or shafts (without lateral ground movement) may be negligible. Likewise, a thin liquefied layer at the ground surface results in essentially no downdrag loads, whereas the same liquefied layer deeper in the soil profile could result in large downdrag loads. Given these potential variations, site investigation plays a fundamental part of the liquefaction assessment. Article 10.4 identifies requirements for site investigations.

When assessing the effects of liquefaction on bridge response, the recommendations herein require that structure be designed for two cases, one in which the full seismic acceleration is applied to the structure assuming the soil does not liquefy, and one in which the full seismic acceleration is applied to the structure assuming the soil does liquefy but the spectrum is unchanged by liquefaction. This approach should produce conservative results for bridges with periods less than 1 sec. However, Youd and Carter (2005) suggest that at periods greater than 1 second, it is possible for liquefaction to result in higher spectral accelerations than occur for equivalent nonliquefied cases, all other conditions being equal. For Site Class C or D and bridges with periods greater than 1 sec., the Designer may consider using a response spectrum constructed using Site Class E for the liquefied condition. Alternately, site-specific ground motion response evaluations may be used to evaluate this potential.

There is currently no consensus on how to address this issue of timing of seismic acceleration and the development of full liquefaction and its combined impact on the structure without resorting to more rigorous analyses, such as by using nonlinear, effective stress methods. In general, the larger the earthquake magnitude (e.g.,  $M > 8$ ), the longer the period of time over which strong shaking acts, and the more likely the strong shaking and liquefaction effects will be acting concurrently. The smaller the earthquake magnitude, the more likely that these two effects will not be concurrent, in which case the peak inertial response of the bridge may occur before much, if any, reduction in soil support from liquefaction occurs.

Site-specific dynamic ground motion response analyses offers one method of evaluating the effects of pore-water pressure increases and timing on the development of the response spectrum. These analyses can be conducted using a nonlinear, effective stress method that accounts for the build-up in pore-water pressure and stiffness degradation in liquefiable layers. Use of this approach requires considerable skill in terms of selecting model parameters, particularly the pore pressure model. The complexity of this approach is such that Owner's approval is mandatory, and it is highly advisable that an independent peer review panel with expertise in nonlinear, effective stress modeling be used to review the methods and the resulting spectrum.

The limit of two-thirds for reduction of the liquefied response spectrum below the nonliquefied spectrum is meant to apply to any ordinate of the response spectrum. Generally, liquefied conditions may produce significant reductions in the shorter period range, but the reductions will be smaller or could be increased over nonliquefied conditions in the longer period range over about 1–2 sec. The developer of the site response analysis should capture accurate estimates of response for all periods that could be of importance in both nonliquefied and liquefied conditions. This consideration is particularly important if the conventional spectral shapes of Article 3.10.4.1 are being used.

The timing of liquefaction relative to the development of strong shaking also can be an important consideration for sites where lateral ground movement occurs. Both the development of liquefaction and the ground movement are dependent on the size and magnitude of the earthquake, but they do not necessarily occur at the same time. This issue is especially important when determining how to combine the inertial response of the structure and the response to lateral movement of the soil against the foundations and other substructure elements due to lateral spreading, slope instability, and flow failure. Current practice is to consider these two mechanisms to be independent, and therefore, the analyses are decoupled; i.e., the analysis is first performed to evaluate inertial effects during liquefaction following the same guidance as for level-

ground sites, and then the foundation is evaluated for the moving ground, but without the inertial effects of the bridge superimposed. For critical bridges or in areas where very large magnitude earthquakes could occur, detailed studies addressing the two mechanisms acting concurrently may be warranted. This timing issue also affects liquefaction-induced downdrag, in that settlement and downdrag generally does not occur until the pore pressures induced by ground shaking begin to dissipate after shaking ceases.

For assessment of existing structures, the Designer should consider using Seismic Zone 4 regardless of the magnitude of  $A_s$ , even when significant lateral soil movement is not expected, if the structure is particularly weak with regard to its ability to resist the forces and displacements that could be caused by liquefaction. Examples of weaknesses that could exacerbate the impact of liquefaction to the structure include presence of shallow foundations, deep foundations tipped in liquefiable soil, very limited bridge support lengths that have little tolerance of lateral movement of the substructure, deterioration of superstructure or substructure components due to advanced age of the structure or severe environmental conditions, and the absence of substructure redundancy.

The intent of these Specifications is to limit inelastic deformations under seismic loading to above-ground locations that can be inspected. However, if liquefaction occurs, it may be difficult or impossible to restrict inelastic action solely to above-ground locations without site improvement. If inelastic deformations are expected in the foundation, then the Owner may consider installation of devices that permit post-earthquake assessment; for example, installation of inclinometer tubes in drilled shafts permits limited evaluation of the deformations of the foundation, which would otherwise be impossible to inspect at any significant depth. Permitting inelastic behavior below the ground implies that the shaft or piles will be damaged, possibly along with other parts of the bridge, and may need to be replaced.

Design options range from (a) an acceptance of the movements with significant damage to the piles and columns if the movements are large (possibly requiring demolition but still preserving the no-collapse philosophy) to (b) designing the piles to resist the forces generated by lateral spreading. Between these options are a range of mitigation measures to limit the amount of movement to tolerable levels for the desired performance objective. However, tolerable structural movements should be evaluated quantitatively.

Quantitative assessments of liquefaction-induced deformations on foundations may be accomplished using the nonlinear static “push over” methodology. However, such analysis is complicated by the need to model nonlinear  $P-y$  behavior of the liquefied soil along with the nonlinear behavior of the structure. Analyses where the liquefied soil is represented by appropriate

residual resistance ( $P-y$  curves or modulus of subgrade reaction values) will generally provide conservative results for the actual inelastic behavior of the foundation structural elements. The approach for such analyses should be developed on a case-by-case basis due to the varied conditions found in liquefiable sites. Careful coordination between the geotechnical and structural engineers is essential to estimating the expected response and to evaluating whether the structure can tolerate the response. Often mitigation strategies may be required to reduce structural movements.

Mitigation of the effects of liquefaction-induced settlement or lateral soil movement may include ground stabilization to either prevent liquefaction or add strength to keep soil deformation from occurring, foundation or superstructure modifications to resist the forces and accommodate the deformations that may occur, or both.

It is often cost prohibitive to design the bridge foundation system to resist the loads imposed by liquefaction-induced lateral loads, especially if the depth of liquefaction extends more than about 20 ft below the ground surface and if a nonliquefied crust is part of the failure surface. Ground improvement to mitigate the liquefaction hazard is the likely alternative if it is not practical to design the foundation system to accommodate the lateral loads.

The primary ground improvement techniques to mitigate liquefaction fall into five general categories, namely removal and replacement, densification, reinforcement, altering the soil composition, and enhanced drainage. Any one or a combination of methods can be used. However, drainage improvement is not currently considered adequately reliable to prevent liquefaction-induced, excess pore-water pressure build-up due to (1) the time required for excess pore-water pressures to dissipate through the drainage paths, and (2) the potential for drainage materials to become clogged during installation and in service. In addition, with drainage enhancements some settlement is still likely. Therefore, drainage enhancements should not be used as a means to fully mitigate liquefaction. For further discussion of ground improvement methods, see FHWA-SA-98-086, *Ground Improvement Technical Summaries* (Elias, et al., 2000); FHWA-SA-95-037; Geotechnical Engineering Circular No. 1, *Dynamic Compaction* (Lukas, 1995); and FHWA/RD-83/O2C, *Design and Construction of Stone Columns* (Barkdale and Bachus, 1983).

The use of large diameter shafts in lieu of the conventional pile cap foundation type may be considered in order to achieve the lateral strength and stiffness required to sustain the column demand while minimizing the foundation exposed surface area normal to the lateral flow direction.

## 10.5.5—Resistance Factors

### 10.5.5.1—Service Limit States

Resistance factors for the service limit states shall be taken as 1.0, except as provided for overall stability in Article 11.6.2.3.

A resistance factor of 1.0 shall be used to assess the ability of the foundation to meet the specified deflection criteria after scour due to the design flood.

### 10.5.5.2—Strength Limit States

#### 10.5.5.2.1—General

Resistance factors for different types of foundation systems at the strength limit state shall be taken as specified in Articles 10.5.5.2.2, 10.5.5.2.3, 10.5.5.2.4, and 10.5.5.2.5, unless regionally specific values or substantial successful experience is available to justify higher values.

#### C10.5.5.2.1

Regionally specific values should be determined based on substantial statistical data combined with calibration or substantial successful experience to justify higher values. Smaller resistance factors should be used if site or material variability is anticipated to be unusually high or if design assumptions are required that increase design uncertainty that have not been mitigated through conservative selection of design parameters.

Certain resistance factors in Articles 10.5.5.2.2, 10.5.5.2.3, 10.5.5.2.4, and 10.5.5.2.5 are presented as a function of soil type, e.g., sand or clay. Naturally occurring soils do not fall neatly into these two classifications. In general, the terms “sand” and “cohesionless soil” may be connote to mean drained conditions during loading, while “clay” or “cohesive soil” implies undrained conditions. For other or intermediate soil classifications, such as silts or gravels, the designer should choose, depending on the load case under consideration, whether the resistance provided by the soil will be a drained or undrained strength, and select the method of computing resistance and associated resistance factor accordingly.

In general, resistance factors for bridge and other structure design have been derived to achieve a reliability index,  $\beta$ , of 3.5, an approximate probability of failure,  $P_f$ , of 1 in 5,000. However, past geotechnical design practice has resulted in an effective reliability index,  $\beta$ , of 3.0, or an approximate probability of a failure of 1 in 1,000, for foundations in general, and for highly redundant systems, such as pile groups, an approximate reliability index,  $\beta$ , of 2.3, an approximate probability of failure of 1 in 100 (Zhang et al., 2001; Paikowsky et al., 2004; Allen, 2005). If the resistance factors provided in this Article are adjusted to account for regional practices using statistical data and calibration, they should be developed using the  $\beta$  values provided above, with consideration given to the redundancy in the foundation system.

For bearing resistance, lateral resistance, and uplift calculations, the focus of the calculation is on the individual foundation element, e.g., a single pile or drilled shaft. Since these foundation elements are usually part of a foundation unit that contains multiple

The foundation resistance after scour due to the design flood shall provide adequate foundation resistance using the resistance factors given in this Article.

#### 10.5.5.2.2—Spread Footings

The resistance factors provided in Table 10.5.5.2.2-1 shall be used for strength limit state design of spread footings, with the exception of the deviations allowed for local practices and site specific considerations in Article 10.5.5.2.

elements, failure of one of these foundation elements usually does not cause the entire foundation unit to reach failure, i.e., due to load sharing and overall redundancy. Therefore, the reliability of the foundation unit is usually more, and in many cases considerably more, than the reliability of the individual foundation element. Hence, a lower reliability can be successfully used for redundant foundations than is typically the case for the superstructure.

Note that not all of the resistance factors provided in this Article have been derived using statistical data from which a specific  $\beta$  value can be estimated, since such data were not always available. In those cases, where data were not available, resistance factors were estimated through calibration by fitting to past allowable stress design safety factors, e.g., the AASHTO *Standard Specifications for Highway Bridges* (2002).

Additional discussion regarding the basis for the resistance factors for each foundation type and limit state is provided in Articles 10.5.5.2.2, 10.5.5.2.3, 10.5.5.2.4, and 10.5.5.2.5. Additional, more detailed information on the development of the resistance factors for foundations provided in this Article, and a comparison of those resistance factors to previous Allowable Stress Design practice, e.g., AASHTO (2002), is provided in Allen (2005).

Scour design for the design flood must satisfy the requirement that the factored foundation resistance after scour is greater than the factored load determined with the scoured soil removed. The resistance factors will be those used in the Strength Limit State, without scour.

#### C10.5.5.2.2

**Table 10.5.5.2.2-1—Resistance Factors for Geotechnical Resistance of Shallow Foundations at the Strength Limit State**

		Method/Soil/Condition	Resistance Factor
Bearing Resistance	$\varphi_b$	Theoretical method (Munfakh et al., 2001), in clay	0.50
		Theoretical method (Munfakh et al., 2001), in sand, using <i>CPT</i>	0.50
		Theoretical method (Munfakh et al., 2001), in sand, using <i>SPT</i>	0.45
		Semi-empirical methods (Meyerhof, 1957), all soils	0.45
		Footings on rock	0.45
		Plate Load Test	0.55
Sliding	$\varphi_t$	Precast concrete placed on sand	0.90
		Cast-in-Place Concrete on sand	0.80
		Cast-in-Place or precast Concrete on Clay	0.85
		Soil on soil	0.90
		$\varphi_{ep}$ Passive earth pressure component of sliding resistance	0.50

The resistance factors in Table 10.5.5.2.2-1 were developed using both reliability theory and calibration by fitting to Allowable Stress Design (ASD). In general, ASD safety factors for footing bearing capacity range from 2.5 to 3.0, corresponding to a resistance factor of approximately 0.55 to 0.45, respectively, and for sliding, an ASD safety factor of 1.5, corresponding to a resistance factor of approximately 0.9. Calibration by fitting to ASD controlled the selection of the resistance factor in cases where statistical data were limited in quality or quantity. The resistance factor for sliding of cast-in-place concrete on sand is slightly lower than the other sliding resistance factors based on reliability theory analysis (Barker et al., 1991). The higher interface friction coefficient used for sliding of cast-in-place concrete on sand relative to that used for precast concrete on sand causes the cast-in-place concrete sliding analysis to be less conservative, resulting in the need for the lower resistance factor. A more detailed explanation of the development of the resistance factors provided in Table 10.5.5.2.2-1 is provided in Allen (2005).

The resistance factors for plate load tests and passive resistance were based on engineering judgment and past ASD practice.

#### *10.5.5.2.3—Driven Piles*

Resistance factors shall be selected from Table 10.5.5.2.3-1 based on the method used for determining the driving criterion necessary to achieve the required nominal bearing pile resistance.

Regarding load tests, and dynamic tests with signal matching, the number of tests to be conducted to justify the design resistance factors selected should be based on the variability in the properties and geologic stratification of the site to which the test results are to be applied. A site shall be defined as a project site, or a portion of it, where the subsurface conditions can be characterized as geologically similar in terms of subsurface stratification, i.e., sequence, thickness, and geologic history of strata, the engineering properties of the strata, and groundwater conditions.

#### *C10.5.5.2.3*

Where nominal pile bearing resistance is determined by static load test, dynamic testing, wave equation, or dynamic formulas, the uncertainty in the nominal resistance is strictly due to the reliability of the resistance determination method used in the field during pile installation.

In most cases, the nominal bearing resistance of each production pile is field-verified based on compliance with a driving criterion developed using a dynamic method (see Articles 10.7.3.8.2, 10.7.3.8.3, 10.7.3.8.4, or 10.7.3.8.5). The actual penetration depth where the pile is stopped using the driving criterion (e.g., a blow count measured during pile driving) will likely not be the same as the estimated depth from the static analysis. Hence, the reliability of the nominal pile bearing resistance is dependent on the reliability of the method used to verify the nominal resistance during pile installation (see Allen, 2005, for additional discussion on this issue). Therefore, the resistance factor for the field verification method should be used to determine the number of piles of a given nominal resistance needed to resist the factored loads in the strength limit state.

If the resistance factors provided in Table 10.5.5.2.3-1 are to be applied to small pile groups, the resistance factor values in the table should be reduced by 20 percent to reflect the reduced ability for overstressing of an individual foundation element to be carried by adjacent foundation elements. The minimum size of a pile group necessary to provide significant opportunity for load sharing ranges from 2 or 3 (Isenhower and Long, 1997) to 5 (Paikowsky, et al., 2004).

The ability to share load between structural elements should an overstress occur is addressed in Article 1.3.4 through the use of  $\eta_R$ . The values for  $\eta_R$  provided in that Article have been developed in general for the superstructure, and no specific guidance on the application of  $\eta_R$  to foundations is provided. The  $\eta_R$  factor values recommended in Article 1.3.4 are not adequate to address this ability to shed load to other foundation elements when some of the foundation elements become overstressed, based on the results provided by Paikowsky et al. (2004) and others (see also Allen, 2005). Therefore, the resistance factors specified in Table 10.5.5.2.3-1 should be reduced based on the guidance provided in this Article to account for the lack of load sharing opportunities due to the small pile group size.

Dynamic methods may underpredict the nominal axial resistance of piles driven in soft silts or clays where a large amount of setup is anticipated and it is not feasible to perform static load or dynamic tests over a sufficient length of time to assess soil setup.

See Allen (2005) for an explanation on the development of the resistance factors for pile foundation design.

For all axial resistance calculation methods, the resistance factors were, in general, developed from load test results obtained on piles with diameters of 24 in. or less. Very little data were available for larger diameter piles. Therefore, these resistance factors should be used with caution for design of significantly larger diameter piles. In general, experience has shown that the static analysis methods identified in Table 10.5.5.2.3-1 tend to significantly overestimate the available nominal resistance for larger diameter piles. A static or dynamic load test should be considered if piles larger than 24 in. in diameter are anticipated.

Note that a site as defined herein may be only a portion of the area in which the structure (or structures) is located. For sites where conditions are highly variable, a site could even be limited to a single pier.

Where driving criteria are established based on a static load test, the potential for site variability should be considered. The number of load tests required should be established based on the characterization of site subsurface conditions by the field and laboratory exploration and testing program.

One of the following alternative approaches may be used to address site variability when extrapolating pile load test results, and the application of driving criteria from those load test results, to piles not load tested:

1. Divide up the site into zones where subsurface conditions are relatively uniform using engineering judgment, conducting one static pile load test in each zone, and dynamic testing with signal matching on a minimum of two percent of the production piles, but no less than two production piles. A resistance factor of 0.80 is recommended if this approach is used. If production pile dynamic testing is not conducted, then a resistance factor of 0.75 should be used.
2. Characterize the site variability and select resistance factors using the approach described by Paikowsky et al. (2004).

The dynamic testing with signal matching should be evenly distributed within a pier and across the entire structure. However, within a particular footing, an increase in safety is realized where the most heavily loaded piles are tested.

The resistance factors in Table 10.5.5.2.3-1 for the case where dynamic testing is conducted without static load testing were developed using reliability theory for beginning of redrive (BOR) conditions. These resistance factors may be used for end of driving (EOD) conditions, but it should be recognized that dynamic testing with signal matching at EOD will likely produce conservative results because soil set up, which causes nominal pile bearing resistance to increase, is not taken into account. If, instead, relaxation is anticipated to occur, these resistance factors for dynamic testing should only be used at BOR.

The 0.50 resistance factor in Table 10.5.5.2.3-1 for use of the wave equation without dynamic measurements to estimate nominal pile bearing resistance is based on calibration by fitting to past allowable stress design practice. Using default wave equation hammer and soil input values, reliability theory calibrations performed by Paikowsky et al. (2004) suggest that a resistance factor of 0.40 should be used if the wave equation is used to estimate nominal pile bearing resistance. Their recommendation is more conservative than the resistance factor implied by past allowable stress design practice. Their recommendation should be considered representative of the reliability of the wave equation to estimate nominal pile bearing resistance by designers who lack experience with the

wave equation and its application to local or regional subsurface conditions. Application of default wave equation input parameters without consideration to local site conditions and observed hammer performance in combination with this lower resistance factor is not recommended.

Local experience or site-specific test results should be used to refine the wave equation soil input values, or to at least use the input values selected with greater confidence, and field verification of the hammer performance should be conducted to justify the use of the resistance factor of 0.50 provided in Table 10.5.5.2.3-1. Field verification of hammer performance is considered to be a direct measurement of either stroke or kinetic energy.

See Articles 10.7.3.8.2, 10.7.3.8.3, 10.7.3.8.4, and 10.7.3.8.5 for additional guidance regarding static pile load testing, dynamic testing and signal matching, wave equation analysis, and dynamic formulas, respectively, as they apply to the resistance factors provided in Table 10.5.5.2.3-1.

The dynamic pile formulas, i.e., FHWA modified Gates and Engineering News, identified in Table 10.5.5.2.3-1 require the pile hammer energy as an input parameter. The developed hammer energy should be used for this purpose, defined as the product of actual stroke developed during the driving of the pile (or equivalent stroke as determined from the bounce chamber pressure for double acting hammers) and the hammer ram weight.

The resistance factors provided in Table 10.5.5.2.3-1 are specifically applicable to the dynamic pile formula as provided in Article 10.7.3.8.5. Note that for the Engineering News (EN) formula, the built-in safety factor of 6 has been removed so that it predicts nominal resistance. Therefore, the resistance factor shown in Table 10.5.5.2.3-1 for EN formula should not be applied to the traditional “allowable stress” form of the equation.

The resistance factors for the dynamic pile formulas, i.e., FHWA modified Gates and EN, in Table 10.5.5.2.3-1 have been specifically developed for EOD conditions. Since static pile load test data, which include the effects of soil setup or relaxation (for the database used, primarily soil setup), were used to develop the resistance factors for these formulas, the resistance factors reflect soil setup occurring after the pile installation. At BOR, the blow count obtained already includes the soil setup. Therefore, a lower resistance factor for the driving formulas should be used for BOR conditions than the ones shown in Table 10.5.5.2.3-1 for EOD conditions. In general, dynamic testing should be conducted to verify nominal pile resistance at BOR in lieu of the use of driving formulas.

Paikowsky et al. (2004) indicate that the resistance factors for static pile resistance analysis methods can vary significantly for different pile types. The resistance factors presented are average values for the method. See Paikowsky et al. (2004) and Allen (2005) for additional information regarding this issue.

The resistance factor for the Nordlund/Thurman method was derived primarily using the Peck et al. (1974) correlation between  $SPT N_{160}$  and the soil friction angle, using a maximum design soil friction angle of 36 degrees, assuming the contributing zone for the end bearing resistance is from the tip to two pile diameters below the tip. These assumptions should be considered when using the resistance factor specified in Table 10.5.5.2.3-1 for this static analysis method.

For the clay static pile analysis methods, if the soil cohesion was not measured in the laboratory, the correlation between  $SPT N$  and  $S_u$  by Hara et al. (1974) was used for the calibration. Use of other methods to estimate  $S_u$  may require the development of resistance factors based on those methods.

The resistance factors provided for uplift of single piles are generally less than the resistance factors for axial side resistance under compressive loading. This is consistent with past practice that recognizes the side resistance in uplift is generally less than the side resistance under compressive loading, and is also consistent with the statistical calibrations performed in Paikowsky et al. (2004). Since the reduction in uplift resistance that occurs in tension relative to the side resistance in compression is taken into account through the resistance factor, the calculation of side resistance using a static pile resistance analysis method should not be reduced from what is calculated from the methods provided in Article 10.7.3.8.6.

For uplift, the number of pile load tests required to justify a specific resistance factor are the same as that required for determining compression resistance. Extrapolating the pile load test results to other untested piles as specified in Article 10.7.3.10 does create some uncertainty, since there is not a way to directly verify that the desired uplift resistance has been obtained for each production pile. This uncertainty has not been quantified. Therefore, it is recommended that a resistance factor of not greater than 0.60 be used if an uplift load test is conducted.

Regarding pile drivability analysis, the only source of load is from the pile driving hammer. Therefore, the load factors provided in Section 3 do not apply. In past practice, e.g., AASHTO (2002), no load factors were applied to the stresses imparted to the pile top by the pile hammer. Therefore, a load factor of 1.0 should be used for this type of analysis. Generally, either a wave equation analysis or dynamic testing, or both, are used to determine the stresses in the pile resulting from hammer impact forces. See Article 10.7.8 for the specific calculation of the pile structural resistance available for analysis of pile drivability. The structural resistance available during driving determined as specified in Article 10.7.8 considers the ability of the pile to handle the transient stresses resulting from hammer impact, considering variations in the materials, pile/hammer misalignment, and variations in the pile straightness and uniformity of the pile head impact surface.

**Table 10.5.5.2.3-1—Resistance Factors for Driven Piles**

Condition/Resistance Determination Method	Resistance Factor
Nominal Bearing Resistance of Single Pile—Dynamic Analysis and Static Load Test Methods, $\phi_{dyn}$	Driving criteria established by successful static load test of at least one pile per site condition and dynamic testing* of at least two piles per site condition, but no less than 2% of the production piles
	Driving criteria established by successful static load test of at least one pile per site condition without dynamic testing
	Driving criteria established by dynamic testing* conducted on 100% of production piles
	Driving criteria established by dynamic test with signal matching at beginning of redrive (BOR) conditions only of at least one production pile per pier, but no less than the number of tests per site provided in Table 10.5.5.2.3-3.
	Wave equation analysis, without pile dynamic measurements or load test, at end of drive conditions only
	FHWA-modified Gates dynamic pile formula (End of Drive condition only)
	Engineering News Record (as defined in Article 10.7.3.8.5) dynamic pile formula (End of Drive condition only)

**Table 10.5.5.2.3-1—Resistance Factors for Driven Piles (continued)**

Condition/Resistance Determination Method		Resistance Factor
Nominal Resistance of Single Pile in Axial Compression— Static Analysis Methods, $\phi_{stat}$	Skin Friction and End Bearing: Clay and Mixed Soils $\alpha$ -method (Tomlinson, 1987; Skempton, 1951) $\beta$ -method (Esrig & Kirby, 1979; Skempton, 1951) $\lambda$ -method (Vijayvergiya & Focht, 1972; Skempton, 1951)	0.35 0.25 0.40
	Skin Friction and End Bearing: Sand Nordlund/Thurman Method (Hannigan et al., 2005) <i>SPT</i> -method (Meyerhof)	0.45 0.30

#### 10.5.5.2.4—Drilled Shafts

Resistance factors shall be selected based on the method used for determining the nominal shaft resistance. When selecting a resistance factor for shafts in clays or other easily disturbed formations, local experience with the geologic formations and with typical shaft construction practices shall be considered.

Where the resistance factors provided in Table 10.5.5.2.4-1 are to be applied to a nonredundant foundation such as a single shaft supporting a bridge pier, the resistance factor values in the Table should be reduced by 20 percent to reflect a higher target  $\beta$  value of 3.5, an approximate probability of failure of one in 5,000, to be consistent with what has been used generally for design of the superstructure. Where the resistance factor is decreased in this manner, the  $\eta_R$  factor provided in Article 1.3.4 shall not be increased to address the lack of foundation redundancy.

The number of static load tests to be conducted to justify the resistance factors provided in Tables 10.5.5.2.4-1 and 10.5.5.2.3-2 shall be based on the variability in the properties and geologic stratification of the site to which the test results are to be applied. A site, for the purpose of assessing variability, shall be defined in accordance with Article 10.5.5.2.3.

#### C10.5.5.2.4

The resistance factors in Table 10.5.5.2.4-1 were developed using either statistical analysis of shaft load tests combined with reliability theory (Paikowsky et al., 2004), fitting to allowable stress design (ASD), or both. Where the two approaches resulted in a significantly different resistance factor, engineering judgment was used to establish the final resistance factor, considering the quality and quantity of the available data used in the calibration. The available reliability theory calibrations were conducted for the Reese and O'Neill (1988) method, with the exception of shafts in intermediate geo-materials (IGMs), in which case the O'Neill and Reese (1999) method was used. In Article 10.8, the O'Neill and Reese (1999) method is recommended. See Allen (2005) for a more detailed explanation on the development of the resistance factors for shaft foundation design, and the implications of the differences in these two shaft design methods on the selection of resistance factors.

For the statistical calibrations using reliability theory, a target reliability index,  $\beta$ , of 3.0, an approximate probability of failure of one in 1,000, was used. The selection of this target reliability assumes a small amount of redundancy in the foundation system is present, which is typical for shaft groups containing at least two to four shafts in the group (Paikowsky et al., 2004). For single shafts, less redundancy will be present. The issue of redundancy, or the lack of it, is addressed in Article 1.3.4 through the use of  $\eta_R$ . The values for  $\eta_R$  provided in that Article have been developed in general for the superstructure, and no specific guidance on the application of  $\eta_R$  to foundations is provided. The  $\eta_R$  factor values recommended in Article 1.3.4 are not adequate to address the difference in foundation redundancy, based on the results provided by Paikowsky et al. (2004) and others (see also Allen, 2005). Therefore, the resistance factors specified in Table 10.5.5.2.4-1 should be reduced to account for the reduced redundancy.

Where installation criteria are established based on a static load test, the potential for site variability should be considered. The number of load tests required should be established based on the characterization of site subsurface conditions by the field and laboratory exploration and testing program. One or more static load tests should be performed per site to justify using the resistance factor in Table 10.5.5.2.3-2 for drilled shafts installed within the site.

Table 10.5.5.2.3-2 identifies resistance factors to be used and numbers of tests needed depending on whether the site variability is classified as low, medium, or high. Site variability may be determined based on judgment, or based on the following suggested criteria (Paikowsky et al., 2004):

- Step 1: For each identified significant stratum at each boring location, determine the average property value, e.g., SPT value,  $q_c$  value, etc., within the stratum for each boring.
- Step 2: Determine the mean and coefficient of variation of the average values for each stratum determined in Step 1.
- Step 3: Categorize the site variability as low if the COV is less than 25 percent, medium if the COV is 25 percent or more, but less than 40 percent, and high if the COV is 40 percent or more.

See Paikowsky et al. (2004) for additional discussion regarding these site variability criteria.

For the specific case of shafts in clay, the resistance factor recommended by Paikowsky et al. (2004) is much lower than the recommendation from Barker et al. (1991). Since the shaft design method for clay is nearly the same for both the 1988 and 1999 methods, a resistance factor that represents the average of the two resistance factor recommendations is provided in Table 10.5.5.2.4-1. This difference may point to the differences in local geologic formations and local construction practices, pointing to the importance of taking such issues into consideration when selecting resistance factors, especially for shafts in clay.

IGMs are materials that are transitional between soil and rock in terms of their strength and compressibility, such as residual soils, glacial tills, or very weak rock. See Article C10.8.2.2.3 for a more detailed definition of an IGM.

Since the mobilization of shaft base resistance is less certain than side resistance due to the greater deformation required to mobilize the base resistance, a lower resistance factor relative to the side resistance is provided for the base resistance in Table 10.5.5.2.4-1. O'Neill and Reese (1999) make further comment that the recommended resistance factor for tip resistance in sand is applicable for conditions of high quality control

on the properties of drilling slurries and base cleanout procedures. If high quality control procedures are not used, the resistance factor for the O'Neill and Reese (1999) method for tip resistance in sand should be also be reduced. The amount of reduction should be based on engineering judgment.

Shaft compression load test data should be extrapolated to production shafts that are not load tested as specified in Article 10.8.3.5.6. There is no way to verify shaft resistance for the untested production shafts, other than through good construction inspection and visual observation of the soil or rock encountered in each shaft. Because of this, extrapolation of the shaft load test results to the untested production shafts may introduce some uncertainty. Hence, a reduction of the resistance factor used for design relative to the values provided in Table 10.5.5.2.3-2 may be warranted. Statistical data are not available to quantify this at this time. A resistance factor somewhere between the resistance factors specified for the static analysis method in Table 10.5.5.2.3-1 and the load test resistance factors specified in Table 10.5.5.2.3-2 should be used. Historically, resistance factors higher than 0.70, or their equivalent safety factor in previous practice, have not been used. Therefore, it is recommended that Table 10.5.5.2.3-2 be used, but that the resistance factor not be greater than 0.70.

This issue of uncertainty in how the load test are applied to shafts not load tested is even more acute for shafts subjected to uplift load tests, as failure in uplift can be more abrupt than failure in compression. Hence, a resistance factor of 0.60 for the use of uplift load test results is recommended.

**Table 10.5.5.2.4-1—Resistance Factors for Geotechnical Resistance of Drilled Shafts**

Method/Soil/Condition			Resistance Factor
Nominal Axial Compressive Resistance of Single-Drilled Shafts, $\phi_{stat}$	Side resistance in clay	$\alpha$ -method (O'Neill and Reese, 1999)	0.45
	Tip resistance in clay	Total Stress (O'Neill and Reese, 1999)	0.40
	Side resistance in sand	$\beta$ -method (O'Neill and Reese, 1999)	0.55
	Tip resistance in sand	O'Neill and Reese (1999)	0.50
	Side resistance in IGMs	O'Neill and Reese (1999)	0.60
	Tip resistance in IGMs	O'Neill and Reese (1999)	0.55
	Side resistance in rock	Horvath and Kenney (1979) O'Neill and Reese (1999)	0.55
	Side resistance in rock	Carter and Kulhawy (1988)	0.50
	Tip resistance in rock	Canadian Geotechnical Society (1985) Pressuremeter Method (Canadian Geotechnical Society, 1985) O'Neill and Reese (1999)	0.50
Block Failure, $\phi_{bl}$	Clay		0.55
Uplift Resistance of Single-Drilled Shafts, $\phi_{up}$	Clay	$\alpha$ -method (O'Neill and Reese, 1999)	0.35
	Sand	$\beta$ -method (O'Neill and Reese, 1999)	0.45
	Rock	Horvath and Kenney (1979) Carter and Kulhawy (1988)	0.40
Group Uplift Resistance, $\phi_{ug}$	Sand and clay		0.45
Horizontal Geotechnical Resistance of Single Shaft or Shaft Group	All materials		1.0
Static Load Test (compression), $\phi_{load}$	All Materials	Values in Table 10.5.5.2.3-2, but no greater than 0.70	
Static Load Test (uplift), $\phi_{upload}$	All Materials		0.60

**10.5.5.2.5—Micropiles****C10.5.5.2.5**

Resistance factors shall be selected from Table 10.5.5.2.5-1 based on the method used for determining the nominal axial pile resistance. If the resistance factors provided in Table 10.5.5.2.5-1 are to be applied to piles in potentially creeping soils, highly plastic soils, weak rock, or other marginal ground type, the resistance factor values in the Table should be reduced by 20 percent to reflect greater design uncertainty.

The resistance factors in Table 10.5.5.2.5-1 were calibrated by fitting to ASD procedures tempered with engineering judgment. The resistance factors in Table 10.5.5.2.5-2 for structural resistance were calibrated by fitting to ASD procedures and are equal to or slightly more conservative than corresponding resistance factors from Section 5 of the AASHTO LRFD Specifications for reinforced concrete column design.

**Table 10.5.5.2.5-1—Resistance Factors for Geotechnical Resistance of Axially Loaded Micropiles**

Limit State	Method/ Ground Condition	Resistance Factor
Compression Resistance of Single Micropile, $\phi_{stat}$	Side Resistance (Bond Resistance): Presumptive Values	0.55 <sup>(1)</sup>
	Tip Resistance on Rock O'Neill and Reese (1999)	0.50
	Side Resistance and Tip Resistance Load Test	Values in Table 10.5.5.2.3-1, but no greater than 0.70
Block Failure, $\phi_{bl}$	Clay	0.60
Uplift Resistance of Single Micropile, $\phi_{up}$	Presumptive Values	0.55 <sup>(1)</sup>
	Tension Load Test	Values in Table 10.5.5.2.3-1, but no greater than 0.70
Group Uplift Resistance, $\phi_{ug}$	Sand & Clay	0.50

<sup>(1)</sup> Apply to presumptive grout-to-ground bond values for preliminary design only in Article C10.9.3.5.2.

**Table 10.5.5.2.5-2—Resistance Factors for Structural Resistance of Axially Loaded Micropiles**

Section / Loading Condition		Resistance Factor
Pile Cased Length	Tension, $\phi_{TC}$	0.80
	Compression, $\phi_{CC}$	0.75
Pile Uncased Length	Tension, $\phi_{TU}$	0.80
	Compression, $\phi_{CU}$	0.75

### 10.5.5.3—Extreme Limit States

#### 10.5.5.3.1—General

Design of foundations at extreme limit states shall be consistent with the expectation that structure collapse is prevented and that life safety is protected.

#### 10.5.5.3.2—Scour

The provisions of Articles 2.6.4.4.2 and 3.7.5 shall apply to the changed foundation conditions resulting from scour. Resistance factors at the strength limit state shall be taken as specified herein. Resistance factors at the extreme event shall be taken as 1.0 except that for uplift resistance of piles and shafts, the resistance factor shall be taken as 0.80 or less.

The foundation shall resist not only the loads applied from the structure but also any debris loads occurring during the flood event.

#### C10.5.5.3.2

The specified resistance factors should be used provided that the method used to compute the nominal resistance does not exhibit bias that is unconservative. See Paikowsky et al. (2004) regarding bias values for pile resistance prediction methods.

Design for scour is discussed in Hannigan et al. (2005).

**10.5.5.3.3—Other Extreme Limit States**

Resistance factors for extreme limit state, including the design of foundations to resist earthquake, ice, vehicle or vessel impact loads, shall be taken as 1.0. For uplift resistance of piles and shafts, the resistance factor shall be taken as 0.80 or less.

**10.6—SPREAD FOOTINGS****10.6.1—General Considerations****10.6.1.1—General**

Provisions of this Article shall apply to design of isolated, continuous strip and combined footings for use in support of columns, walls and other substructure and superstructure elements. Special attention shall be given to footings on fill, to make sure that the quality of the fill placed below the footing is well controlled and of adequate quality in terms of shear strength and compressibility to support the footing loads.

Spread footings shall be proportioned and designed such that the supporting soil or rock provides adequate nominal resistance, considering both the potential for adequate bearing strength and the potential for settlement, under all applicable limit states in accordance with the provisions of this Section.

Spread footings shall be proportioned and located to maintain stability under all applicable limit states, considering the potential for, but not necessarily limited to, overturning (eccentricity), sliding, uplift, overall stability and loss of lateral support.

**10.6.1.2—Bearing Depth**

Where the potential for scour, erosion or undermining exists, spread footings shall be located to bear below the maximum anticipated depth of scour, erosion, or undermining as specified in Article 2.6.4.4.

**C10.5.5.3.3**

The difference between compression skin friction and tension skin friction should be taken into account through the resistance factor, to be consistent with how this is done for the strength limit state (see Article 10.5.5.2.3).

**C10.6.1.1**

Problems with insufficient bearing and/or excessive settlements in fill can be significant, particularly if poor, e.g., soft, wet, frozen, or nondurable, material is used, or if the material is not properly compacted.

Spread footings should not be used on soil or rock conditions that are determined to be too soft or weak to support the design loads without excessive movement or loss of stability. Alternatively, the unsuitable material can be removed and replaced with suitable and properly compacted engineered fill material, or improved in place, at reasonable cost as compared to other foundation support alternatives.

Footings should be proportioned so that the stress under the footing is as nearly uniform as practicable at the service limit state. The distribution of soil stress should be consistent with properties of the soil or rock and the structure and with established principles of soil and rock mechanics.

**C10.6.1.2**

Consideration should be given to the use of either a geotextile or graded granular filter material to reduce the susceptibility of fine grained material piping into rip rap or open-graded granular foundation material.

For spread footings founded on excavated or blasted rock, attention should be paid to the effect of excavation and/or blasting. Blasting of highly resistant competent rock formations may result in overbreak and fracturing of the rock to some depth below the bearing elevation. Blasting may reduce the resistance to scour within the zone of overbreak or fracturing.

Evaluation of seepage forces and hydraulic gradients should be performed as part of the design of foundations that will extend below the groundwater table. Upward seepage forces in the bottom of excavations can result in piping loss of soil and/or heaving and loss of stability in the base of foundation excavations. Dewatering with wells or wellpoints can control these problems. Dewatering can result in settlement of adjacent ground or structures. If adjacent structures may be damaged by settlement induced by dewatering, seepage cut-off methods such as sheet piling or slurry walls may be necessary.

Spread footings shall be located below the depth of frost potential. Depth of frost potential shall be determined on the basis of local or regional frost penetration data.

#### 10.6.1.3—Effective Footing Dimensions

For eccentrically loaded footings, a reduced effective area,  $B' \times L'$ , within the confines of the physical footing shall be used in geotechnical design for settlement or bearing resistance. The point of load application shall be at the centroid of the reduced effective area.

The reduced dimensions for an eccentrically loaded rectangular footing shall be taken as:

$$B' = B - 2e_B \quad (10.6.1.3-1)$$

$$L' = L - 2e_L$$

where:

$e_B$  = eccentricity parallel to dimension  $B$  (ft)

$e_L$  = eccentricity parallel to dimension  $L$  (ft)

Footings under eccentric loads shall be designed to ensure that the factored bearing resistance is not less than the effects of factored loads at all applicable limit states.

For footings that are not rectangular, similar procedures should be used based upon the principles specified above.

#### 10.6.1.4—Bearing Stress Distributions

When proportioning footing dimensions to meet settlement and bearing resistance requirements at all applicable limit states, the distribution of bearing stress on the effective area shall be assumed to be:

- Uniform for footings on soils, or
- Linearly varying, i.e., triangular or trapezoidal as applicable, for footings on rock

The distribution of bearing stress shall be determined as specified in Article 11.6.3.2.

Bearing stress distributions for structural design of the footing shall be as specified in Article 10.6.5.

Consideration may be given to over-excavation of frost susceptible material to below the frost depth and replacement with material that is not frost susceptible.

#### C10.6.1.3

The reduced dimensions for a rectangular footing are shown in Figure C10.6.1.3-1.

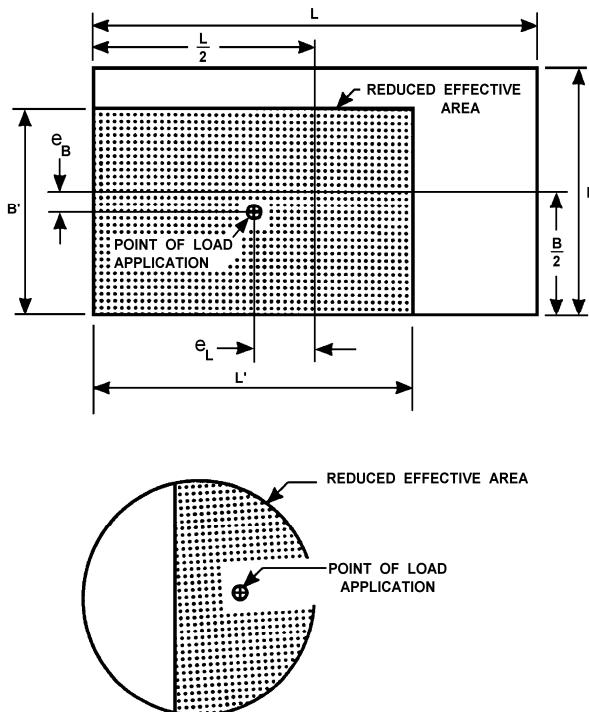

Figure C10.6.1.3-1—Reduced Footing Dimensions

For footings that are not rectangular, such as the circular footing shown in Figure C10.6.1.3-1, the reduced effective area is always concentrically loaded and can be estimated by approximation and judgment. Such an approximation could be made, assuming a reduced rectangular footing size having the same area and centroid as the shaded area of the circular footing shown in Figure C10.6.1.3-1.

### **10.6.1.5—Anchorage of Inclined Footings**

Footings that are founded on inclined smooth solid rock surfaces and that are not restrained by an overburden of resistant material shall be effectively anchored by means of rock anchors, rock bolts, dowels, keys or other suitable means. Shallow keying of large footings shall be avoided where blasting is required for rock removal.

### **10.6.1.6—Groundwater**

Spread footings shall be designed in consideration of the highest anticipated groundwater table.

The influences of groundwater table on the bearing resistance of soils or rock and on the settlement of the structure shall be considered. In cases where seepage forces are present, they should also be included in the analyses.

### **10.6.1.7—Uplift**

Where spread footings are subjected to uplift forces, they shall be investigated both for resistance to uplift and for structural strength.

### **10.6.1.8—Nearby Structures**

Where foundations are placed adjacent to existing structures, the influence of the existing structure on the behavior of the foundation and the effect of the foundation on the existing structures shall be investigated.

## **10.6.2—Service Limit State Design**

### **10.6.2.1—General**

Service limit state design of spread footings shall include evaluation of total and differential settlement and overall stability. Overall stability of a footing shall be evaluated where one or more of the following conditions exist:

- Horizontal or inclined loads are present,
- The foundation is placed on embankment,
- The footing is located on, near or within a slope,
- The possibility of loss of foundation support through erosion or scour exists, or
- Bearing strata are significantly inclined.

### **10.6.2.2—Tolerable Movements**

The requirements of Article 10.5.2.1 shall apply.

### **C10.6.1.5**

Design of anchorages should include consideration of corrosion potential and protection.

### **C10.6.2.1**

The design of spread footings is frequently controlled by movement at the service limit state. It is therefore usually advantageous to proportion spread footings at the service limit state and check for adequate design at the strength and extreme limit states.

### 10.6.2.3—Loads

Immediate settlement shall be determined using load combination Service I, as specified in Table 3.4.1-1. Time-dependent settlements in cohesive soils should be determined using only the permanent loads, i.e., transient loads should not be considered.

### C10.6.2.3

The type of load or the load characteristics may have a significant effect on spread footing deformation. The following factors should be considered in the estimation of footing deformation:

- The ratio of sustained load to total load,
- The duration of sustained loads, and
- The time interval over which settlement or lateral displacement occurs.

The consolidation settlements in cohesive soils are time-dependent; consequently, transient loads have negligible effect. However, in cohesionless soils where the permeability is sufficiently high, elastic deformation of the supporting soil due to transient load can take place. Because deformation in cohesionless soils often takes place during construction while the loads are being applied, it can be accommodated by the structure to an extent, depending on the type of structure and construction method.

Deformation in cohesionless, or granular, soils often occurs as soon as loads are applied. As a consequence, settlements due to transient loads may be significant in cohesionless soils, and they should be included in settlement analyses.

### 10.6.2.4—Settlement Analyses

#### 10.6.2.4.1—General

Foundation settlements should be estimated using computational methods based on the results of laboratory or insitu testing, or both. The soil parameters used in the computations should be chosen to reflect the loading history of the ground, the construction sequence, and the effects of soil layering.

Both total and differential settlements, including time dependant effects, shall be considered.

Total settlement, including elastic, consolidation, and secondary components may be taken as:

$$S_t = S_e + S_c + S_s \quad (10.6.2.4.1-1)$$

where:

$S_e$  = elastic settlement (ft)

$S_c$  = primary consolidation settlement (ft)

$S_s$  = secondary settlement (ft)

#### C10.6.2.4.1

Elastic, or immediate, settlement is the instantaneous deformation of the soil mass that occurs as the soil is loaded. The magnitude of elastic settlement is estimated as a function of the applied stress beneath a footing or embankment. Elastic settlement is usually small and neglected in design, but where settlement is critical, it is the most important deformation consideration in cohesionless soil deposits and for footings bearing on rock. For footings located on over-consolidated clays, the magnitude of elastic settlement is not necessarily small and should be checked.

In a nearly saturated or saturated cohesive soil, the pore water pressure initially carries the applied stress. As pore water is forced from the voids in the soil by the applied load, the load is transferred to the soil skeleton. Consolidation settlement is the gradual compression of the soil skeleton as the pore water is forced from the voids in the soil. Consolidation settlement is the most important deformation consideration in cohesive soil deposits that possess sufficient strength to safely support a spread footing. While consolidation settlement can occur in saturated cohesionless soils, the consolidation occurs quickly and is normally not distinguishable from the elastic settlement.

Secondary settlement, or creep, occurs as a result of the plastic deformation of the soil skeleton under a constant effective stress. Secondary settlement is of principal concern in highly plastic or organic soil deposits. Such deposits are normally so obviously weak and soft as to preclude consideration of bearing a spread footing on such materials.

The principal deformation component for footings on rock is elastic settlement, unless the rock or included discontinuities exhibit noticeable time-dependent behavior.

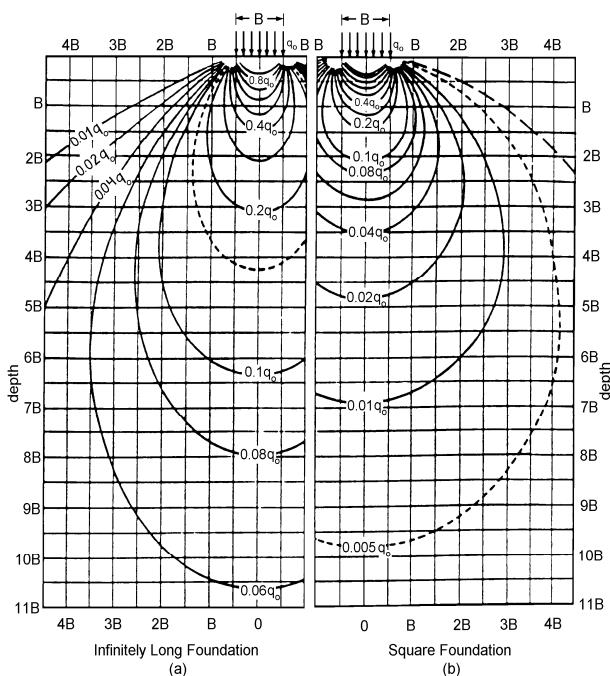

For guidance on vertical stress distribution for complex footing geometries, see Poulos and Davis (1974) or Lambe and Whitman (1969).

Some methods used for estimating settlement of footings on sand include an integral method to account for the effects of vertical stress increase variations. For guidance regarding application of these procedures, see Gifford et al. (1987).

The effects of the zone of stress influence, or vertical stress distribution, beneath a footing shall be considered in estimating the settlement of the footing.

Spread footings bearing on a layered profile consisting of a combination of cohesive soil, cohesionless soil and/or rock shall be evaluated using an appropriate settlement estimation procedure for each layer within the zone of influence of induced stress beneath the footing.

The distribution of vertical stress increase below circular or square and long rectangular footings, i.e., where  $L > 5B$ , may be estimated using Figure 10.6.2.4.1-1.

**Figure 10.6.2.4.1-1—Boussinesq Vertical Stress Contours for Continuous and Square Footings Modified after Sowers (1979)**

#### 10.6.2.4.2—Settlement of Footings on Cohesionless Soils

The settlement of spread footings bearing on cohesionless soil deposits shall be estimated as a function of effective footing width and shall consider the effects of footing geometry and soil and rock layering with depth.

#### C10.6.2.4.2

Although methods are recommended for the determination of settlement of cohesionless soils, experience has indicated that settlements can vary considerably in a construction site, and this variation may not be predicted by conventional calculations.

Settlements of footings on cohesionless soils shall be estimated using elastic theory or empirical procedures.

Settlements of cohesionless soils occur rapidly, essentially as soon as the foundation is loaded. Therefore, the total settlement under the service loads may not be as important as the incremental settlement between intermediate load stages. For example, the total and differential settlement due to loads applied by columns and cross beams is generally less important than the total and differential settlements due to girder placement and casting of continuous concrete decks.

Generally conservative settlement estimates may be obtained using the elastic half-space procedure or the empirical method by Hough. Additional information regarding the accuracy of the methods described herein is provided in Gifford et al. (1987) and Kimmerling (2002). This information, in combination with local experience and engineering judgment, should be used when determining the estimated settlement for a structure foundation, as there may be cases, such as attempting to build a structure grade high to account for the estimated settlement, when overestimating the settlement magnitude could be problematic.

Details of other procedures can be found in textbooks and engineering manuals, including:

- Terzaghi and Peck (1967)
- Sowers (1979)
- U.S. Department of the Navy (1982)
- D'Appolonia (Gifford et al., 1987)—This method includes consideration for over-consolidated sands.
- Tomlinson (1986)
- Gifford et al. (1987)

For general guidance regarding the estimation of elastic settlement of footings on sand, see Gifford et al. (1987) and Kimmerling (2002).

The stress distributions used to calculate elastic settlement assume the footing is flexible and supported on a homogeneous soil of infinite depth. The settlement below a flexible footing varies from a maximum near the center to a minimum at the edge equal to about 50 percent and 64 percent of the maximum for rectangular and circular footings, respectively. The settlement profile for rigid footings is assumed to be uniform across the width of the footing.

Spread footings of the dimensions normally used for bridges are generally assumed to be rigid, although the actual performance will be somewhere between perfectly rigid and perfectly flexible, even for relatively thick concrete footings, due to stress redistribution and concrete creep.

The accuracy of settlement estimates using elastic theory are strongly affected by the selection of soil modulus and the inherent assumptions of infinite elastic half space. Accurate estimates of soil moduli are difficult to obtain because the analyses are based on

The elastic half-space method assumes the footing is flexible and is supported on a homogeneous soil of infinite depth. The elastic settlement of spread footings, in feet, by the elastic half-space method shall be estimated as:

$$S_e = \frac{q_o (1 - \nu^2) \sqrt{A'}}{144 E_s \beta_z} \quad (10.6.2.4.2-1)$$

where:

$q_o$  = applied vertical stress (ksf)

$A'$  = effective area of footing ( $\text{ft}^2$ )

$E_s$  = Young's modulus of soil taken as specified in Article 10.4.6.3 if direct measurements of  $E_s$  are not available from the results of in situ or laboratory tests (ksi)

$\beta_z$  = shape factor taken as specified in Table 10.6.2.4.2-1 (dim)

$\nu$  = Poisson's Ratio, taken as specified in Article 10.4.6.3 if direct measurements of  $\nu$  are not available from the results of in situ or laboratory tests (dim)

Unless  $E_s$  varies significantly with depth,  $E_s$  should be determined at a depth of about 1/2 to 2/3 of  $B$  below the footing, where  $B$  is the footing width. If the soil modulus varies significantly with depth, a weighted average value of  $E_s$  should be used.

**Table 10.6.2.4.2-1—Elastic Shape and Rigidity Factors, EPRI (1983)**

$L/B$	Flexible, $\beta_z$ (average)	$\beta_z$ Rigid
Circular	1.04	1.13
1	1.06	1.08
2	1.09	1.10
3	1.13	1.15
5	1.22	1.24
10	1.41	1.41

Estimation of spread footing settlement on cohesionless soils by the empirical Hough method shall be determined using Eqs. 10.6.2.4.2-2 and 10.6.2.4.2-3. SPT blow counts shall be corrected as specified in Article 10.4.6.2.4 for depth, i.e. overburden stress, before correlating the SPT blow counts to the bearing capacity index,  $C'$ .

$$S_e = \sum_{i=1}^n \Delta H_i \quad (10.6.2.4.2-2)$$

in which:

$$\Delta H_i = H_c \frac{1}{C'} \log \left( \frac{\sigma'_o + \Delta \sigma_v}{\sigma'_o} \right) \quad (10.6.2.4.2-3)$$

where:

$n$  = number of soil layers within zone of stress influence of the footing

$\Delta H_i$  = elastic settlement of layer  $i$  (ft)

$H_c$  = initial height of layer  $i$  (ft)

$C'$  = bearing capacity index from Figure 10.6.2.4.2-1 (dim)

In Figure 10.5.2.4.2-1,  $N'$  shall be taken as  $N1_{60}$ , Standard Penetration Resistance,  $N$  (blows/ft), corrected for overburden pressure as specified in Article 10.4.6.2.4.

only a single value of soil modulus, and Young's modulus varies with depth as a function of overburden stress. Therefore, in selecting an appropriate value for soil modulus, consideration should be given to the influence of soil layering, bedrock at a shallow depth, and adjacent footings.

For footings with eccentric loads, the area,  $A'$ , should be computed based on reduced footing dimensions as specified in Article 10.6.1.3.

The Hough method was developed for normally consolidated cohesionless soils.

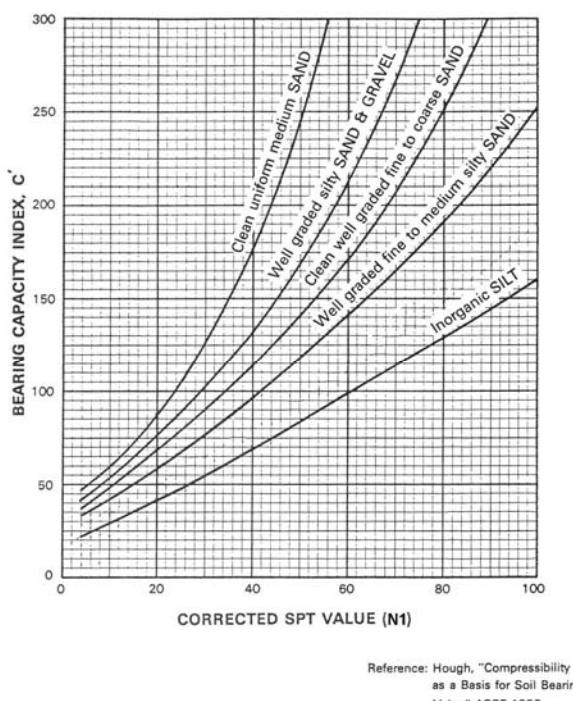

The Hough method has several advantages over other methods used to estimate settlement in cohesionless soil deposits, including express consideration of soil layering and the zone of stress influence beneath a footing of finite size.

The subsurface soil profile should be subdivided into layers based on stratigraphy to a depth of about three times the footing width. The maximum layer thickness should be about 10 ft.

While Cheney and Chassie (2000), and Hough (1959), did not specifically state that the SPT  $N$  values should be corrected for hammer energy in addition to overburden pressure, due to the vintage of the original work, hammers that typically have an efficiency of approximately 60 percent were in general used to develop the empirical correlations contained in the method. If using SPT hammers with efficiencies that differ significantly from this 60 percent value, the  $N$  values should also be corrected for hammer energy, in effect requiring that  $N1_{60}$  be used.

$\sigma'_o$  = initial vertical effective stress at the midpoint of layer  $i$  (ksf)

$\Delta\sigma_v$  = increase in vertical stress at the midpoint of layer  $i$  (ksf)

**Figure 10.6.2.4.2-1—Bearing Capacity Index versus Corrected SPT (modified from Cheney and Chassie, 2000, after Hough, 1959)**

#### 10.6.2.4.3—Settlement of Footings on Cohesive Soils

Spread footings in which cohesive soils are located within the zone of stress influence shall be investigated for consolidation settlement. Elastic and secondary settlement shall also be investigated in consideration of the timing and sequence of construction loading and the tolerance of the structure to total and differential movements.

Where laboratory test results are expressed in terms of void ratio,  $e$ , the consolidation settlement of footings shall be taken as:

- For overconsolidated soils where  $\sigma'_p > \sigma'_o$ , see Figure 10.6.2.4.3-1:

$$S_c = \left[ \frac{H_c}{1 + e_o} \right] \left[ C_r \log \left( \frac{\sigma'_p}{\sigma'_o} \right) + C_c \log \left( \frac{\sigma'_f}{\sigma'_p} \right) \right] \quad (10.6.2.4.3-1)$$

- For normally consolidated soils where  $\sigma'_p = \sigma'_o$ :

The Hough method is applicable to cohesionless soil deposits. The “Inorganic Silt” curve should generally not be applied to soils that exhibit plasticity. The settlement characteristics of cohesive soils that exhibit plasticity should be investigated using undisturbed samples and laboratory consolidation tests as prescribed in Article 10.6.2.4.3.

#### C10.6.2.4.3

In practice, footings on cohesive soils are most likely founded on overconsolidated clays, and settlements can be estimated using elastic theory (Baguelin et al., 1978), or the tangent modulus method (Janbu, 1963, 1967). Settlements of footings on overconsolidated clay usually occur at approximately one order of magnitude faster than soils without preconsolidation, and it is reasonable to assume that they take place as rapidly as the loads are applied. Infrequently, a layer of cohesive soil may exhibit a preconsolidation stress less than the calculated existing overburden stress. The soil is then said to be underconsolidated because a state of equilibrium has not yet been reached under the applied overburden stress. Such a condition may have been caused by a recent lowering of the groundwater table. In this case, consolidation settlement will occur due to the additional load of the structure and the settlement that is occurring to reach a state of equilibrium. The total consolidation settlement due to these two components can be estimated by Eq. 10.6.2.4.3-3 or Eq. 10.6.2.4.3-6.

$$S_c = \left[ \frac{H_c}{1 + e_o} \right] \left[ C_c \log \left( \frac{\sigma'_f}{\sigma'_o} \right) \right] \quad (10.6.2.4.3-2)$$

- For underconsolidated soils where  $\sigma'_p < \sigma'_o$ :

$$S_c = \left[ \frac{H_c}{1 + e_o} \right] \left[ C_c \log \left( \frac{\sigma'_f}{\sigma'_{pc}} \right) \right] \quad (10.6.2.4.3-3)$$

Where laboratory test results are expressed in terms of vertical strain,  $\varepsilon_v$ , the consolidation settlement of footings shall be taken as:

- For overconsolidated soils where  $\sigma'_p > \sigma'_o$ , see Figure 10.6.2.4.3-2:

$$S_c = H_c \left[ C_{re} \log \left( \frac{\sigma'_p}{\sigma'_o} \right) + C_{ce} \log \left( \frac{\sigma'_f}{\sigma'_p} \right) \right] \quad (10.6.2.4.3-4)$$

- For normally consolidated soils where  $\sigma'_p = \sigma'_o$ :

$$S_c = H_c C_{ce} \log \left( \frac{\sigma'_f}{\sigma'_p} \right) \quad (10.6.2.4.3-5)$$

- For underconsolidated soils where  $\sigma'_p < \sigma'_o$ :

$$S_c = H_c C_{ce} \log \left( \frac{\sigma'_f}{\sigma'_{pc}} \right) \quad (10.6.2.4.3-6)$$

where:

$H_c$  = initial height of compressible soil layer (ft)

$e_o$  = void ratio at initial vertical effective stress (dim)

$C_r$  = recompression index (dim)

$C_c$  = compression index (dim)

$C_{re}$  = recompression ratio (dim)

$C_{ce}$  = compression ratio (dim)

$\sigma'_p$  = maximum past vertical effective stress in soil at midpoint of soil layer under consideration (ksf)

$\sigma'_o$  = initial vertical effective stress in soil at midpoint of soil layer under consideration (ksf)

Normally consolidated and underconsolidated soils should be considered unsuitable for direct support of spread footings due to the magnitude of potential settlement, the time required for settlement, for low shear strength concerns, or any combination of these design considerations. Preloading or vertical drains may be considered to mitigate these concerns.

To account for the decreasing stress with increased depth below a footing and variations in soil compressibility with depth, the compressible layer should be divided into vertical increments, i.e., typically 5.0 to 10.0 ft for most normal width footings for highway applications, and the consolidation settlement of each increment analyzed separately. The total value of  $S_c$  is the summation of  $S_c$  for each increment.

The magnitude of consolidation settlement depends on the consolidation properties of the soil. These properties include the compression and recompression constants,  $C_c$  and  $C_r$ , or  $C_{ce}$  and  $C_{re}$ ; the preconsolidation stress,  $\sigma'_p$ ; the current, initial vertical effective stress,  $\sigma'_o$ ; and the final vertical effective stress after application of additional loading,  $\sigma'_f$ . An overconsolidated soil has been subjected to larger stresses in the past than at present. This could be a result of preloading by previously overlying strata, desiccation, groundwater lowering, glacial overriding or an engineered preload. If  $\sigma'_o = \sigma'_p$ , the soil is normally consolidated. Because the recompression constant is typically about an order of magnitude smaller than the compression constant, an accurate determination of the preconsolidation stress,  $\sigma'_p$ , is needed to make reliable estimates of consolidation settlement.

The reliability of consolidation settlement estimates is also affected by the quality of the consolidation test sample and by the accuracy with which changes in  $\sigma'_p$  with depth are known or estimated. As shown in Figure C10.6.2.4.3-1, the slope of the  $e$  or  $\varepsilon_v$  versus  $\log \sigma'_v$  curve and the location of  $\sigma'_p$  can be strongly affected by the quality of samples used for the laboratory consolidation tests. In general, the use of poor quality samples will result in an overestimate of consolidation settlement. Typically, the value of  $\sigma'_p$  will vary with depth as shown in Figure C10.6.2.4.3-2. If the variation of  $\sigma'_p$  with depth is unknown, e.g., only one consolidation test was conducted in the soil profile, actual settlements could be higher or lower than the computed value based on a single value of  $\sigma'_p$ .

The cone penetrometer test may be used to improve understanding of both soil layering and variation of  $\sigma'_p$  with depth by correlation to laboratory tests from discrete locations.

$\sigma'_f$  = final vertical effective stress in soil at midpoint of soil layer under consideration (ksf)

$\sigma'_{pc}$  = current vertical effective stress in soil, not including the additional stress due to the footing loads, at midpoint of soil layer under consideration (ksf)

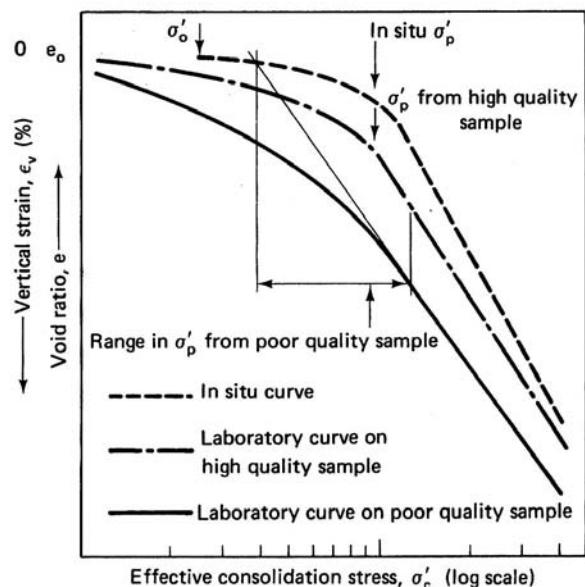

Figure C10.6.2.4.3-1—Effects of Sample Quality on Consolidation Test Results, Holtz and Kovacs (1981)

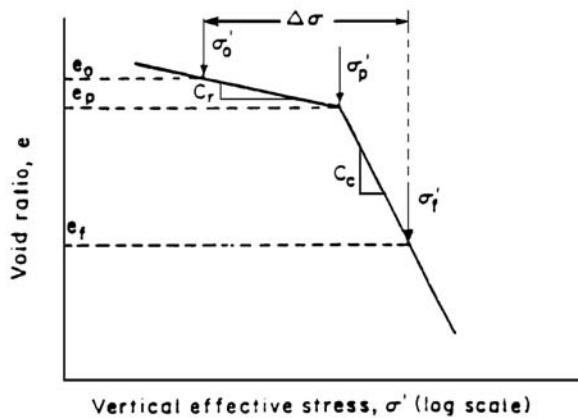

Figure 10.6.2.4.3-1—Typical Consolidation Compression Curve for Overconsolidated Soil: Void Ratio versus Vertical Effective Stress, EPRI (1983)

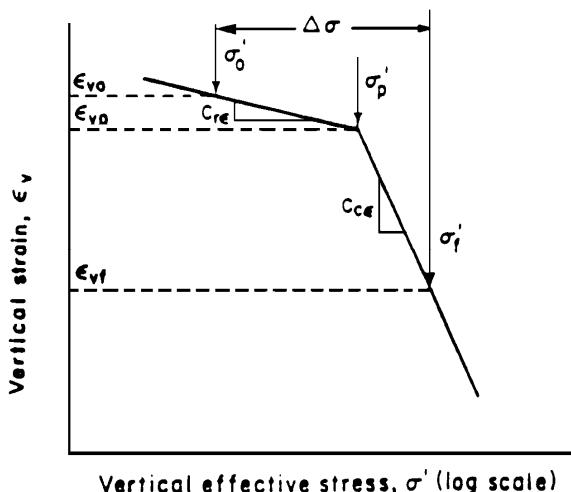

Figure 10.6.2.4.3-2—Typical Consolidation Compression Curve for Overconsolidated Soil: Vertical Strain versus Vertical Effective Stress, EPRI (1983)

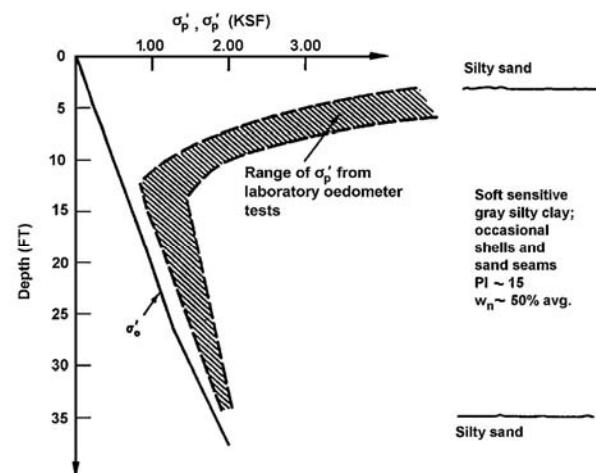

Figure C10.6.2.4.3-2—Typical Variation of Preconsolidation Stress with Depth, Holtz and Kovacs (1981)

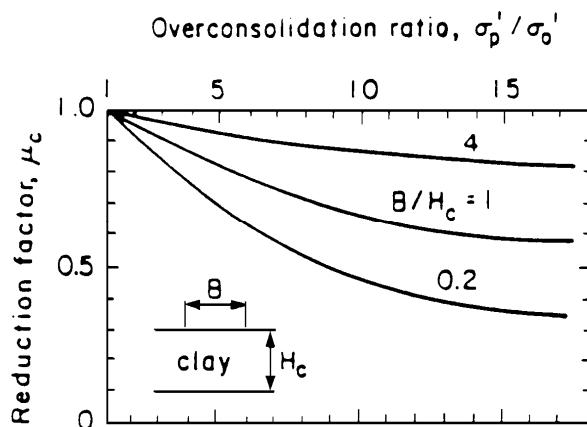

If the footing width,  $B$ , is small relative to the thickness of the compressible soil,  $H_c$ , the effect of three-dimensional loading shall be considered and shall be taken as:

$$S_{c(3-D)} = \mu_c S_{c(1-D)} \quad (10.6.2.4.3-7)$$

where:

$\mu_c$  = reduction factor taken as specified in Figure 10.6.2.4.3-3 (dim)

$S_{c(1-D)}$  = single dimensional consolidation settlement (ft)

**Figure 10.6.2.4.3-3—Reduction Factor to Account for Effects of Three-Dimensional Consolidation Settlement (EPRI, 1983)**

The time,  $t$ , to achieve a given percentage of the total estimated one-dimensional consolidation settlement shall be taken as:

$$t = \frac{TH_d^2}{c_v} \quad (10.6.2.4.3-8)$$

where:

$T$  = time factor taken as specified in Figure 10.6.2.4.3-4 for the excess pore pressure distributions shown in the Figure (dim)

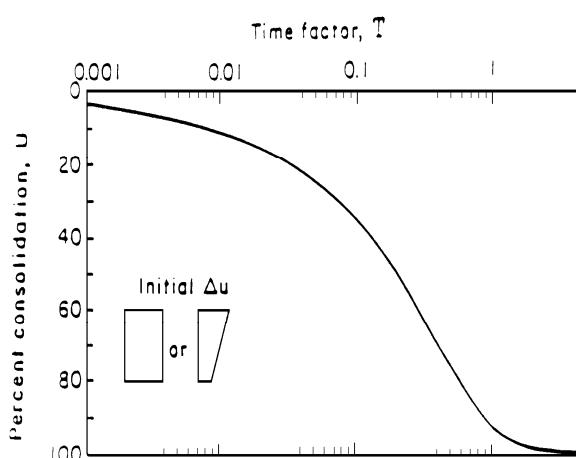

$H_d$  = length of longest drainage path in compressible layer under consideration (ft)

$c_v$  = coefficient of consolidation ( $\text{ft}^2/\text{yr}$ )

Consolidation occurs when a saturated compressible layer of soil is loaded and water is squeezed out of the layer. The time required for the (primary) consolidation process to end will depend on the permeability of the soil. Because the time factor,  $T$ , is defined as logarithmic, the consolidation process theoretically never ends. The practical assumption is usually made that the additional consolidation past 90 percent or 95 percent consolidation is negligible, or is taken into consideration as part of the total long term settlement.

Refer to Winterkorn and Fang (1975) for values of  $T$  for excess pore pressure distributions other than indicated in Figure 10.6.2.4.3-4.

The length of the drainage path is the longest distance from any point in a compressible layer to a drainage boundary at the top or bottom of the compressible soil unit. Where a compressible layer is located between two drainage boundaries,  $H_d$  equals one-half the actual height of the layer. Where a compressible layer is adjacent to an impermeable boundary (usually below),  $H_d$  equals the full height of the layer.

**Figure 10.6.2.4.3-4 Percentage of Consolidation as a Function of Time Factor,  $T$  (EPRI, 1983)**

Where laboratory test results are expressed in terms of void ratio,  $e$ , the secondary settlement of footings on cohesive soil shall be taken as:

$$S_s = \frac{C_a}{1+e_o} H_c \log\left(\frac{t_2}{t_1}\right) \quad (10.6.2.4.3-9)$$

Where laboratory test results are expressed in terms of vertical strain,  $\epsilon_v$ , the secondary settlement of footings on cohesive soils shall be taken as:

$$S_s = C_{ae} H_c \log\left(\frac{t_2}{t_1}\right) \quad (10.6.2.4.3-10)$$

where:

$H_c$  = initial height of compressible soil layer (ft)

$e_o$  = void ratio at initial vertical effective stress (dim)

$t_1$  = time when secondary settlement begins, i.e., typically at a time equivalent to 90 percent average degree of primary consolidation (yr)

$t_2$  = arbitrary time that could represent the service life of the structure (yr)

Computations to predict the time rate of consolidation based on the result of laboratory tests generally tend to over-estimate the actual time required for consolidation in the field. This over-estimation is principally due to:

- The presence of thin drainage layers within the compressible layer that are not observed from the subsurface exploration nor considered in the settlement computations,
- The effects of three-dimensional dissipation of pore water pressures in the field, rather than the one-dimensional dissipation that is imposed by laboratory odometer tests and assumed in the computations, and
- The effects of sample disturbance, which tend to reduce the permeability of the laboratory tested samples.

If the total consolidation settlement is within the serviceability limits for the structure, the time rate of consolidation is usually of lesser concern for spread footings. If the total consolidation settlement exceeds the serviceability limitations, superstructure damage will occur unless provisions are made for timing of closure pours as a function of settlement, simple support of spans and/or periodic jacking of bearing supports.

Secondary compression component of settlement results from compression of bonds between individual clay particles and domains, as well as other effects on the microscale that are not yet clearly understood (Holtz and Kovacs, 1981). Secondary settlement is most important for highly plastic clays and organic and micaceous soils. Accordingly, secondary settlement predictions should be considered as approximate estimates only.

If secondary compression is estimated to exceed serviceability limitations, either deep foundations or ground improvement should be considered to mitigate the effects of secondary compression. Experience indicates preloading and surcharging may not be effective in eliminating secondary compression.

$C_\alpha$  = secondary compression index estimated from the results of laboratory consolidation testing of undisturbed soil samples (dim)

$C_{\alpha e}$  = modified secondary compression index estimated from the results of laboratory consolidation testing of undisturbed soil samples (dim)

#### 10.6.2.4.4—Settlement of Footings on Rock

For footings bearing on fair to very good rock, according to the Geomechanics Classification system, as defined in Article 10.4.6.4, and designed in accordance with the provisions of this Section, elastic settlements may generally be assumed to be less than 0.5 in. When elastic settlements of this magnitude are unacceptable or when the rock is not competent, an analysis of settlement based on rock mass characteristics shall be made.

Where rock is broken or jointed (relative rating of ten or less for  $RQD$  and joint spacing), the rock joint condition is poor (relative rating of ten or less) or the criteria for fair to very good rock are not met, a settlement analysis should be conducted, and the influence of rock type, condition of discontinuities, and degree of weathering shall be considered in the settlement analysis.

The elastic settlement of footings on broken or jointed rock, in feet, should be taken as:

- For circular (or square) footings:

$$\rho = q_o \left(1 - \nu^2\right) \frac{rI_p}{144 E_m} \quad (10.6.2.4.4-1)$$

in which:

$$I_p = \frac{(\sqrt{\pi})}{\beta_z} \quad (10.6.2.4.4-2)$$

- For rectangular footings:

$$\rho = q_o \left(1 - \nu^2\right) \frac{BI_p}{144 E_m} \quad (10.6.2.4.4-3)$$

in which:

$$I_p = \frac{(L/B)^{1/2}}{\beta_z} \quad (10.6.2.4.4-4)$$

#### C10.6.2.4.4

In most cases, it is sufficient to determine settlement using the average bearing stress under the footing.

Where the foundations are subjected to a very large load or where settlement tolerance may be small, settlements of footings on rock may be estimated using elastic theory. The stiffness of the rock mass should be used in such analyses.

The accuracy with which settlements can be estimated by using elastic theory is dependent on the accuracy of the estimated rock mass modulus,  $E_m$ . In some cases, the value of  $E_m$  can be estimated through empirical correlation with the value of the modulus of elasticity for the intact rock between joints. For unusual or poor rock mass conditions, it may be necessary to determine the modulus from in-situ tests, such as plate loading and pressuremeter tests.

where:

$q_o$  = applied vertical stress at base of loaded area (ksf)

$\nu$  = Poisson's Ratio (dim)

$r$  = radius of circular footing or  $B/2$  for square footing (ft)

$I_p$  = influence coefficient to account for rigidity and dimensions of footing (dim)

$E_m$  = rock mass modulus (ksi)

$\beta_z$  = factor to account for footing shape and rigidity (dim)

Values of  $I_p$  should be computed using the  $\beta_z$  values presented in Table 10.6.2.4.2-1 for rigid footings. Where the results of laboratory testing are not available, values of Poisson's ratio,  $\nu$ , for typical rock types may be taken as specified in Table C10.4.6.5-2. Determination of the rock mass modulus,  $E_m$ , should be based on the methods described in Article 10.4.6.5.

The magnitude of consolidation and secondary settlements in rock masses containing soft seams or other material with time-dependent settlement characteristics should be estimated by applying procedures specified in Article 10.6.2.4.3.

### 10.6.2.5—Overall Stability

Overall stability of spread footings shall be investigated using Service I Load Combination and the provisions of Articles 3.4.1, 10.5.2.3, and 11.6.3.4.

### 10.6.2.6—Bearing Resistance at the Service Limit State

#### 10.6.2.6.1—Presumptive Values for Bearing Resistance

The use of presumptive values shall be based on knowledge of geological conditions at or near the structure site.

#### C10.6.2.6.1

Unless more appropriate regional data are available, the presumptive values given in Table C10.6.2.6.1-1 may be used. These bearing resistances are settlement limited, e.g., 1.0 in., and apply only at the service limit state.

**Table C10.6.2.6.1-1—Presumptive Bearing Resistance for Spread Footing Foundations at the Service Limit State Modified after U.S. Department of the Navy (1982)**

Type of Bearing Material	Consistency in Place	Bearing Resistance (ksf)	
		Ordinary Range	Recommended Value of Use
Massive crystalline igneous and metamorphic rock: granite, diorite, basalt, gneiss, thoroughly cemented conglomerate (sound condition allows minor cracks)	Very hard, sound rock	120–200	160
Foliated metamorphic rock: slate, schist (sound condition allows minor cracks)	Hard sound rock	60–80	70
Sedimentary rock: hard cemented shales, siltstone, sandstone, limestone without cavities	Hard sound rock	30–50	40
Weathered or broken bedrock of any kind, except highly argillaceous rock (shale)	Medium hard rock	16–24	20
Compaction shale or other highly argillaceous rock in sound condition	Medium hard rock	16–24	20
Well-graded mixture of fine- and coarse-grained soil: glacial till, hardpan, boulder clay (GW-GC, GC, SC)	Very dense	16–24	20
Gravel, gravel-sand mixture, boulder-gravel mixtures (GW, GP, SW, SP)	Very dense Medium dense to dense Loose	12–20 8–14 4–12	14 10 6
Coarse to medium sand, and with little gravel (SW, SP)	Very dense Medium dense to dense Loose	8–12 4–8 2–6	8 6 3
Fine to medium sand, silty or clayey medium to coarse sand (SW, SM, SC)	Very dense Medium dense to dense Loose	6–10 4–8 2–4	6 5 3
Fine sand, silty or clayey medium to fine sand (SP, SM, SC)	Very dense Medium dense to dense Loose	6–10 4–8 2–4	6 5 3
Homogeneous inorganic clay, sandy or silty clay (CL, CH)	Very dense Medium dense to dense Loose	6–12 2–6 1–2	8 4 1
Inorganic silt, sandy or clayey silt, varved silt-clay-fine sand (ML, MH)	Very stiff to hard Medium stiff to stiff Soft	4–8 2–6 1–2	6 3 1

#### 10.6.2.6.2—Semiempirical Procedures for Bearing Resistance

Bearing resistance on rock shall be determined using empirical correlation to the Geomechanic Rock Mass Rating System, RMR, as specified in Article 10.4.6.4. Local experience should be considered in the use of these semi-empirical procedures.

If the recommended value of presumptive bearing resistance exceeds either the unconfined compressive strength of the rock or the nominal resistance of the concrete, the presumptive bearing resistance shall be taken as the lesser of the unconfined compressive strength of the rock or the nominal resistance of the concrete. The nominal resistance of concrete shall be taken as  $0.3 f'_c$ .

### 10.6.3—Strength Limit State Design

#### 10.6.3.1—Bearing Resistance of Soil

##### 10.6.3.1.1—General

Bearing resistance of spread footings shall be determined based on the highest anticipated position of groundwater level at the footing location.

The factored resistance,  $q_R$ , at the strength limit state shall be taken as:

$$q_R = \varphi_b q_n \quad (10.6.3.1.1-1)$$

where:

$\varphi_b$  = resistance factor specified in Article 10.5.5.2.2

$q_n$  = nominal bearing resistance (ksf)

##### C10.6.3.1.1

The bearing resistance of footings on soil should be evaluated using soil shear strength parameters that are representative of the soil shear strength under the loading conditions being analyzed. The bearing resistance of footings supported on granular soils should be evaluated for both permanent dead loading conditions and short-duration live loading conditions using effective stress methods of analysis and drained soil shear strength parameters. The bearing resistance of footings supported on cohesive soils should be evaluated for short-duration live loading conditions using total stress methods of analysis and undrained soil shear strength parameters. In addition, the bearing resistance of footings supported on cohesive soils, which could soften and lose strength with time, should be evaluated for permanent dead loading conditions using effective stress methods of analysis and drained soil shear strength parameters.

The position of the groundwater table can significantly influence the bearing resistance of soils through its effect on shear strength and unit weight of the foundation soils. In general, the submergence of soils will reduce the effective shear strength of cohesionless (or granular) materials, as well as the long-term (or drained) shear strength of cohesive (clayey) soils. Moreover, the effective unit weights of submerged soils are about half of those for the same soils under dry conditions. Thus, submergence may lead to a significant reduction in the bearing resistance provided by the foundation soils, and it is essential that the bearing resistance analyses be carried out under the assumption of the highest groundwater table expected within the service life of the structure.

Footings with inclined bases should be avoided wherever possible. Where use of an inclined footing base cannot be avoided, the nominal bearing resistance determined in accordance with the provisions herein should be further reduced using accepted corrections for inclined footing bases in Munfakh, et al. (2001).

Because the effective dimensions will vary slightly for each limit state under consideration, strict adherence to this provision will require re-computation of the nominal bearing resistance at each limit state.

Further, some of the equations for the bearing resistance modification factors based on  $L$  and  $B$  were not necessarily or specifically developed with the intention that effective dimensions be used. The designer should ensure that appropriate values of  $L$  and  $B$  are used, and that effective footing dimensions  $L'$  and  $B'$  are used appropriately.

Where loads are eccentric, the effective footing dimensions,  $L'$  and  $B'$ , as specified in Article 10.6.1.3, shall be used instead of the overall dimensions  $L$  and  $B$  in all equations, tables, and figures pertaining to bearing resistance.

Consideration should be given to the relative change in the computed nominal resistance based on effective versus gross footing dimensions for the size of footings typically used for bridges. Judgment should be used in deciding whether the use of gross footing dimensions for computing nominal bearing resistance at the strength limit state would result in a conservative design.

#### 10.6.3.1.2—Theoretical Estimation

##### 10.6.3.1.2a—Basic Formulation

The nominal bearing resistance shall be estimated using accepted soil mechanics theories and should be based on measured soil parameters. The soil parameters used in the analyses shall be representative of the soil shear strength under the considered loading and subsurface conditions.

The nominal bearing resistance of spread footings on cohesionless soils shall be evaluated using effective stress analyses and drained soil strength parameters.

The nominal bearing resistance of spread footings on cohesive soils shall be evaluated for total stress analyses and undrained soil strength parameters. In cases where the cohesive soils may soften and lose strength with time, the bearing resistance of these soils shall also be evaluated for permanent loading conditions using effective stress analyses and drained soil strength parameters.

For spread footings bearing on compacted soils, the nominal bearing resistance shall be evaluated using the more critical of either total or effective stress analyses.

Except as noted below, the nominal bearing resistance of a soil layer, in ksf, should be taken as:

$$q_n = cN_{cm} + \gamma D_f N_{qm} C_{wq} + 0.5\gamma BN_{wm} C_{w\gamma} \quad (10.6.3.1.2a-1)$$

in which:

$$N_{cm} = N_c s_c i_c \quad (10.6.3.1.2a-2)$$

$$N_{qm} = N_q s_q d_q i_q \quad (10.6.3.1.2a-3)$$

$$N_{wm} = N_\gamma s_\gamma i_\gamma \quad (10.6.3.1.2a-4)$$

where:

$c$  = cohesion, taken as undrained shear strength (ksf)

$N_c$  = cohesion term (undrained loading) bearing capacity factor as specified in Table 10.6.3.1.2a-1 (dim)

##### C10.6.3.1.2a

The bearing resistance formulation provided in Eqs. 10.6.3.1.2a-1 though 10.6.3.1.2a-4 is the complete formulation as described in the Munfakh, et al. (2001). However, in practice, not all of the factors included in these equations have been routinely used.

- $N_q$  = surcharge (embedment) term (drained or undrained loading) bearing capacity factor as specified in Table 10.6.3.1.2a-1 (dim)
- $N_\gamma$  = unit weight (footing width) term (drained loading) bearing capacity factor as specified in Table 10.6.3.1.2a-1 (dim)
- $\gamma$  = total (moist) unit weight of soil above or below the bearing depth of the footing (kcf)
- $D_f$  = footing embedment depth (ft)
- $B$  = footing width (ft)
- $C_{wq}, C_{wl}$  = correction factors to account for the location of the groundwater table as specified in Table 10.6.3.1.2a-2 (dim)
- $s_c, s_\gamma, s_q$  = footing shape correction factors as specified in Table 10.6.3.1.2a-3 (dim)
- $d_q$  = correction factor to account for the shearing resistance along the failure surface passing through cohesionless material above the bearing elevation as specified in Table 10.6.3.1.2a-4 (dim)
- $i_c, i_\gamma, i_q$  = load inclination factors determined from Eqs. 10.6.3.1.2a-5 or 10.6.3.1.2a-6, and 10.6.3.1.2a-7 and 10.6.3.1.2a-8 (dim)

For  $\phi_f = 0$ :

$$i_c = 1 - (nH/cBLN_c) \quad (10.6.3.1.2a-5)$$

For  $\phi_f > 0$ :

$$i_c = i_q - [(1 - i_q)/(N_q - 1)] \quad (10.6.3.1.2a-6)$$

in which:

$$i_q = \left[ 1 - \frac{H}{(V + cBL \cot \phi_f)} \right]^n \quad (10.6.3.1.2a-7)$$

$$i_\gamma = \left[ 1 - \frac{H}{V + cBL \cot \phi_f} \right]^{(n+1)} \quad (10.6.3.1.2a-8)$$

$$n = [(2 + L/B)/(1 + L/B)] \cos^2 \theta + [(2 + B/L)/(1 + B/L)] \sin^2 \theta \quad (10.6.3.1.2a-9)$$

Most geotechnical engineers nationwide have not used the load inclination factors. This is due, in part, to the lack of knowledge of the vertical and horizontal loads at the time of geotechnical explorations and preparation of bearing resistance recommendations.

Furthermore, the basis of the load inclination factors computed by Eqs. 10.6.3.1.2a-5 to 10.6.3.1.2a-8 is a combination of bearing resistance theory and small scale load tests on 1 in. wide plates on London Clay and Ham River Sand (Meyerhof, 1953). Therefore, the factors do not take into consideration the effects of depth of embedment. Meyerhof further showed that for footings with a depth of embedment ratio of  $D_f/B = 1$ , the effects of load inclination on bearing resistance are relatively small. The theoretical formulation of load inclination factors were further examined by Brinch-Hansen (1970), with additional modification by Vesic (1973) into the form provided in Eqs. 10.6.3.1.2a-5 to 10.6.3.1.2a-8.

It should further be noted that the resistance factors provided in Article 10.5.5.2.2 were derived for vertical loads. The applicability of these resistance factors to design of footings resisting inclined load combinations is not currently known. The combination of the resistance factors and the load inclination factors may be overly conservative for footings with an embedment of approximately  $D_f/B = 1$  or deeper because the load inclination factors were derived for footings without embedment.

where:

$B$  = footing width (ft)

$L$  = footing length (ft)

$H$  = unfactored horizontal load (kips)

$V$  = unfactored vertical load (kips)

$\theta$  = projected direction of load in the plane of the footing, measured from the side of length  $L$  (degrees)

In practice, therefore, for footings with modest embedment, consideration may be given to omission of the load inclination factors.

Figure C10.6.3.1.2a-1 shows the convention for determining the  $\theta$  angle in Eq. 10.6.3.1.2a-9.

	4	1.30
	8	1.35
42	1	1.15
	2	1.20
	4	1.25
	8	1.30

The depth correction factor should be used only when the soils above the footing bearing elevation are as competent as the soils beneath the footing level; otherwise, the depth correction factor should be taken as 1.0.

Linear interpolations may be made for friction angles in between those values shown in Table 10.6.3.1.2a-4.

#### 10.6.3.1.2b—Considerations for Punching Shear

If local or punching shear failure is possible, the nominal bearing resistance shall be estimated using reduced shear strength parameters  $c^*$  and  $\phi^*$  in Eqs. 10.6.3.1.2b-1 and 10.6.3.1.2b-2. The reduced shear parameters may be taken as:

$$c^* = 0.67c \quad (10.6.3.1.2b-1)$$

The parent information from which Table 10.6.3.1.2a-4 was developed covered the indicated range of friction angle,  $\phi_f$ . Information beyond the range indicated is not available at this time.

#### C10.6.3.1.2b

Local shear failure is characterized by a failure surface that is similar to that of a general shear failure but that does not extend to the ground surface, ending somewhere in the soil below the footing. Local shear failure is accompanied by vertical compression of soil below the footing and visible bulging of soil adjacent to the footing but not by sudden rotation or tilting of the

$$\phi^* = \tan^{-1}(0.67 \tan \phi_f) \quad (10.6.3.1.2b-2)$$

where:

$c^*$  = reduced effective stress soil cohesion for punching shear (ksf)

$\phi^*$  = reduced effective stress soil friction angle for punching shear (degrees)

footing. Local shear failure is a transitional condition between general and punching shear failure. Punching shear failure is characterized by vertical shear around the perimeter of the footing and is accompanied by a vertical movement of the footing and compression of the soil immediately below the footing but does not affect the soil outside the loaded area. Punching shear failure occurs in loose or compressible soils, in weak soils under slow (drained) loading, and in dense sands for deep footings subjected to high loads.

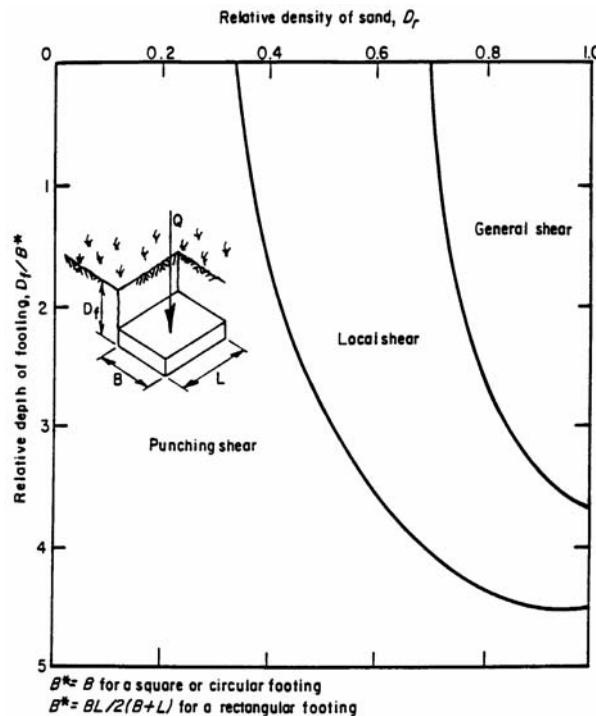

Figure C10.6.3.1.2b-1—Modes of Bearing Capacity Failure for Footings in Sand

#### 10.6.3.1.2c—Considerations for Footings on Slopes

#### C10.6.3.1.2c

For footings bearing on or near slopes:

$$N_q = 0.0 \quad (10.6.3.1.2c-1)$$

In Eq. 10.6.3.1.2a-1,  $N_c$  and  $N_\gamma$  shall be replaced with  $N_{cq}$  and  $N_{\gamma q}$ , respectively, from Figures 10.6.3.1.2c-1 and 10.6.3.1.2c-2 for footings bearing on or near slopes. In Figure 10.6.3.1.2c-1, the slope stability factor,  $N_s$ , shall be taken as:

- For  $B < H_s$ :

$$N_s = 0 \quad (10.6.3.1.2c-2)$$

- For  $B \geq H_s$ :

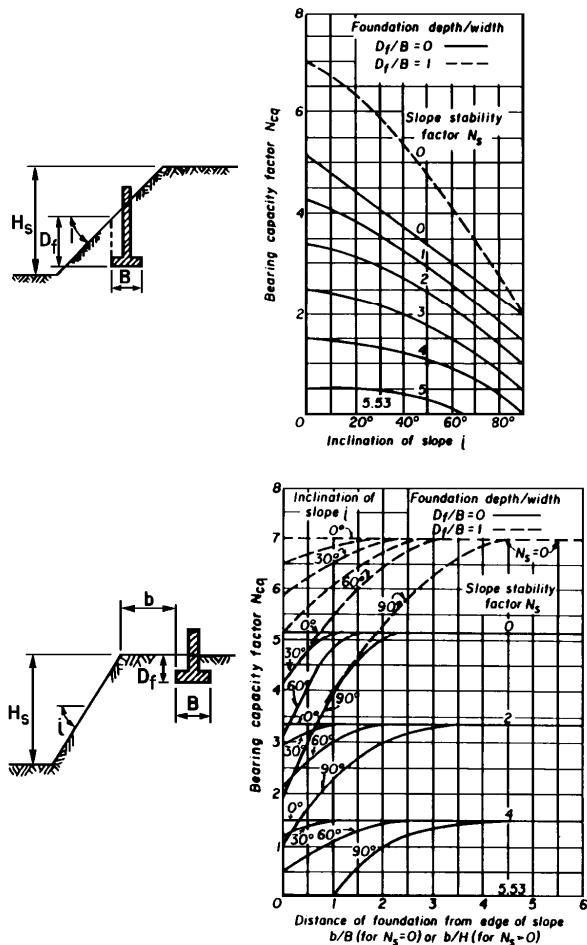

A rational numerical approach for determining a modified bearing capacity factor,  $N_{cq}$ , for footings on or near a slope is given in Bowles (1988).

$$N_s = \frac{\gamma H_s}{c} \quad (10.6.3.1.2c-3)$$

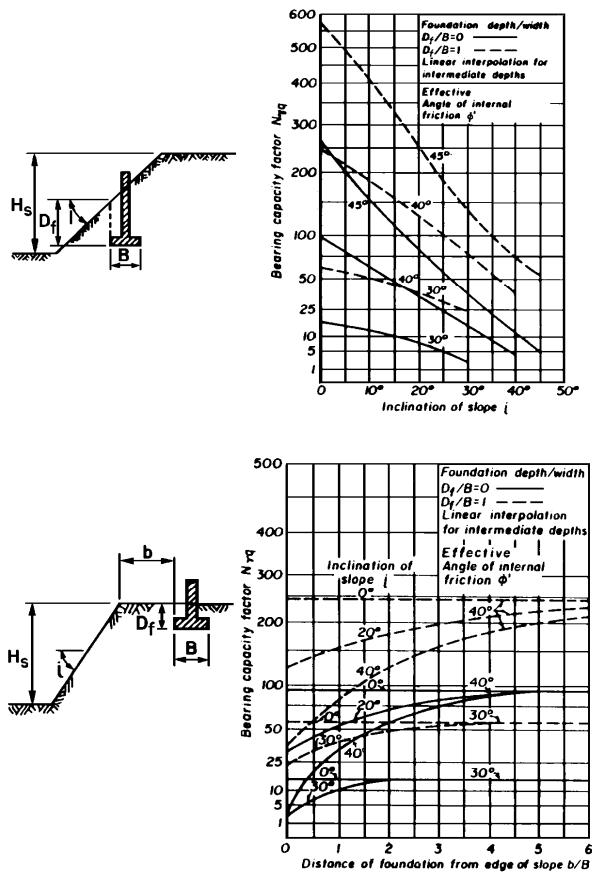

where:

$B$  = footing width (ft)

$H_s$  = height of sloping ground mass (ft)

**Figure 10.6.3.1.2c-1—Modified Bearing Capacity Factors for Footing in Cohesive Soils and on or adjacent to Sloping Ground after Meyerhof (1957)**

**Figure 10.6.3.1.2c-2—Modified Bearing Capacity Factors for Footing in Cohesionless Soils and on or adjacent to Sloping Ground after Meyerhof (1957)**

#### 10.6.3.1.2d—Considerations for Two-Layer Soil Systems—Critical Depth

Where the soil profile contains a second layer of soil with different properties affecting shear strength within a distance below the footing less than  $H_{crit}$ , the bearing resistance of the layered soil profile shall be determined using the provisions for two-layered soil systems herein. The distance  $H_{crit}$ , in feet, may be taken as:

$$H_{crit} = \frac{(3B) \ln \left( \frac{q_1}{q_2} \right)}{2 \left( 1 + \frac{B}{L} \right)} \quad (10.6.3.1.2d-1)$$

where:

$q_1$  = nominal bearing resistance of footing supported in the upper layer of a two-layer system, assuming the upper layer is infinitely thick (ksf)

$q_2$  = nominal bearing resistance of a fictitious footing of the same size and shape as the actual footing but supported on surface of the second (lower) layer of a two-layer system (ksf)

$B$  = footing width (ft)

$L$  = footing length (ft)

#### 10.6.3.1.2e—Two-Layered Soil System in Undrained Loading

Where a footing is supported on a two-layered soil system subjected to undrained loading, the nominal bearing resistance may be determined using Eq. 10.6.3.1.2a-1 with the following modifications:

$c_1$  = undrained shear strength of the top layer of soil as depicted in Figure 10.6.3.1.2e-1 (ksf)

$N_{cm}$  =  $N_m$ , a bearing capacity factor as specified below (dim)

$N_{qm} = 1.0$  (dim)

Where the bearing stratum overlies a stiffer cohesive soil,  $N_m$ , may be taken as specified in Figure 10.6.3.1.2e-2.

Where the bearing stratum overlies a softer cohesive soil,  $N_m$  may be taken as:

$$N_m = \left( \frac{1}{\beta_m} + \kappa s_c N_c \right) \leq s_c N_c \quad (10.6.3.1.2e-1)$$

in which:

$$\beta_m = \frac{BL}{2(B+L)H_{s2}} \quad (10.6.3.1.2e-2)$$

$$\kappa = \frac{c_2}{c_1} \quad (10.6.3.1.2e-3)$$

where:

$\beta_m$  = the punching index (dim)

$c_1$  = undrained shear strength of upper soil layer (ksf)

$c_2$  = undrained shear strength of lower soil layer (ksf)

$H_{s2}$  = distance from bottom of footing to top of the second soil layer (ft)

#### C10.6.3.1.2e

Vesic' (1970) developed a rigorous solution for the modified bearing capacity factor,  $N_m$ , for the weak undrained layer over strong undrained layer situation. This solution is given by the following equation:

$$N_m = \frac{\kappa N_c^*(N_c^* + \beta_m - 1)A}{B(C - (\kappa N_c^* + \beta_m - 1))(N_c^* + 1)} \quad (C10.6.3.1.2e-1)$$

in which:

$$A = [(\kappa + 1)N_c^{*2} + (1 + \kappa\beta_m)N_c^* + \beta_m - 1] \quad (C10.6.3.1.2e-2)$$

$$B = [\kappa(\kappa + 1)N_c^* + \kappa + \beta_m - 1] \quad (C10.6.3.1.2e-3)$$

$$C = [(N_c^* + \beta_m)N_c^* + \beta_m - 1] \quad (C10.6.3.1.2e-4)$$

- For circular or square footings:

$$\beta_m = \frac{B}{4H} \quad (C10.6.3.1.2e-5)$$

$$N_c^* = 6.17$$

- For strip footings:

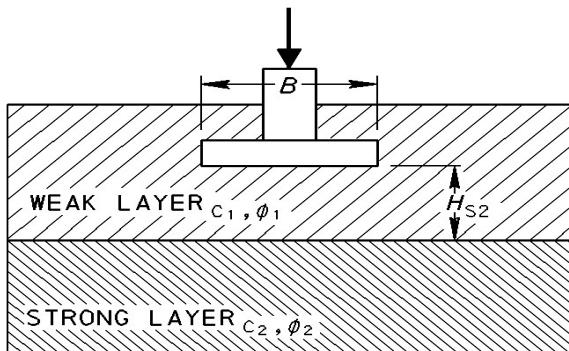

$$\beta_m = \frac{B}{2H} \quad (C10.6.3.1.2e-6)$$

$$N_c^* = 5.14$$

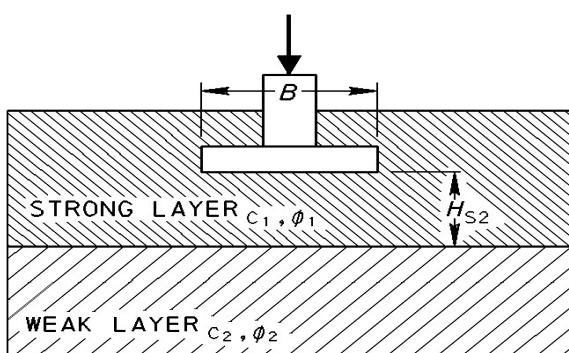

$s_c$  = shape correction factor determined from Table 10.6.3.1.2a-3

$N_c$  = bearing capacity factor determined herein (dim)

$N_{qm}$  = bearing capacity factor determined herein (dim)

(a)

(b)

Figure 10.6.3.1.2e-1—Two-Layer Soil Profiles

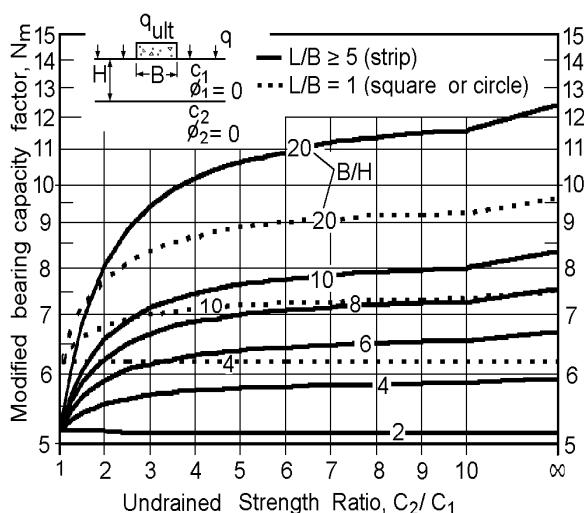

Figure 10.6.3.1.2e-2—Modified Bearing Factor for Two-Layer Cohesive Soil with Weaker Soil Overlying Stronger Soil (EPRI, 1983)

*10.6.3.1.2f—Two-Layered Soil System in Drained Loading*

Where a footing supported on a two-layered soil system is subjected to a drained loading, the nominal bearing resistance, in ksf, may be taken as:

$$q_n = \left[ q_2 + \left( \frac{1}{K} \right) c'_1 \cot \phi'_1 \right] e^{2 \left[ 1 + \left( \frac{B}{L} \right) K \tan \phi'_1 \left( \frac{H}{B} \right) \right]} - \left( \frac{1}{K} \right) c'_1 \cot \phi'_1 \quad (10.6.3.1.2f-1)$$

in which:

$$K = \frac{1 - \sin^2 \phi'_1}{1 + \sin^2 \phi'_1} \quad (10.6.3.1.2f-2)$$

where:

$c'_1$  = drained shear strength of the top layer of soil as depicted in Figure 10.6.3.1.2e-1 (ksf)

$q_2$  = nominal bearing resistance of a fictitious footing of the same size and shape as the actual footing but supported on surface of the second (lower) layer of a two-layer system (ksf)

$\phi'_1$  = effective stress angle of internal friction of the top layer of soil (degrees)

*10.6.3.1.3—Semiempirical Procedures*

The nominal bearing resistance of foundation soils may be estimated from the results of in-situ tests or by observed resistance of similar soils. The use of a particular in-situ test and the interpretation of test results should take local experience into consideration. The following in-situ tests may be used:

- Standard Penetration Test
- Cone Penetration Test

The nominal bearing resistance in sand, in ksf, based on SPT results may be taken as:

$$q_n = \frac{\bar{N}1_{60} B}{5} \left( C_{wq} \frac{D_f}{B} + C_{wy} \right) \quad (10.6.3.1.3-1)$$

where:

$\bar{N}1_{60}$  = average SPT blow count corrected for both overburden and hammer efficiency effects (blows/ft) as specified in Article 10.4.6.2.4.  
Average the blow count over a depth range from the bottom of the footing to  $1.5B$  below the bottom of the footing.

*C10.6.3.1.2f*

If the upper layer is a cohesionless soil and  $\phi'$  equals 25–50 degrees, Eq. 10.6.3.1.2f-1 reduces to:

$$q_n = q_2 e^{0.67 \left[ 1 + \left( \frac{B}{L} \right) \right] \frac{H}{B}} \quad (C10.6.3.1.2f-1)$$

*C10.6.3.1.3*

In application of these empirical methods, the use of average *SPT* blow counts and *CPT* tip resistances is specified. The resistance factors recommended for bearing resistance included in Table 10.5.5.2.2-1 assume the use of average values for these parameters. The use of lower bound values may result in an overly conservative design. However, depending on the availability of soil property data and the variability of the geologic strata under consideration, it may not be possible to reliably estimate the average value of the properties needed for design. In such cases, the Engineer may have no choice but to use a more conservative selection of design input parameters to mitigate the additional risks created by potential variability or the paucity of relevant data.

The original derivation of Eqs. 10.6.3.1.3-1 and 10.6.3.1.3-2 did not include inclination factors (Meyerhof, 1956).

$B$  = footing width (ft)

$C_{wq}, C_{w\gamma}$  = correction factors to account for the location of the groundwater table as specified in Table 10.6.3.1.2a-2 (dim)

$D_f$  = footing embedment depth taken to the bottom of the footing (ft)

The nominal bearing resistance, in ksf, for footings on cohesionless soils based on *CPT* results may be taken as:

$$q_n = \frac{\overline{q}_c B}{40} \left( C_{wq} \frac{D_f}{B} + C_{w\gamma} \right) \quad (10.6.3.1.3-2)$$

where:

$\overline{q}_c$  = average cone tip resistance within a depth range  $B$  below the bottom of the footing (ksf)

$B$  = footing width (ft)

$C_{wq}, C_{w\gamma}$  = correction factors to account for the location of the groundwater table as specified in Table 10.6.3.1.2a-2 (dim)

$D_f$  = footing embedment depth taken to the bottom of the footing (ft)

#### 10.6.3.1.4—Plate Load Tests

The nominal bearing resistance may be determined by plate load tests, provided that adequate subsurface explorations have been made to determine the soil profile below the foundation. Where plate load tests are conducted, they should be conducted in accordance with AASHTO T 235 and [ASTM D1194](#).

The nominal bearing resistance determined from a plate load test may be extrapolated to adjacent footings where the subsurface profile is confirmed by subsurface exploration to be similar.

#### C10.6.3.1.4

Plate load tests have a limited depth of influence and furthermore may not disclose the potential for long-term consolidation of foundation soils.

Scale effects should be addressed when extrapolating the results to performance of full scale footings. Extrapolation of the plate load test data to a full scale footing should be based on the design procedures provided herein for settlement (service limit state) and bearing resistance (strength and extreme event limit state), with consideration to the effect of the stratification, i.e., layer thicknesses, depths, and properties. Plate load test results should be applied only within a sub-area of the project site for which the subsurface conditions, i.e., stratification, geologic history, and properties, are relatively uniform.

#### 10.6.3.2—Bearing Resistance of Rock

##### 10.6.3.2.1—General

The methods used for design of footings on rock shall consider the presence, orientation, and condition of discontinuities, weathering profiles, and other similar profiles as they apply at a particular site.

##### C10.6.3.2.1

The design of spread footings bearing on rock is frequently controlled by either overall stability, i.e., the orientation and conditions of discontinuities, or load eccentricity considerations. The designer should verify

For footings on competent rock, reliance on simple and direct analyses based on uniaxial compressive rock strengths and *RQD* may be applicable. For footings on less competent rock, more detailed investigations and analyses shall be performed to account for the effects of weathering and the presence and condition of discontinuities.

The designer shall judge the competency of a rock mass by taking into consideration both the nature of the intact rock and the orientation and condition of discontinuities of the overall rock mass. Where engineering judgment does not verify the presence of competent rock, the competency of the rock mass should be verified using the procedures for *RMR* rating in Article 10.4.6.4.

#### *10.6.3.2.2—Semiempirical Procedures*

The nominal bearing resistance of rock should be determined using empirical correlation with the Geomechanics Rock Mass Rating system. Local experience shall be considered in the use of these semi-empirical procedures.

The factored bearing stress of the foundation shall not be taken to be greater than the factored compressive resistance of the footing concrete.

#### *10.6.3.2.3—Analytic Method*

The nominal bearing resistance of foundations on rock shall be determined using established rock mechanics principles based on the rock mass strength parameters. The influence of discontinuities on the failure mode shall also be considered.

#### *10.6.3.2.4—Load Test*

Where appropriate, load tests may be performed to determine the nominal bearing resistance of foundations on rock.

#### **10.6.3.3—Eccentric Load Limitations**

The eccentricity of loading at the strength limit state, evaluated based on factored loads shall not exceed:

- One-fourth of the corresponding footing dimension, *B* or *L*, for footings on soils, or
- Three-eighths of the corresponding footing dimensions *B* or *L*, for footings on rock.

adequate overall stability at the service limit state and size the footing based on eccentricity requirements at the strength limit state before checking nominal bearing resistance at both the service and strength limit states.

#### *C10.6.3.2.2*

The bearing resistance of jointed or broken rock may be estimated using the semi-empirical procedure developed by Carter and Kulhawy (1988). This procedure is based on the unconfined compressive strength of the intact rock core sample. Depending on rock mass quality measured in terms of *RMR* system, the nominal bearing resistance of a rock mass varies from a small fraction to six times the unconfined compressive strength of intact rock core samples.

#### *C10.6.3.2.3*

Depending upon the relative spacing of joints and rock layering, bearing capacity failures for foundations on rock may take several forms. Except for the case of a rock mass with closed joints, the failure modes are different from those in soil. Procedures for estimating bearing resistance for each of the failure modes can be found in Kulhawy and Goodman (1987), Goodman (1989), and Sowers (1979).

#### **C10.6.3.3**

A comprehensive parametric study was conducted for cantilevered retaining walls of various heights and soil conditions. The base widths obtained using the LRFD load factors and eccentricity of *B*/4 were comparable to those of ASD with an eccentricity of *B*/6.

#### 10.6.3.4—Failure by Sliding

Failure by sliding shall be investigated for footings that support horizontal or inclined load and/or are founded on slopes.

For foundations on clay soils, the possible presence of a shrinkage gap between the soil and the foundation shall be considered. If passive resistance is included as part of the shear resistance required for resisting sliding, consideration shall also be given to possible future removal of the soil in front of the foundation.

The factored resistance against failure by sliding, in kips, shall be taken as:

$$R_R = \varphi R_n = \varphi_\tau R_\tau + \varphi_{ep} R_{ep} \quad (10.6.3.4-1)$$

where:

$R_n$  = nominal sliding resistance against failure by sliding (kips)

$\varphi_\tau$  = resistance factor for shear resistance between soil and foundation specified in Table 10.5.5.2.2-1

$R_\tau$  = nominal sliding resistance between soil and foundation (kips)

$\varphi_{ep}$  = resistance factor for passive resistance specified in Table 10.5.5.2.2-1

$R_{ep}$  = nominal passive resistance of soil available throughout the design life of the structure (kips)

If the soil beneath the footing is cohesionless, the nominal sliding resistance between soil and foundation shall be taken as:

$$R_\tau = V \tan \delta \quad (10.6.3.4-2)$$

for which:

$\tan \delta = \tan \phi_f$  for concrete cast against soil

=  $0.8 \tan \phi_f$  for precast concrete footing

where:

$\phi_f$  = internal friction angle of drained soil (degrees)

$V$  = total vertical force (kips)

#### C10.6.3.4

Sliding failure occurs if the force effects due to the horizontal component of loads exceed the more critical of either the factored shear resistance of the soils or the factored shear resistance at the interface between the soil and the foundation.

For footings on cohesionless soils, sliding resistance depends on the roughness of the interface between the foundation and the soil.

The magnitudes of active earth load and passive resistance depend on the type of backfill material, the wall movement, and the compactive effort. Their magnitude can be estimated using procedures described in Sections 3 and 11.

In most cases, the movement of the structure and its foundation will be small. Consequently, if passive resistance is included in the resistance, its magnitude is commonly taken as 50 percent of the maximum passive resistance. This is the basis for the resistance factor,  $\varphi_{ep}$ , in Table 10.5.5.2.2-1.

The units for  $R_R$ ,  $R_n$ , and  $R_{ep}$  are shown in kips. For elements designed on a unit length basis, these quantities will have the units of kips per unit length.

Rough footing bases usually occur where footings are cast in-situ. Precast concrete footings may have smooth bases.

For footings that rest on clay, the sliding resistance may be taken as the lesser of:

- The cohesion of the clay, or
- Where footings are supported on at least 6.0 in. of compacted granular material, one-half the normal stress on the interface between the footing and soil, as shown in Figure 10.6.3.4-1 for retaining walls.

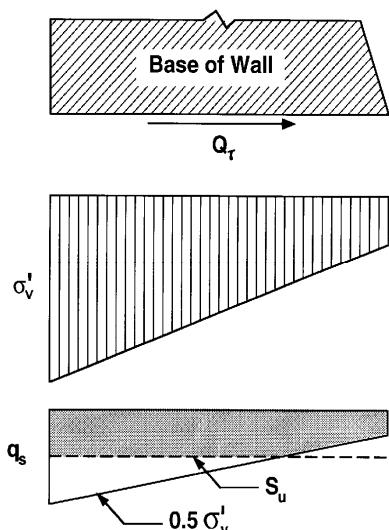

The following notation shall be taken to apply to Figure 10.6.3.4-1:

$q_s$  = unit shear resistance, equal to  $S_u$  or  $0.5 \sigma'_v$ , whichever is less

$R_t$  = nominal sliding resistance between soil and foundation (kips) expressed as the shaded area under the  $q_s$  diagram

$S_u$  = undrained shear strength (ksf)

$\sigma'_v$  = vertical effective stress (ksf)

**Figure 10.6.3.4-1—Procedure for Estimating Nominal Sliding Resistance for Walls on Clay**

#### 10.6.4—Extreme Event Limit State Design

##### 10.6.4.1—General

Extreme limit state design checks for spread footings shall include, but not necessarily be limited to:

- Bearing resistance,
- Eccentric load limitations (overturning),
- Sliding, and
- Overall stability.

Resistance factors shall be as specified in Article 10.5.5.3.

#### 10.6.4.2—Eccentric Load Limitations

For footings, whether on soil or on rock, the eccentricity of loading for extreme limit states shall not exceed the limits provided in Article 11.6.5.

If live loads act to reduce the eccentricity for the Extreme I limit state,  $\gamma_{EQ}$  shall be taken as 0.0.

#### 10.6.5—Structural Design

The structural design of footings shall comply with the requirements given in Section 5.

For structural design of an eccentrically loaded foundation, a triangular or trapezoidal contact stress distribution based on factored loads shall be used for footings bearing on all soil and rock conditions.

For purposes of structural design, it is usually assumed that the bearing stress varies linearly across the bottom of the footing. This assumption results in the slightly conservative triangular or trapezoidal contact stress distribution.

### 10.7—DRIVEN PILES

#### 10.7.1—General

##### 10.7.1.1—Application

Piling should be considered when spread footings cannot be founded on rock, or on competent soils at a reasonable cost. At locations where soil conditions would normally permit the use of spread footings but the potential exists for scour, liquefaction or lateral spreading, piles bearing on suitable materials below susceptible soils should be considered for use as a protection against these problems. Piles should also be considered where right-of-way or other space limitations would not allow the use of spread footings, or where removal of existing soil that is contaminated by hazardous materials for construction of shallow foundations is not desirable.

Piles should also be considered where an unacceptable amount of settlement of spread footings may occur.

##### 10.7.1.2—Minimum Pile Spacing, Clearance, and Embedment into Cap

Center-to-center pile spacing should not be less than 30.0 in. or 2.5 pile diameters. The distance from the side of any pile to the nearest edge of the pile cap shall not be less than 9.0 in.

The tops of piles shall project at least 12.0 in. into the pile cap after all damaged material has been removed. If the pile is attached to the cap by embedded bars or strands, the pile shall extend no less than 6.0 in. into the cap.

Where a reinforced concrete beam is cast-in-place and used as a bent cap supported by piles, the concrete cover on the sides of the piles shall not be less than 6.0 in., plus an allowance for permissible pile misalignment. Where pile reinforcement is anchored in the cap satisfying the requirements of Article 5.13.4.1, the projection may be less than 6.0 in.

### **10.7.1.3—Piles through Embankment Fill**

Piles to be driven through embankments should penetrate a minimum of 10 ft through original ground unless refusal on bedrock or competent bearing strata occurs at a lesser penetration.

Fill used for embankment construction should be a select material, which does not obstruct pile penetration to the required depth.

### **C10.7.1.3**

If refusal occurs at a depth of less than 10 ft, other foundation types, e.g., footings or shafts, may be more effective.

To minimize the potential for obstruction of the piles, the maximum size of any rock particles in the fill should not exceed 6.0 in. Pre-drilling or spudding pile locations should be considered in situations where obstructions in the embankment fill cannot be avoided, particularly for displacement piles. Note that predrilling or spudding may reduce the pile skin friction and lateral resistance, depending on how the predrilling or spudding is conducted. The diameter of the predrilled or spudded hole, and the potential for caving of the hole before the pile is installed will need to be considered to assess the effect this will have on skin friction and lateral resistance.

If compressible soils are located beneath the embankment, piles should be driven after embankment settlement is complete, if possible, to minimize or eliminate downdrag forces.

### **10.7.1.4—Batter Piles**

When the lateral resistance of the soil surrounding the piles is inadequate to counteract the horizontal forces transmitted to the foundation, or when increased rigidity of the entire structure is required, batter piles should be considered for use in the foundation. Where negative skin friction (downdrag) loads are expected, batter piles should be avoided. If batter piles are used in areas of significant seismic loading, the design of the pile foundation shall recognize the increased foundation stiffness that results.

### **C10.7.1.4**

In some cases, it may be desirable to use batter piles. From a general viewpoint, batter piles provide a much stiffer resistance to horizontal loads than would be possible with vertical piles. They can be very effective in resisting static horizontal loads.

Due to increased foundation stiffness, batter piles may not be desirable in resisting horizontal dynamic loads if the structure is located in an area where seismic loads are potentially high.

### **10.7.1.5—Pile Design Requirements**

Pile design shall address the following issues as appropriate:

- Nominal axial resistance to be specified in the contract, type of pile, and size of pile group required to provide adequate support, with consideration of how nominal axial pile resistance will be determined in the field.
- Group interaction.
- Pile quantity estimation from estimated pile penetration required to meet nominal axial resistance and other design requirements.
- Minimum pile penetration necessary to satisfy the requirements caused by uplift, scour, downdrag, settlement, liquefaction, lateral loads, and seismic conditions.
- Foundation deflection to meet the established movement and associated structure performance criteria.

### **C10.7.1.5**

The driven pile design process is discussed in detail in Hannigan et al. (2005).

- Pile foundation nominal structural resistance.
- Verification of pile drivability to confirm that acceptable driving stresses and blow counts can be achieved with an available driving system to meet all contract acceptance criteria.
- Long-term durability of the pile in service, i.e. corrosion and deterioration.

### **10.7.1.6—Determination of Pile Loads**

#### *10.7.1.6.1—General*

The loads and load factors to be used in pile foundation design shall be as specified in Section 3. Computational assumptions that shall be used in determining individual pile loads are described in Section 4.

#### *10.7.1.6.2—Downdrag*

The provisions of Article 3.11.8 shall apply for determination of load due to negative skin resistance.

Where piles are driven to end bearing on a dense stratum or rock and the design of the pile is structurally controlled, downdrag shall be considered at the strength and extreme limit states.

For friction piles that can experience settlement at the pile tip, downdrag shall be considered at the service, strength and extreme limit states. Determine pile and pile group settlement according to Article 10.7.2.

The nominal pile resistance available to support structure loads plus downdrag shall be estimated by considering only the positive skin and tip resistance below the lowest layer acting in negative skin resistance computed as specified in Article 3.11.8.

#### *10.7.1.6.3—Uplift Due to Expansive Soils*

Piles penetrating expansive soil shall extend to a depth into moisture-stable soils sufficient to provide adequate anchorage to resist uplift. Sufficient clearance should be provided between the ground surface and underside of caps or beams connecting piles to preclude the application of uplift loads at the pile/cap connection due to swelling ground conditions.

#### *C10.7.1.6.1*

The specification and determination of top of cap loads is discussed in Section 3. The Engineer should select different levels of analysis, detail and accuracy as appropriate for the structure under consideration. Details are discussed in Section 4.

#### *C10.7.1.6.2*

Downdrag occurs when settlement of soils along the side of the piles results in downward movement of the soil relative to the pile. See commentary to Article C3.11.8.

In the case of friction piles with limited tip resistance, the downdrag load can exceed the geotechnical resistance of the pile, causing the pile to move downward enough to allow service limit state criteria for the structure to be exceeded. Where pile settlement is not limited by pile bearing below the downdrag zone, service limit state tolerances will govern the geotechnical design of piles subjected to downdrag.

This design situation is not desirable and the preferred practice is to mitigate the downdrag induced foundation settlement through a properly designed surcharge and/or preloading program, or by extending the piles deeper for higher resistance.

The static analysis procedures in Article 10.7.3.8.6 may be used to estimate the available pile resistance to withstand the downdrag plus structure loads.

#### *C10.7.1.6.3*

Evaluation of potential uplift loads on piles extending through expansive soils requires evaluation of the swell potential of the soil and the extent of the soil strata that may affect the pile. One reasonably reliable method for identifying swell potential is presented in Table 10.4.6.3-1. Alternatively, [ASTM D4829](#) may be used to evaluate swell potential. The thickness of the potentially expansive stratum must be identified by:

- Examination of soil samples from borings for the presence of jointing, slickensiding, or a blocky structure and for changes in color, and
- Laboratory testing for determination of soil moisture content profiles.

#### *10.7.1.6.4—Nearby Structures*

Where pile foundations are placed adjacent to existing structures, the influence of the existing structure on the behavior of the foundation, and the effect of the new foundation on the existing structures, including vibration effects due to pile installation, shall be investigated.

### **10.7.2—Service Limit State Design**

#### **10.7.2.1—General**

Service limit state design of driven pile foundations includes the evaluation of settlement due to static loads, and downdrag loads if present, overall stability, lateral squeeze, and lateral deformation. Overall stability of a pile supported foundation shall be evaluated where:

- The foundation is placed through an embankment,
- The pile foundation is located on, near or within a slope,
- The possibility of loss of foundation support through erosion or scour exists, or
- Bearing strata are significantly inclined.

Unbalanced lateral forces caused by lack of overall stability or lateral squeeze should be mitigated through stabilization measures, if possible.

#### **10.7.2.2—Tolerable Movements**

The provisions of Article 10.5.2.1 shall apply.

#### *C10.7.1.6.4*

Vibration due to pile driving can cause settlement of existing foundations as well as structural damage to the adjacent facility. The combination of taking measures to mitigate the vibration levels through use of nondisplacement piles, predrilling, etc., and a good vibration monitoring program should be considered.

#### **C10.7.2.1**

Lateral analysis of pile foundations is conducted to establish the load distribution between the superstructure and foundations for all limit states, and to estimate the deformation in the foundation that will occur due to those loads. This Article only addresses the evaluation of the lateral deformation of the foundation resulting from the distributed loads.

In general, it is not desirable to subject the pile foundation to unbalanced lateral loading caused by lack of overall stability or caused by lateral squeeze.

#### **10.7.2.3—Settlement**

##### *10.7.2.3.1—Equivalent Footing Analogy*

For purposes of calculating the settlements of pile groups, loads should be assumed to act on an equivalent footing based on the depth of embedment of the piles into the layer that provides support as shown in Figures 10.7.2.3.1-1 and 10.7.2.3.1-2.

Pile group settlement shall be evaluated for pile foundations in cohesive soils, soils that include cohesive layers, and piles in loose granular soils. The load used in calculating settlement shall be the permanently applied load on the foundation.

In applying the equivalent footing analogy for pile foundation, the reduction to equivalent dimensions  $B'$  and  $L'$  as used for spread footing design does not apply.

#### **C10.7.2.2**

See Article C10.5.2.1.

#### *C10.7.2.3.1*

Pile design should ensure that strength limit state considerations are satisfied before checking service limit state considerations.

For piles tipped adequately into dense granular soils such that the equivalent footing is located on or within the dense granular soil, and furthermore are not subjected to downdrag loads, a detailed assessment of the pile group settlement may be waived.

Methods for calculating settlement are discussed in Hannigan et al., (2005).

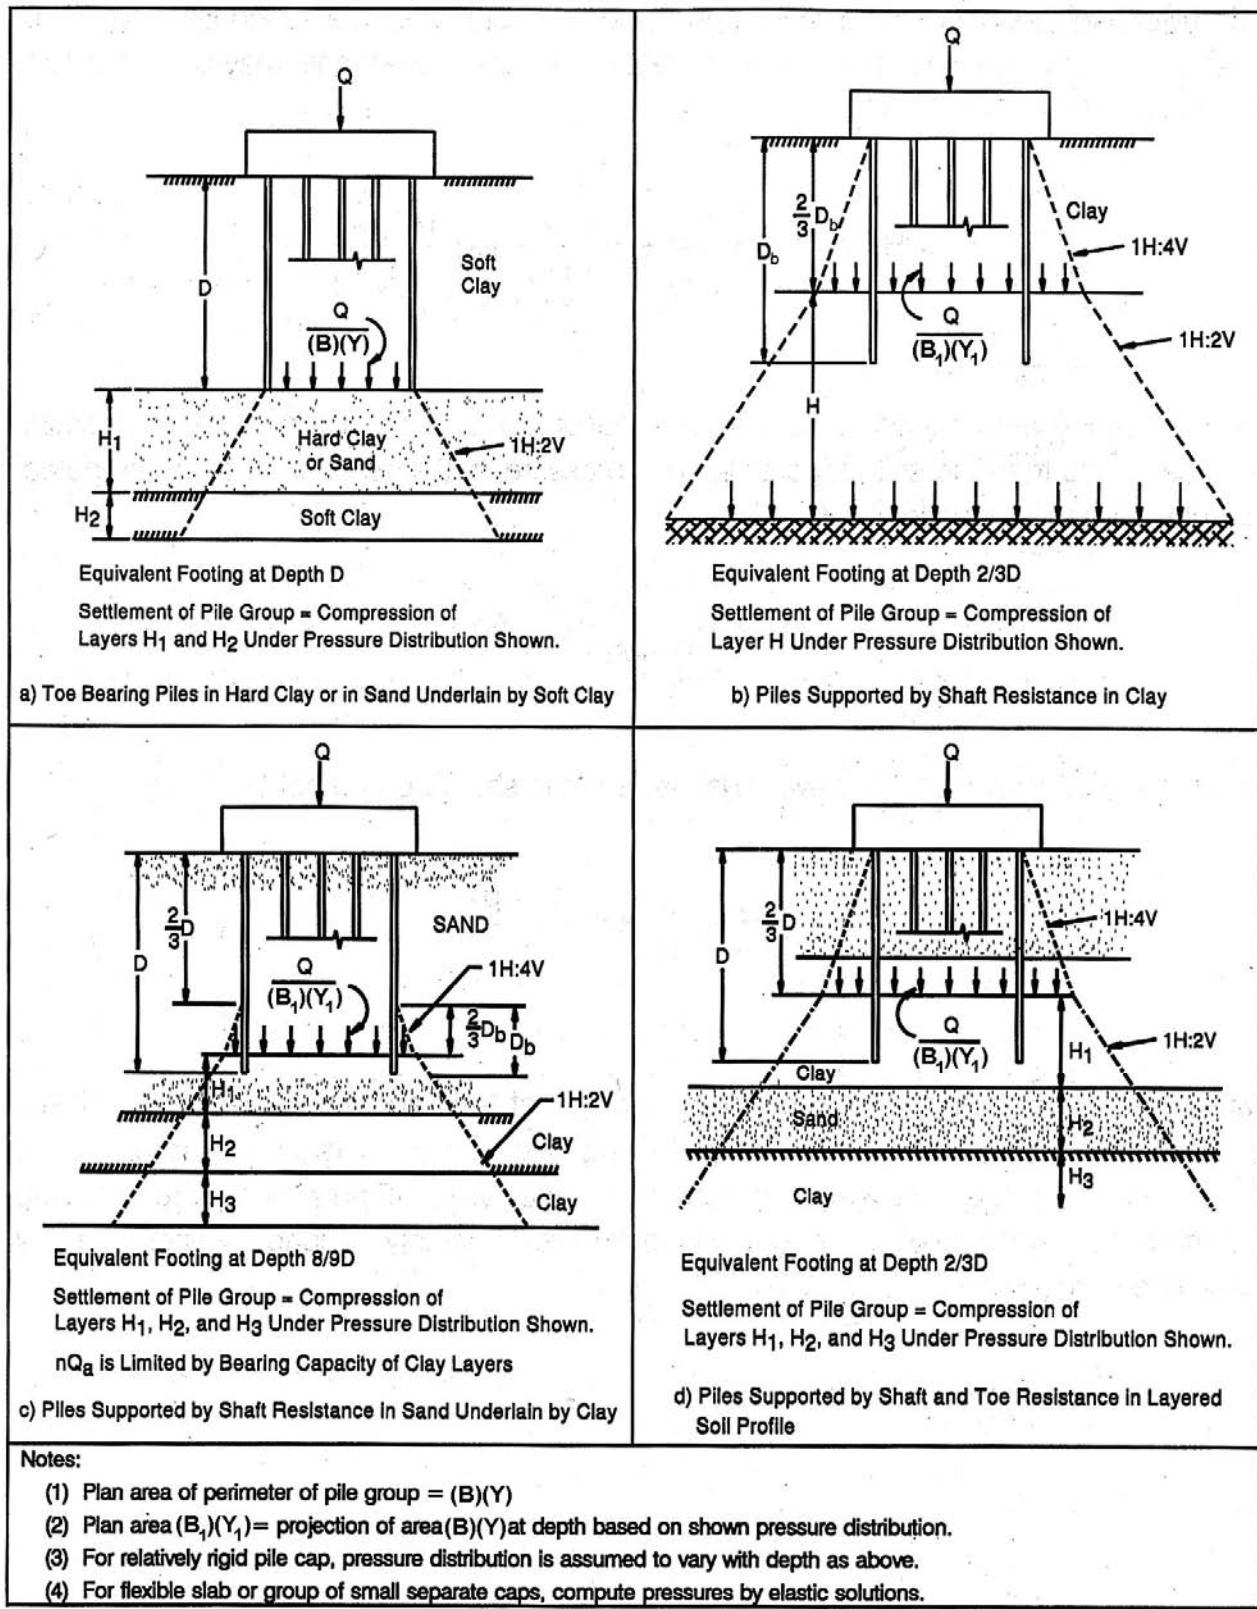

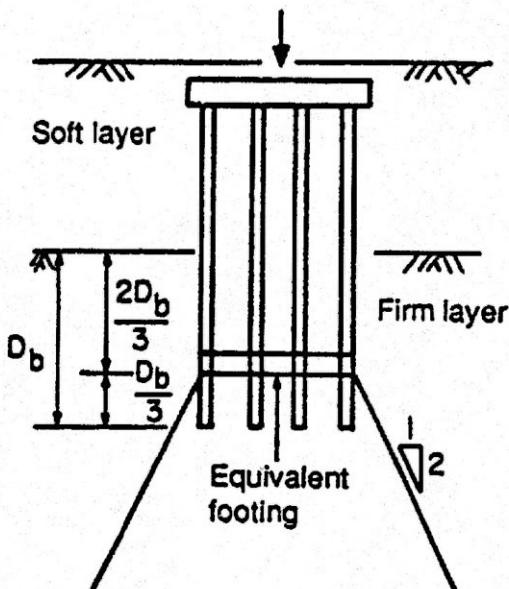

Figure 10.7.2.3.1-1—Stress Distribution below Equivalent Footing for Pile Group after Hannigan et al. (2005)

**Figure 10.7.2.3.1-2—Location of Equivalent Footing  
(after Duncan and Buchignani, 1976)**

#### 10.7.2.3.2—Pile Groups in Cohesive Soil

#### C10.7.2.3.2

Shallow foundation settlement estimation procedures shall be used to estimate the settlement of a pile group, using the equivalent footing location specified in Figure 10.7.2.3-1.1 or Figure 10.7.2.3.1-2.

The settlement of pile groups in cohesionless soils may be taken as:

$$\text{Using SPT: } \rho = \frac{qI\sqrt{B}}{N_{60}} \quad (10.7.2.3.2-1)$$

$$\text{Using CPT: } \rho = \frac{qBI}{2q_c} \quad (10.7.2.3.2-2)$$

in which:

$$I = 1 - 0.125 \frac{D'}{B} \geq 0.5 \quad (10.7.2.3.2-3)$$

where:

$\rho$  = settlement of pile group (in.)

$q$  = net foundation pressure applied at  $2D_b/3$ , as shown in Figure 10.7.2.3.1-1; this pressure is equal to the applied load at the top of the group divided by the area of the equivalent footing and does not include the weight of the piles or the soil between the piles (ksf)

$B$  = width or smallest dimension of pile group (ft)

The provisions are based upon the use of empirical correlations proposed by Meyerhof (1976). These are empirical correlations and the units of measure must match those specified for correct computations. This method may tend to over-predict settlements.

$I$	= influence factor of the effective group embedment (dim)
$D'$	= effective depth taken as $2D_b/3$ (ft)
$D_b$	= depth of embedment of piles in layer that provides support, as specified in Figure 10.7.2.3.1-1 (ft)
$N_{160}$	= SPT blow count corrected for both overburden and hammer efficiency effects (blows/ft) as specified in Article 10.4.6.2.4.
$q_c$	= static cone tip resistance (ksf)

Alternatively, other methods for computing settlement in cohesionless soil, such as the Hough method as specified in Article 10.6.2.4.2 may also be used in connection with the equivalent footing approach.

The corrected SPT blow count or the static cone tip resistance should be averaged over a depth equal to the pile group width  $B$  below the equivalent footing. The SPT and CPT methods (Eqs. 10.7.2.3.2-1 and 10.7.2.3.2-2) shall only be considered applicable to the distributions shown in Figure 10.7.2.3.1-1b and Figure 10.7.2.3.1-2.

#### 10.7.2.4—Horizontal Pile Foundation Movement

Horizontal movement induced by lateral loads shall be evaluated. The provisions of Article 10.5.2.1 shall apply regarding horizontal movement criteria.

The horizontal movement of pile foundations shall be estimated using procedures that consider soil-structure interaction. Tolerable lateral movements of piles shall be established on the basis of confirming compatible movements of structural components, e.g., pile to column connections, for the loading condition under consideration.

The effects of the lateral resistance provided by an embedded cap may be considered in the evaluation of horizontal movement.

The orientation of nonsymmetrical pile cross-sections shall be considered when computing the pile lateral stiffness.

Lateral resistance of single piles may be determined by static load test. If a static lateral load test is to be performed, it shall follow the procedures specified in [ASTM D3966](#).

The effects of group interaction shall be taken into account when evaluating pile group horizontal movement. When the  $P-y$  method of analysis is used, the values of  $P$  shall be multiplied by  $P$ -multiplier values,  $P_m$ , to account for group effects. The values of  $P_m$  provided in Table 10.7.2.4-1 should be used.

#### C10.7.2.4

Pile foundations are subjected to horizontal loads due to wind, traffic loads, bridge curvature, vessel or traffic impact and earthquake. Batter piles are sometimes used but they are somewhat more expensive than vertical piles, and vertical piles are more effective against dynamic loads.

Methods of analysis that use manual computation were developed by Broms (1964a and 1964b). They are discussed in detail by Hannigan et al. (2005). Reese developed analysis methods that model the horizontal soil resistance using  $P-y$  curves. This analysis has been well developed and software is available for analyzing single piles and pile groups (Reese, 1986; Williams et al., 2003; and Hannigan et al., 2005).

Deep foundation horizontal movement at the foundation design stage may be analyzed using computer applications that consider soil-structure interaction. Application formulations are available that consider the total structure including pile cap, pier and superstructure (Williams et al., 2003).

If a static load test is used to assess the site specific lateral resistance of a pile, information on the methods of analysis and interpretation of lateral load tests presented in the *Handbook on Design of Piles and Drilled Shafts Under Lateral Load*, Reese (1984) and *Static Testing of Deep Foundations*, Kyfor et al. (1992) should be used.

Table 10.7.2.4-1—Pile P-Multipliers,  $P_m$ , for Multiple Row Shading (averaged from Hannigan et al., 2005)

Pile CTC spacing (in the direction of loading)	P-Multipliers, $P_m$		
	Row 1	Row 2	Row 3 and higher
3B	0.7	0.5	0.35
5B	1.0	0.85	0.7

Loading direction and spacing shall be taken as defined in Figure 10.7.2.4-1. If the loading direction for a single row of piles is perpendicular to the row (bottom detail in the Figure), a group reduction factor of less than 1.0 should only be used if the pile spacing is  $5B$  or less, i.e., a  $P_m$  of 0.7 for a spacing of  $3B$ , as shown in Figure 10.7.2.4-1.

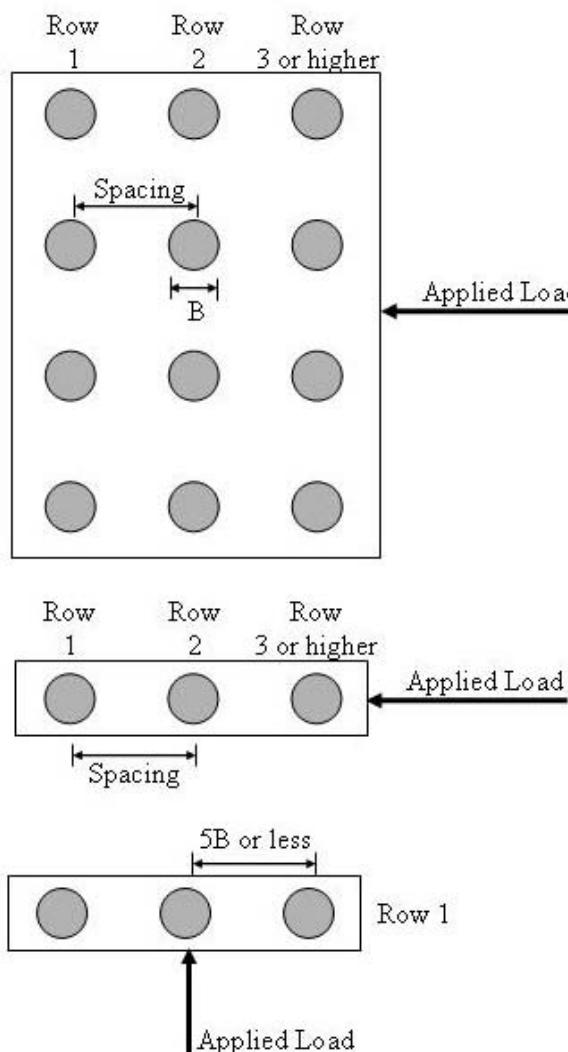

Figure 10.7.2.4-1—Definition of Loading Direction and Spacing for Group Effects

Since many piles are installed in groups, the horizontal resistance of the group has been studied and it has been found that multiple rows of piles will have less resistance than the sum of the single pile resistance. The front piles “shade” rows that are further back.

The  $P$ -multipliers,  $P_m$ , in Table 10.7.2.4-1 are a function of the center-to-center (CTC) spacing of piles in the group in the direction of loading expressed in multiples of the pile diameter,  $B$ . The values of  $P_m$  in Table 10.7.2.4-1 were developed for vertical piles only.

Horizontal load tests have been performed on pile groups, and multipliers have been determined that can be used in the analysis for the various rows. Those multipliers have been found to depend on the pile spacing and the row number in the direction of loading. To establish values of  $P_m$  for other pile spacing values, interpolation between values should be conducted.

The multipliers on the pile rows are a topic of current research and may change in the future. Values from recent research have been tabulated by Hannigan et al. (2005). Averaged values are provided in Table 10.7.2.4-1.

Note that these  $P$ -y methods generally apply to foundation elements that have some ability to bend and deflect. For large diameter, relatively short foundation elements, e.g., drilled shafts or relatively short stiff piles, the foundation element rotates rather than bends, in which case strain wedge theory (Norris, 1986; Ashour et al., 1998) may be more applicable. When strain wedge theory is used to assess the lateral load response of groups of short, large diameter piles or shaft groups, group effects should be addressed through evaluation of the overlap between shear zones formed due to the passive wedge that develops in front of each shaft in the group as lateral deflection increases. Note that  $P_m$  in Table 10.7.2.4-1 is not applicable if strain wedge theory is used.

Batter piles provide a much stiffer lateral response than vertical piles when loaded in the direction of the batter.

### 10.7.2.5—Settlement Due to Downdrag

The nominal pile resistance available to support structure loads plus downdrag shall be estimated by considering only the positive skin and tip resistance below the lowest layer contributing to the downdrag. In general, the available factored geotechnical resistance should be greater than the factored loads applied to the pile, including the downdrag, at the service limit state. In the instance where it is not possible to obtain adequate geotechnical resistance below the lowest layer contributing to downdrag, e.g., friction piles, to fully resist the downdrag, the structure should be designed to tolerate the full amount of settlement resulting from the downdrag and the other applied loads.

If adequate geotechnical resistance is available to resist the downdrag plus structure loads in the service limit state, the amount of deformation needed to fully mobilize the geotechnical resistance should be estimated, and the structure designed to tolerate the anticipated movement.

### C10.7.2.5

The static analysis procedures in Article 10.7.3.8.6 may be used to estimate the available pile resistance to withstand the downdrag plus structure loads.

Resistance may also be estimated using a dynamic method, e.g., dynamic measurements with signal matching analysis, pile driving formula, etc., per Article 10.7.3.8, provided the skin friction resistance within the zone contributing to downdrag is subtracted from the resistance determined from the dynamic method during pile installation. The skin friction resistance within the zone contributing to downdrag may be estimated using the static analysis methods specified in Article 10.7.3.8.6, from signal matching analysis, or from pile load test results. Note that the static analysis methods may have bias that, on average, over or under predicts the skin friction. The bias of the method selected to estimate the skin friction within the downdrag zone should be taken into account as described in Article 10.7.3.3.

For the establishment of settlement tolerance limits, see Article 10.5.2.1.

### 10.7.2.6—Lateral Squeeze

Bridge abutments supported on pile foundations driven through soft soils that are subject to unbalanced embankment fill loading shall be evaluated for lateral squeeze.

### C10.7.2.6

Guidance on evaluating the potential for lateral squeeze and potential mitigation methods are included in Hannigan et al., (2005).

## 10.7.3—Strength Limit State Design

### 10.7.3.1—General

For strength limit state design, the following shall be determined:

- Loads and performance requirements;
- Pile type, dimensions, and nominal axial pile resistance in compression;
- Size and configuration of the pile group to provide adequate foundation support;
- Estimated pile length to be used in the construction contract documents to provide a basis for bidding;
- A minimum pile penetration, if required, for the particular site conditions and loading, determined based on the maximum (deepest) depth needed to meet all of the applicable requirements identified in Article 10.7.6;

### C10.7.3.1

A minimum pile penetration should only be specified if needed to ensure that uplift, lateral stability, depth to resist downdrag, depth to resist scour, and depth for structural lateral resistance are met for the strength limit state, in addition to similar requirements

- The maximum driving resistance expected in order to reach the minimum pile penetration required, if applicable, including any soil/pile shaft resistance that will not contribute to the long-term nominal axial resistance of the pile, e.g., soil contributing to downdrag, or soil that will be removed by scour;
- The drivability of the selected pile to achieve the required nominal axial resistance or minimum penetration with acceptable driving stresses at a satisfactory blow count per unit length of penetration; and
- The nominal structural resistance of the pile and/or pile group.

### **10.7.3.2—Point Bearing Piles on Rock**

#### *10.7.3.2.1—General*

As applied to pile compressive resistance, this Article shall be considered applicable to soft rock, hard rock, and very strong soils such as very dense glacial tills that will provide high nominal axial resistance in compression with little penetration.

for the service and extreme event limit states. See Article 10.7.6 for additional details. Assuming dynamic methods, e.g., wave equation calibrated to dynamic measurements with signal matching analysis, pile formulae, etc., are used during pile installation to establish when the bearing resistance has been met, a minimum pile penetration should not be used to ensure that the required nominal pile bearing, i.e., compression, resistance is obtained.

A nominal resistance measured during driving exceeding the compressive nominal resistance required by the contract may be needed in order to reach a minimum pile penetration specified in the contract.

The drivability analysis is performed to establish whether a hammer and driving system will likely install the pile in a satisfactory manner.

#### *C10.7.3.2.1*

If pile penetration into rock is expected to be minimal, the prediction of the required pile length will usually be based on the depth to rock.

A definition of hard rock that relates to measurable rock characteristics has not been widely accepted. Local or regional experience with driving piles to rock provides the most reliable definition.

In general, it is not practical to drive piles into rock to obtain significant uplift or lateral resistance. If significant lateral or uplift foundation resistance is required, drilled shaft foundations should be considered. If it is still desired to use piles, a pile drivability study should be performed to verify the feasibility of obtaining the desired penetration into rock.

#### *10.7.3.2.2—Piles Driven to Soft Rock*

Soft rock that can be penetrated by pile driving shall be treated in the same manner as soil for the purpose of design for axial resistance, in accordance with Article 10.7.3.8.

#### *C10.7.3.2.2*

Steel piles driven into soft rock may not require tip protection.

#### *10.7.3.2.3—Piles Driven to Hard Rock*

The nominal resistance of piles driven to point bearing on hard rock where pile penetration into the rock formation is minimal is controlled by the structural limit state. The nominal axial resistance shall not exceed the values obtained from Article 6.9.4.1 with the resistance factors specified in Article 6.5.4.2 and Article 6.15 for severe driving conditions. A pile-driving acceptance criteria shall be developed that will prevent pile damage. Pile dynamic measurements should be used to monitor for pile damage when nominal axial resistances exceed 600 kips.

#### *C10.7.3.2.3*

Care should be exercised in driving piles to hard rock to avoid tip damage. The tips of steel piles driven to hard rock should be protected by high strength, cast steel tip protection.

If the rock is reasonably flat, the installation with pile tip protection will usually be successful. In the case of sloping rock, greater difficulty can arise and the use of tip protection with teeth should be considered. The designer should also consider the following to minimize the risk of pile damage during installation:

- Use a relatively small hammer. If a hydraulic hammer is used, it can be operated with a small stroke to seat the pile and then the axial resistance can be proven with a few larger hammer blows.
- If a larger hammer is used, specify a limited number of hammer blows after the pile tip reaches the rock. An example of a limiting criteria is five blows per one half inch.
- Extensive dynamic testing can be used to verify axial resistance on a large percentage of the piles. This approach could be used to justify larger design nominal resistances.

### 10.7.3.3—Pile Length Estimates for Contract Documents

Subsurface geotechnical information combined with static analysis methods (Article 10.7.3.8.6), preconstruction test pile programs (Article 10.7.9), and/or pile load tests (Article 10.7.3.8.2) shall be used to estimate the depth of penetration required to achieve the desired nominal bearing for establishment of contract pile quantities. Local experience shall also be considered when making pile quantity estimates, both to select an estimation method and to assess the potential prediction bias for the method used to account for any tendency to over-predict or under-predict pile compressive resistance. If the depth of penetration required to obtain the desired nominal bearing, i.e., compressive, resistance is less than the depth required to meet the provisions of Article 10.7.6, the minimum penetration required per Article 10.7.6 should be used as the basis for estimating contract pile quantities.

### C10.7.3.3

The estimated pile length required to support the required nominal resistance is determined using a static analysis; knowledge of the site subsurface conditions, and/or results from a pile load test. The pile length used to estimate quantities for the contract should also consider requirements to satisfy other design considerations, including service and extreme event limit states, as well as minimum pile penetration requirements for lateral stability, uplift, downdrag, scour, group settlement, etc.

One solution to the problem of predicting pile length is the use of a preliminary test program at the site. Such a program can range from a very simple operation of driving a few piles to evaluate drivability, to an extensive program where different pile types are driven and static and dynamic testing is performed.

In lieu of local pile driving experience, if a static analysis method is used to estimate the pile length required to achieve the desired nominal resistance for establishment of contract pile quantities, the factored resistance used to determine the number of piles required in the pile group may be conservatively equated to the factored resistance estimated using the static analysis method as follows:

$$\varphi_{dyn} \times R_n = \varphi_{stat} \times R_{nstat} \quad (C10.7.3.3-1)$$

where:

$\varphi_{dyn}$  = the resistance factor for the dynamic method used to verify pile bearing resistance during driving specified in Table 10.5.5.2.3-1

$R_n$  = the nominal pile bearing resistance (kips)

$\varphi_{stat}$  = the resistance factor for the static analysis method used to estimate the pile penetration depth required to achieve the desired bearing resistance specified in Table 10.5.5.2.3-1

$R_{nstat}$  = the predicted nominal resistance from the static analysis method used to estimate the penetration depth required (kips)

Using Eq. C10.7.3.3-1 and solving for  $R_{nstat}$ , use the static analysis method to determine the penetration depth required to obtain  $R_{nstat}$ .

The resistance factor for the static analysis method inherently accounts for the bias and uncertainty in the static analysis method. However, local experience may dictate that the penetration depth estimated using this approach be adjusted to reflect that experience. Where piles are driven to a well defined firm bearing stratum, the location of the top of bearing stratum will dictate the pile length needed, and Eq. C10.7.3.3-1 is likely not applicable.

Note that  $R_n$  is considered to be nominal bearing resistance of the pile needed to resist the applied loads, and is used as the basis for determining the resistance to be achieved during pile driving,  $R_{ndr}$  (see Articles 10.7.6 and 10.7.7).  $R_{nstat}$  is only used in the static analysis method to estimate the pile penetration depth required.

#### 10.7.3.4—Nominal Axial Resistance Change after Pile Driving

##### 10.7.3.4.1—General

Consideration should be given to the potential for change in the nominal axial pile resistance after the end of pile driving. The effect of soil relaxation or setup should be considered in the determination of nominal axial pile resistance for soils that are likely to be subject to these phenomena.

##### 10.7.3.4.2—Relaxation

If relaxation is possible in the soils at the site the pile shall be tested in re-strike after a sufficient time has elapsed for relaxation to develop.

##### C10.7.3.4.1

Relaxation is not a common phenomenon but more serious than setup since it represents a reduction in the reliability of the foundation.

Pile setup is a common phenomenon that can provide the opportunity for using larger pile nominal resistances at no increase in cost. However, it is necessary that the resistance gain be adequately proven. This is usually accomplished by restrike testing with dynamic measurements (Komurka, et. al, 2003).

##### C10.7.3.4.2

Relaxation is a reduction in axial pile resistance. While relaxation typically occurs at the pile tip, it can also occur along the sides of the pile (Morgan and White, 2004). It can occur in dense sands or sandy silts and in some shales. Relaxation in the sands and silts will usually develop fairly quickly after the end of driving, perhaps in only a few minutes, as a result of the return of the reduced pore pressure induced by dilation of the dense sands during driving. In some shales, relaxation occurs during the driving of adjacent piles and that will be immediate. There are other shales where the pile penetrates the shale and relaxation requires perhaps as much as two weeks to develop. In some cases, the amount of relaxation can be large.

**10.7.3.4.3—Setup**

Setup in the nominal axial resistance may be used to support the applied load. Where increase in resistance due to setup is utilized, the existence of setup shall be verified after a specified length of time by re-striking the pile.

**C10.7.3.4.3**

Setup is an increase in the nominal axial resistance that develops over time predominantly along the pile shaft. Pore pressures increase during pile driving due to a reduction of the soil volume, reducing the effective stress and the shear strength. Setup may occur rapidly in cohesionless soils and more slowly in finer grained soils as excess pore water pressures dissipate. In some clays, setup may continue to develop over a period of weeks and even months, and in large pile groups it can develop even more slowly.

Setup, sometimes called “pile freeze,” can be used to carry applied load, providing the opportunity for using larger pile nominal axial resistances, if it can be proven. Signal matching analysis of dynamic pile measurements made at the end of driving and later in re-strike can be an effective tool in evaluating and quantifying setup. (Komurka et al., 2003; Bogard and Matlock, 1990).

If a dynamic formula is used to evaluate pile axial resistance on re-strike, care should be used as these formulae may not be as effective at beginning of redrive (BOR), and furthermore, the resistance factors provided in Table 10.5.5.2.3-1 for driving formulae were developed for end of driving conditions. See Article C10.5.5.2.3 for additional discussion on this issue. Higher degrees of confidence are provided by dynamic measurements of pile driving with signal matching analyses or static load tests.

**10.7.3.5—Groundwater Effects and Buoyancy**

Nominal axial resistance shall be determined using the groundwater level consistent with that used to calculate the effective stress along the pile sides and tip. The effect of hydrostatic pressure shall be considered in the design.

**C10.7.3.5**

Unless the pile is bearing on rock, the tip resistance is primarily dependent on the effective surcharge that is directly influenced by the groundwater level. For drained loading conditions, the vertical effective stress is related to the groundwater level and thus it affects pile axial resistance. Lateral resistance may also be affected.

Buoyant forces may also act on a hollow pile or unfilled casing if it is sealed so that water does not enter the pile. During pile installation, this may affect the driving resistance observed, especially in very soft soils.

**10.7.3.6—Scour**

The effect of scour shall be considered in selecting the pile penetration. The pile foundation shall be designed so that the pile penetration after the design scour event satisfies the required nominal axial and lateral resistance.

**C10.7.3.6**

The resistance factors will be those used in the design without scour. The axial resistance of the material lost due to scour should be determined using a static analysis and it should not be factored, but consideration should be given to the bias of the static analysis method used to predict resistance. Method bias is discussed in Article 10.7.3.3.

The piles will need to be driven to the required nominal axial resistance plus the side resistance that will be lost due to scour. The resistance of the remaining soil is determined through field verification. The pile is driven to the required nominal axial resistance plus the magnitude of the skin friction lost as a result of scour, considering the prediction method bias.

The pile foundation shall be designed to resist debris loads occurring during the flood event in addition to the loads applied from the structure.

#### 10.7.3.7—Downdrag

The foundation should be designed so that the available factored geotechnical resistance is greater than the factored loads applied to the pile, including the downdrag, at the strength limit state. The nominal pile resistance available to support structure loads plus downdrag shall be estimated by considering only the positive skin and tip resistance below the lowest layer contributing to the downdrag. The pile foundation shall be designed to structurally resist the downdrag plus structure loads.

In the instance where it is not possible to obtain adequate geotechnical resistance below the lowest layer contributing to downdrag, e.g., friction piles, to fully resist the downdrag, or if it is anticipated that significant deformation will be required to mobilize the geotechnical resistance needed to resist the factored loads including the downdrag load, the structure should be designed to tolerate the settlement resulting from the downdrag and the other applied loads as specified in Article 10.7.2.5.

Another approach that may be used takes advantage of dynamic measurements. In this case, the static analysis method is used to determine an estimated length. During the driving of test piles, the skin friction component of the axial resistance of pile in the scourable material may be determined by a signal matching analysis of the dynamic measurements obtained when the pile is tipped below the scour elevation. The material below the scour elevation must provide the required nominal resistance after scour occurs.

In some cases, the flooding stream will carry debris that will induce horizontal loads on the piles.

Additional information regarding pile design for scour is provided in Hannigan et al. (2005).

#### C10.7.3.7

The static analysis procedures in Article 10.7.3.8.6 may be used to estimate the available pile resistance to withstand the downdrag plus structure loads.

Resistance may also be estimated using a dynamic method per Article 10.7.3.8, provided the skin friction resistance within the zone contributing to downdrag is subtracted from the resistance determined from the dynamic method during pile installation. The skin friction resistance within the zone contributing to downdrag may be estimated using the static analysis methods specified in Article 10.7.3.8.6, from signal matching analysis, or from pile load test results. Note that the static analysis method may have a bias, on average over or under predicting the skin friction. The bias of the method selected to estimate the skin friction should be taken into account as described in Article C10.7.3.3.

Pile design for downdrag is illustrated in Figure C10.7.3.7-1.

where:

$R_{Sdd}$  = skin friction which must be overcome during driving through downdrag zone (kips)

$Q_p = \Sigma \gamma_i Q_i$  = factored load per pile, excluding downdrag load (kips)

$DD$  = downdrag load per pile (kips)

$D_{est.}$  = estimated pile length needed to obtain desired nominal resistance per pile (ft)

$\Phi_{dyn}$  = resistance factor, assuming that a dynamic method is used to estimate pile resistance during installation of the pile (if a static analysis method is used instead, use  $\Phi_{stat}$ )

$\gamma_p$  = load factor for downdrag

The summation of the factored loads ( $\sum \gamma_i Q_i$ ) should be less than or equal to the factored resistance ( $\phi_{dyn} R_n$ ). Therefore, the nominal resistance  $R_n$  should be greater than or equal to the sum of the factored loads divided by the resistance factor  $\phi_{dyn}$ . The nominal bearing resistance (kips) of the pile needed to resist the factored loads, including downdrag, is therefore taken as:

$$R_n = \frac{(\sum \gamma_i Q_i)}{\phi_{dyn}} + \frac{\gamma_p DD}{\phi_{dyn}} \quad (\text{C10.7.3.7-1})$$

The total nominal driving resistance,  $R_{ndr}$  (kips), needed to obtain  $R_n$ , accounting for the skin friction that must be overcome during pile driving that does not contribute to the design resistance of the pile, is taken as:

$$R_{ndr} = R_{Sdd} + R_n \quad (\text{C10.7.3.7-2})$$

where:

$R_{ndr}$  = nominal pile driving resistance required (kips)

Note that  $R_{Sdd}$  remains unfactored in this analysis to determine  $R_{ndr}$ .

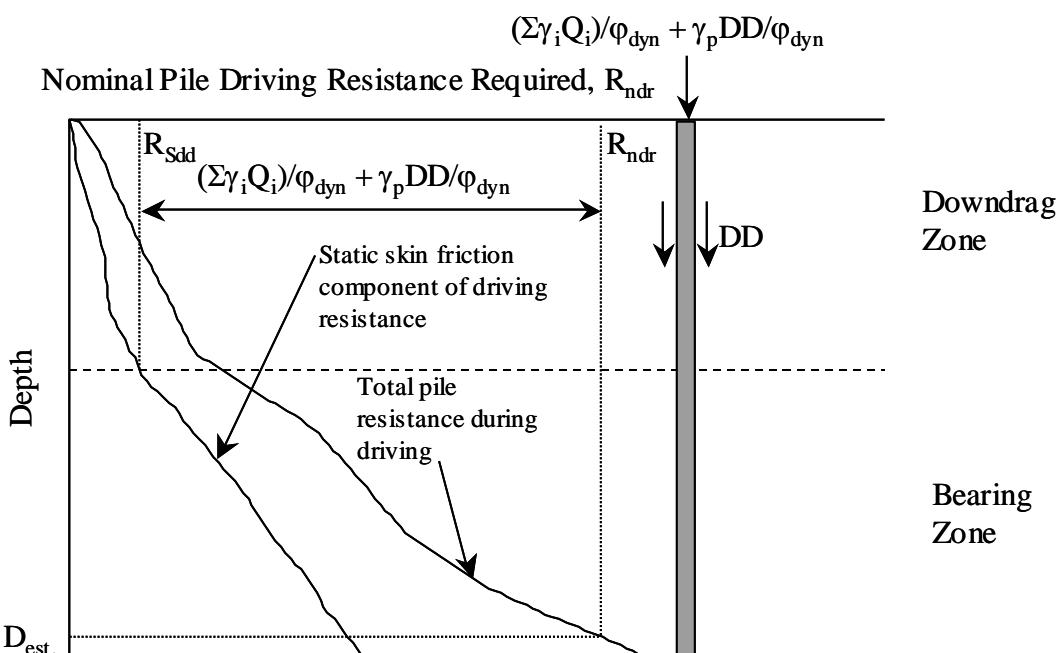

Figure C10.7.3.7-1—Design of Pile Foundations for Downdrag

### 10.7.3.8—Determination of Nominal Axial Pile Resistance in Compression

#### 10.7.3.8.1—General

Pile nominal axial resistance should be field verified during pile installation using load tests, dynamic tests, wave equation or dynamic formula. The resistance factor selected for design shall be based on the method used to verify pile axial resistance as specified in Article 10.5.5.2.3. The production piles shall be driven to the minimum blow count determined from the static load test, dynamic test, wave equation, or formula used unless a deeper penetration is required due to uplift, scour, lateral resistance, or other requirements as specified in Article 10.7.6. If it is determined that dynamic methods are unsuitable for field verification of nominal axial resistance, and a static analysis method is used without verification of axial resistance during pile driving by static load test, dynamic test or formula, the piles shall be driven to the tip elevation determined from the static analysis, and to meet other limit states as required in Article 10.7.6.

#### 10.7.3.8.2—Static Load Test

If a static pile load test is used to determine the pile axial resistance, the test shall not be performed less than 5 days after the test pile was driven unless approved by the Engineer. The load test shall follow the procedures specified in [ASTM D1143](#), and the loading procedure should follow the Quick Load Test Method, unless detailed longer-term load-settlement data is needed, in which case the standard loading procedure should be used. Unless specified otherwise by the Engineer, the pile axial resistance shall be determined from the test data as:

- For piles 24 in. or less in diameter (length of side for square piles), the Davisson Method;
- For piles larger than 36 in. in diameter (length of side for square piles), at a pile top movement,  $s_f$  (in.), as determined from Eq. 10.7.3.8.2-1; and
- For piles greater than 24 in. but less than 36 in. in diameter, a criteria to determine the pile axial resistance that is linearly interpolated between the criteria determined at diameters of 24 and 36 in.

$$s_f = \frac{QL}{12AE} + \frac{B}{2.5} \quad (10.7.3.8.2-1)$$

where:

#### C10.7.3.8.1

This Article addresses the determination of the nominal bearing (compression) resistance needed to meet strength limit state requirements, using factored loads and factored resistance values. From this design step, the number of piles and pile resistance needed to resist the factored loads applied to the foundation are determined. Both the loads and resistance values are factored as specified in Articles 3.4.1 and 10.5.5.2.3, respectively, for this determination.

#### C10.7.3.8.2

The Quick Test Procedure is desirable because it avoids problems that frequently arise when performing a static test that cannot be started and completed within an eight-hour period. Tests that extend over a longer period are difficult to perform due to the limited number of experienced personnel that are usually available. The Quick Test has proven to be easily performed in the field and the results usually are satisfactory. However, if the formation in which the pile is installed may be subject to significant creep settlement, alternative procedures provided in [ASTM D1143](#) should be considered.

The Davisson Method of axial resistance evaluation is performed by constructing a line on the load test curve that is parallel to the elastic compression line of the pile. The elastic compression line is calculated by assuming equal compressive forces are applied to the pile ends. The elastic compression line is offset by a specified amount of displacement. The Davisson Method is illustrated in Figure C10.7.3.8.2-1 and described in more detail in Hannigan et al. (2005).

$Q$  = test load (kips)

$L$  = pile length (ft)

$A$  = pile cross-sectional area ( $\text{ft}^2$ )

$E$  = pile modulus (ksi)

$B$  = pile diameter (length of side for square piles)  
(ft)

Driving criteria should be established in consideration of the static load test results.

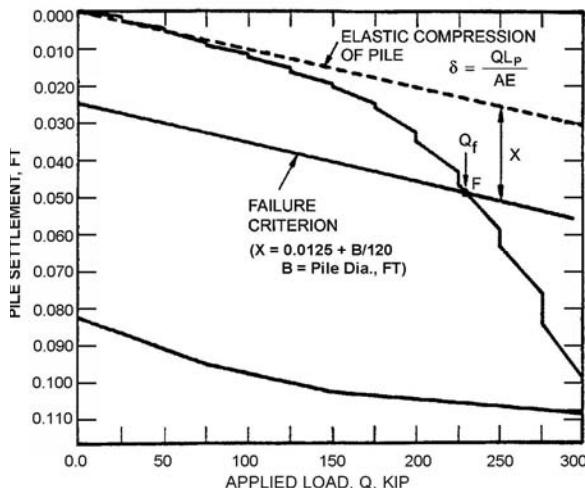

Figure C10.7.3.8.2-1—Alternate Method Load Test Interpretation (Cheney and Chassie, 2000, modified after Davisson, 1972)

For piles with large cross-sections, i.e., greater than 24 in., the Davisson Method will under predict the pile nominal axial resistance.

The specific application of the four driving criteria development approaches provided herein may be site specific, and may also depend on the degree of scatter in the pile load test and dynamic test results. If multiple load tests and dynamic tests with signal matching are conducted at a given site as defined in Article 10.5.5.2.3, the Engineer will need to decide how to “average” the results to establish the final driving criteria for the site, and if local experience is available, in consideration of that local experience. Furthermore, if one or more of the pile load tests yield significantly higher or lower nominal resistance values than the other load tests at a given project site, the reason for the differences should be thoroughly investigated before simply averaging the results together or treating the result(s) as anomalous.

Development of driving criteria in consideration of static load test results is described in Hannigan, et al. (2006).

#### 10.7.3.8.3—Dynamic Testing

Dynamic testing shall be performed according to the procedures given in [ASTM D4945](#). If possible, the dynamic test should be performed as a re-strike test if the Engineer anticipates significant time dependent strength change. The pile nominal axial resistance shall be determined by a signal matching analysis of the dynamic pile test data if the dynamic test is used to establish the driving criteria.

#### C10.7.3.8.3

The dynamic test may be used to establish the driving criteria at the beginning of production driving. The minimum number of piles that should be tested are as specified in Table 10.5.5.2.3-3. A signal matching analysis (Rausche et al., 1972) of the dynamic test data should always be used to determine axial resistance if a static load test is not performed. See Hannigan et al. (2005) for a description of and procedures to conduct a signal matching analysis. Re-strike testing should be performed if setup or relaxation is anticipated.

For example, note that it may not be possible to adjust the dynamic measurements with signal matching analysis to match the static load test results if the driving resistance at the time the dynamic measurement is taken is too large, i.e., the pile set per hammer blow is too small. In this case, adequate hammer energy is not reaching the pile tip to assess end bearing and produce an accurate match, though in such cases, the prediction will usually be very conservative. In general, a tip movement (pile set) of 0.10 to 0.15 in. is needed to provide an accurate signal matching analysis. See Hannigan, et al. (2006) for additional guidance on this issue.

In cases where a significant amount of soil setup occurs and the set at the beginning of redrive (BOR) is less than 0.10 inch per blow, a more accurate nominal resistance may be obtained by combining the end bearing determined using the signal matching analysis obtained for the end of driving (EOD) with the signal matching analysis for the shaft resistance at the beginning of redrive.

Dynamic testing and interpretation of the test data should only be performed by certified, experienced testers.

#### 10.7.3.8.4—Wave Equation Analysis

A wave equation analysis may be used to establish the driving criteria. In this case, the wave equation analysis shall be performed based on the hammer and pile driving system to be used for pile installation. To avoid pile damage, driving stresses shall not exceed the values obtained in Article 10.7.8, using the resistance factors specified or referred to in Table 10.5.5.2.3-1. Furthermore, the blow count needed to obtain the maximum driving resistance anticipated shall be less than the maximum value established based on the provisions in Article 10.7.8.

A wave equation analysis should also be used to evaluate pile drivability.

#### C10.7.3.8.4

Note that without dynamic test results with signal matching analysis and/or pile load test data (see Articles 10.7.3.8.2 and 10.7.3.8.3), considerable judgment is required to use the wave equation to predict the pile bearing resistance. Key soil input values that affect the predicted resistance include the soil damping and quake values, the skin friction distribution, e.g., such as could be obtained from a pile bearing static analysis, and the anticipated amount of soil setup or relaxation. Furthermore, the actual hammer performance is a variable that can only be accurately assessed through dynamic measurements, though “standard” input values are available. The resistance factor of 0.40 provided in Article 10.5.5.2.3 for the wave equation was developed from calibrations performed by Paikowsky et al. (2004), in which default wave equation hammer and soil input values were used. Therefore, their wave equation calibrations did not consider the potential improved pile resistance prediction reliability that could result from measurement of at least some of these key input values. It is for these reasons that the resistance factor specified in Article 10.5.5.2.3 is relatively low (see Paikowsky et al., 2004, for additional information regarding the development of the resistance factor for the wave equation). If additional local experience or site-specific test results are available to allow the wave equation soil or hammer input values to be refined and made more accurate, a higher resistance factor may be used.

The wave equation may be used in combination with dynamic test results with signal matching analysis and/or pile load test data to provide the most accurate wave equation pile resistance prediction. Such data are used to calibrate the wave equation, allowing the resistance factor for dynamic testing and signal matching specified in Article 10.5.5.2.3 to be used.

#### 10.7.3.8.5—Dynamic Formula

If a dynamic formula is used to establish the driving criterion, the FHWA Gates Formula (Eq. 10.7.3.8.5-1) should be used. The nominal pile resistance as measured during driving using this method shall be taken as:

$$R_{ndr} = 1.75\sqrt{E_d} \log_{10}(10N_b) - 100 \quad (10.7.3.8.5-1)$$

where:

$R_{ndr}$  = nominal pile resistance measured during pile driving (kips)

$E_d$  = developed hammer energy. This is the kinetic energy in the ram at impact for a given blow. If ram velocity is not measured, it may be assumed equal to the potential energy of the ram at the height of the stroke, taken as the ram weight times the stroke (ft-lb)

$N_b$  = Number of hammer blows for 1.0 in. of pile permanent set (blows/in.)

The Engineering News Formula, modified to predict a nominal bearing resistance, may be used. The nominal pile resistance using this method shall be taken as:

$$R_{ndr} = \frac{12E_d}{(s + 0.1)} \quad (10.7.3.8.5-2)$$

where:

$R_{ndr}$  = nominal pile resistance measured during driving (kips)

$E_d$  = developed hammer energy. This is the kinetic energy in the ram at impact for a given blow. If ram velocity is not measured, it may be assumed equal to the potential energy of the ram at the height of the stroke, taken as the ram weight times the stroke (ft-kips)

$s$  = pile permanent set, (in.)

If a dynamic formula other than those provided herein is used, it shall be calibrated based on measured load test results to obtain an appropriate resistance factor, consistent with Article C10.5.5.2.

#### C10.7.3.8.5

Two dynamic formulas are provided here for the Engineer. If a dynamic formula is used, the FHWA Modified Gates Formula is preferred over the Engineering News Formula. It is discussed further in the Design and Construction of Driven Pile Foundations (Hannigan et al., 2005). Note that the units in the FHWA Gates formula are not consistent. The specified units in Eq. 10.7.3.8.5-1 must be used.

The Engineering News Formula in its traditional form was intended to contain a factor of safety of 6.0. For LRFD applications, to produce a nominal resistance, the factor of safety has been removed. As is true of the FHWA Gates formula, the units specified in Eq. 10.7.3.8.5-2 must be used for the ENR formula. See Allen (2005) for additional discussion on the development of the ENR formula and its modification to produce a nominal resistance.

Evaluation of pile drivability, including the specific evaluation of driving stresses and the adequacy of the pile to resist those stresses without damage, is strongly recommended. When drivability is not checked it is necessary that the pile design stresses be limited to values that will assure that the pile can be driven without damage. For steel piles, guidance is provided in Article 6.15.2 for the case where risk of pile damage is relatively high. If pile drivability is not checked, it should be assumed that the risk of pile damage is relatively high. For concrete piles and timber piles, no specific guidance is available in Sections 5 and 8, respectively, regarding safe design stresses to reduce the risk of pile damage. In past practice (see AASHTO, 2002), the required nominal axial resistance has been limited to  $0.6 f'_c$  for concrete piles and 2,000 psi for timber piles if pile drivability is not evaluated.

See Article C10.5.5.2.1 for guidance on using load tests to develop resistance factors.

If a drivability analysis is not conducted, for steel piles, design stresses shall be limited as specified in Article 6.15.2.

Dynamic formulas should not be used when the required nominal resistance exceeds 600 kips.

As the required nominal axial compression resistance increases, the reliability of dynamic formulae tends to decrease. The FHWA Gates Formula tends to underpredict pile nominal resistance at higher resistances. The Engineering News Formula tends to become unconservative as the nominal pile resistance increases. If other driving formulae are used, the limitation on the maximum driving resistance to be used should be based upon the limits for which the data is considered reliable, and any tendency of the formula to over or under predict pile nominal resistance.

#### *10.7.3.8.6—Static Analysis*

##### *10.7.3.8.6a—General*

Where a static analysis prediction method is used to determine pile installation criteria, i.e., for bearing resistance, the nominal pile resistance shall be factored at the strength limit state using the resistance factors in Table 10.5.5.2.3-1 associated with the method used to compute the nominal bearing resistance of the pile. The factored bearing resistance of piles,  $R_R$ , may be taken as:

$$R_R = \varphi R_n \quad (10.7.3.8.6a-1)$$

or:

$$R_R = \varphi R_n = \varphi_{stat} R_p + \varphi_{stat} R_s \quad (10.7.3.8.6a-2)$$

in which:

$$R_p = q_p A_p \quad (10.7.3.8.6a-3)$$

$$R_s = q_s A_s \quad (10.7.3.8.6a-4)$$

where:

$\varphi_{stat}$  = resistance factor for the bearing resistance of a single pile specified in Article 10.5.5.2.3

$R_p$  = pile tip resistance (kips)

$R_s$  = pile side resistance (kips)

$q_p$  = unit tip resistance of pile (ksf)

$q_s$  = unit side resistance of pile (ksf)

##### *C10.7.3.8.6a*

While the most common use of static analysis methods is solely for estimating pile quantities, a static analysis may be used to establish pile installation criteria if dynamic methods are determined to be unsuitable for field verification of nominal axial resistance. This is applicable on projects where pile quantities are relatively small, pile loads are relatively low, and/or where the setup time is long so that re-strike testing would require an impractical wait-period by the Contractor on the site, e.g., soft silts or clays where a large amount of setup is anticipated.

For use of static analysis methods for contract pile quantity estimation, see Article 10.7.3.3.

$A_s$  = surface area of pile side ( $\text{ft}^2$ )

$A_p$  = area of pile tip ( $\text{ft}^2$ )

Both total stress and effective stress methods may be used, provided the appropriate soil strength parameters are available. The resistance factors for the skin friction and tip resistance, estimated using these methods, shall be as specified in Table 10.5.5.2.3-1. The limitations of each method as described in Article C10.5.5.2.3 should be applied in the use of these static analysis methods.

#### 10.7.3.8.6b— $\alpha$ -Method

The  $\alpha$ -method, based on total stress, may be used to relate the adhesion between the pile and clay to the undrained strength of the clay. For this method, the nominal unit skin friction, in ksf, shall be taken as:

$$q_s = \alpha S_u \quad (10.7.3.8.6b-1)$$

where:

$S_u$  = undrained shear strength (ksf)

$\alpha$  = adhesion factor applied to  $S_u$  (dim)

The adhesion factor for this method,  $\alpha$ , shall be assumed to vary with the value of the undrained strength,  $S_u$ , as shown in Figure 10.7.3.8.6b-1.

#### C10.7.3.8.6b

The  $\alpha$ -method has been used for many years and gives reasonable results for both displacement and nondisplacement piles in clay.

In general, this method assumes that a mean value of  $S_u$  will be used. It may not always be possible to establish a mean value, as in many cases, data are too limited to reliably establish the mean value. The Engineer should apply engineering judgment and local experience as needed to establish an appropriate value for design (see Article C10.4.6).

For H-piles, the perimeter or “box” area should generally be used to compute the surface area of the pile side.

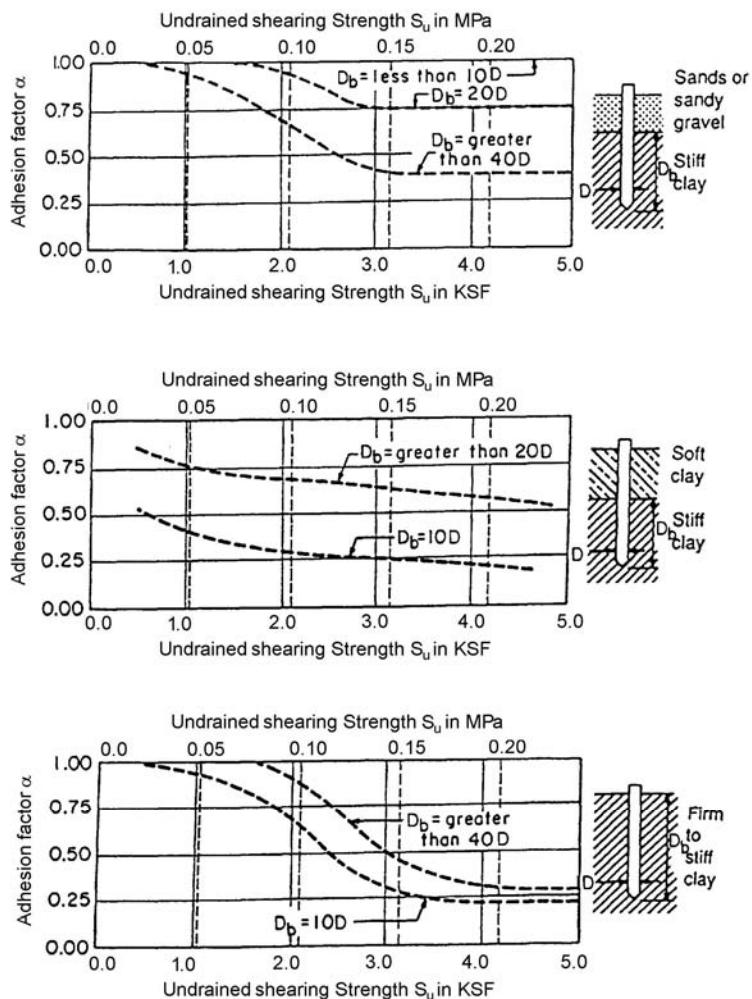

Figure 10.7.3.8.6b-1—Design Curves for Adhesion Factors for Piles Driven into Clay Soils after Tomlinson (1980)

#### 10.7.3.8.6c— $\beta$ -Method

The  $\beta$ -method, based on effective stress, may be used for predicting skin friction of prismatic piles. The nominal unit skin friction for this method, in ksf, shall be related to the effective stresses in the ground as:

$$q_s = \beta \sigma'_v \quad (10.7.3.8.6c-1)$$

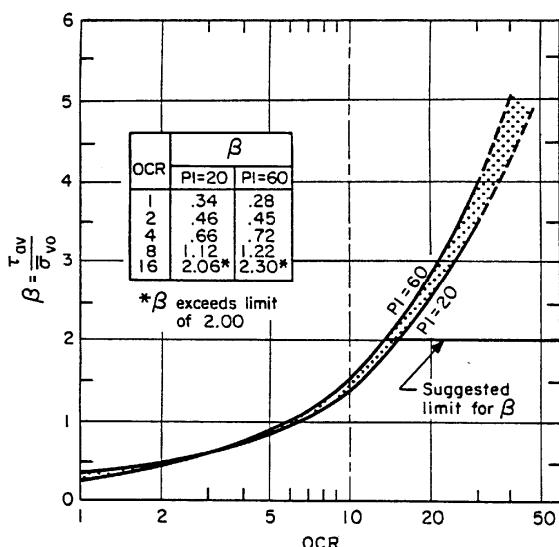

where:

$\sigma'_v$  = vertical effective stress (ksf)

$\beta$  = a factor taken from Figure 10.7.3.8.6c-1

#### C10.7.3.8.6c

The  $\beta$ -method has been found to work best for piles in normally consolidated and lightly overconsolidated clays. The method tends to overestimate skin friction of piles in heavily overconsolidated soils. Esrig and Kirby (1979) suggested that for heavily overconsolidated clays, the value of  $\beta$  should not exceed 2.

**Figure 10.7.3.8.6c-1— $\beta$  Versus OCR for Displacement Piles after Esrig and Kirby (1979)**

### 10.7.3.8.6d— $\lambda$ -Method

The  $\lambda$ -method, based on effective stress (though it does contain a total stress parameter), may be used to relate the unit skin friction, in ksf, to passive earth pressure. For this method, the unit skin friction shall be taken as:

$$q_s = \lambda(\sigma'_v + 2S_u) \quad (10.7.3.8.6d-1)$$

where:

$$\sigma'_v + 2S_u = \text{passive lateral earth pressure (ksf)}$$

$\sigma'_v$  = the effective vertical stress at midpoint of soil layer under consideration (ksf)

$\lambda$  = an empirical coefficient taken from Figure 10.7.3.8.6d-1 (dim).

### *C10.7.3.8.6d*

The value of  $\lambda$  decreases with pile length and was found empirically by examining the results of load tests on steel pipe piles.

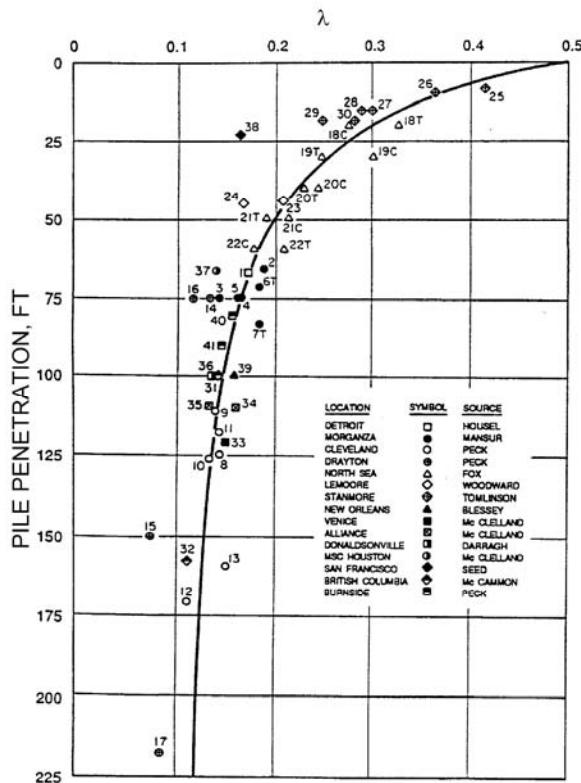

Figure 10.7.3.8.6d-1— $\lambda$  Coefficient for Driven Pipe Piles after Vijayvergiya and Focht (1972)

#### 10.7.3.8.6e—Tip Resistance in Cohesive Soils

The nominal unit tip resistance of piles in saturated clay, in ksf, shall be taken as:

$$q_p = 9S_u \quad (10.7.3.8.6e-1)$$

where:

$S_u$  = undrained shear strength of the clay near the pile base (ksf)

#### 10.7.3.8.6f—Nordlund/Thurman Method in Cohesionless Soils

This effective stress method should be applied only to sands and nonplastic silts. The nominal unit side resistance,  $q_s$ , for this method, in ksf, shall be taken as:

$$q_s = K_\delta C_F \sigma'_v \frac{\sin(\delta + \omega)}{\cos \omega} \quad (10.7.3.8.6f-1)$$

where:

$K_\delta$  = coefficient of lateral earth pressure at mid-point of soil layer under consideration from Figures 10.7.3.8.6f-1 through 10.7.3.8.6f-4 (dim)

#### C10.7.3.8.6f

Detailed design procedures for the Nordlund/Thurman method are provided in Hannigan et al., (2005). This method was derived based on load test data for piles in sand. In practice, it has been used for gravelly soils as well.

The effective overburden stress is not limited in Eq. 10.7.3.8.6f-1.

For H-piles, the perimeter or “box” area should generally be used to compute the surface area of the pile side.

$C_F$  = correction factor for  $K_\delta$  when  $\delta \neq \phi_f$ , from Figure 10.7.3.8.6f-5

$\sigma'_v$  = effective overburden stress at midpoint of soil layer under consideration (ksf)

$\delta$  = friction angle between pile and soil obtained from Figure 10.7.3.8.6f-6 (degrees)

$\omega$  = angle of pile taper from vertical (degrees)

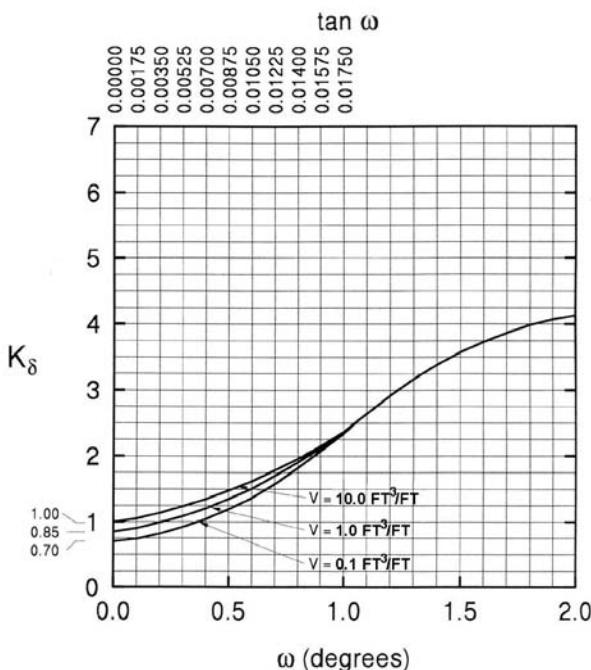

Figure 10.7.3.8.6f-1—Design Curve for Evaluating  $K_\delta$  for Piles where  $\phi_f = 25$  degrees (Hannigan et al., 2005 after Nordlund, 1979)

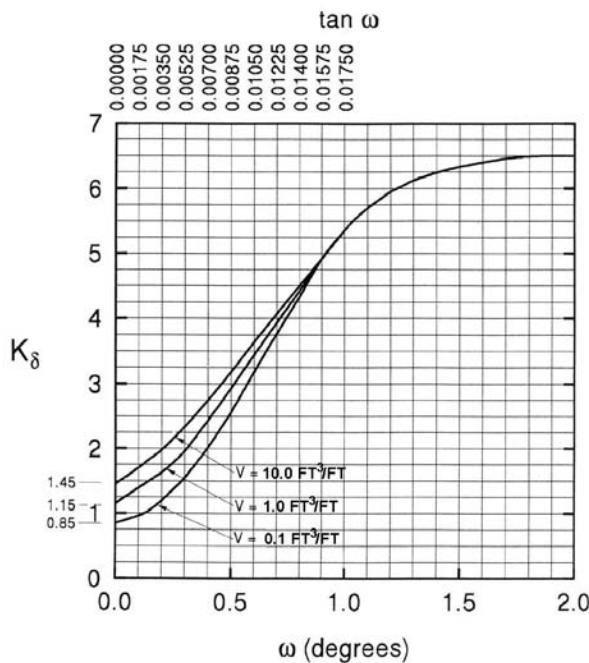

Figure 10.7.3.8.6f-2—Design Curve for Evaluating  $K_\delta$  for Piles where  $\phi_f = 30$  degrees (Hannigan et al., 2005 after Nordlund, 1979)

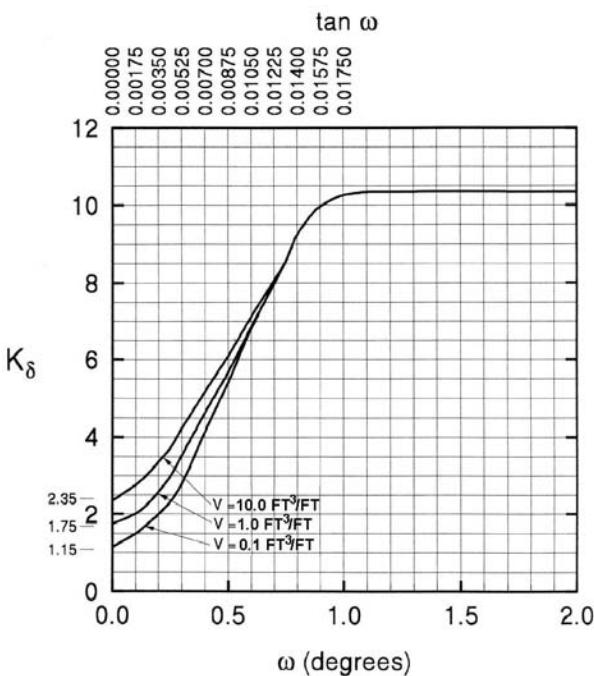

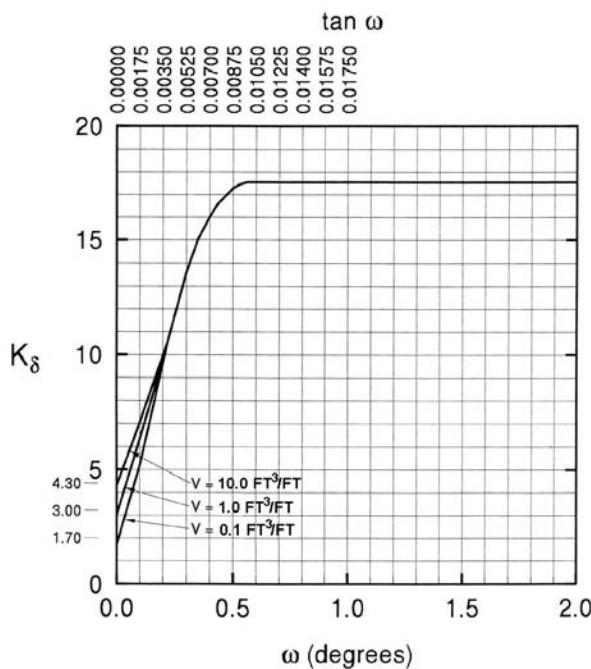

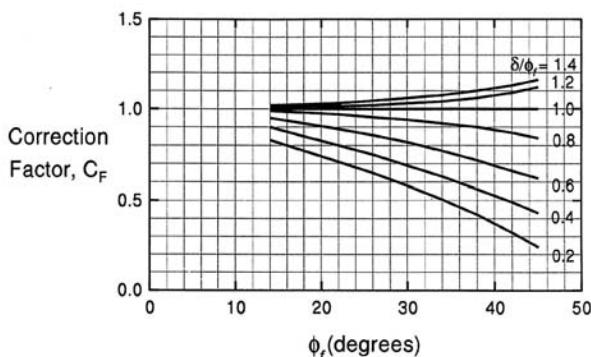

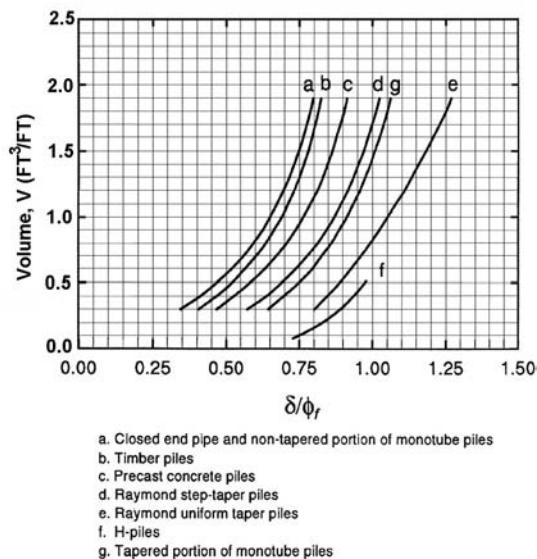

Figure 10.7.3.8.6f-3—Design Curve for Evaluating  $K_\delta$  for Piles where  $\phi_f = 35$  degrees (Hannigan et al., 2005 after Nordlund, 1979)

**Figure 10.7.3.8.6f-4—Design Curve for Evaluating  $K_\delta$  for Piles where  $\phi_f = 40$  degrees (Hannigan et al., 2005 after Nordlund, 1979)**

**Figure 10.7.3.8.6f-5—Correction Factor for  $K_\delta$  where  $\delta \neq \phi_f$  (Hannigan et al., 2005 after Nordlund, 1979)**

**Figure 10.7.3.8.6f-6—Relation of  $\delta/\phi_f$  and Pile Displacement,  $V$ , for Various Types of Piles (Hannigan et al., 2005 after Nordlund, 1979)**

The nominal unit tip resistance,  $q_p$ , in ksf by the Nordlund/Thurman method shall be taken as:

$$q_p = \alpha_t N'_q \sigma'_v \leq q_L \quad (10.7.3.8.6f-2)$$

where:

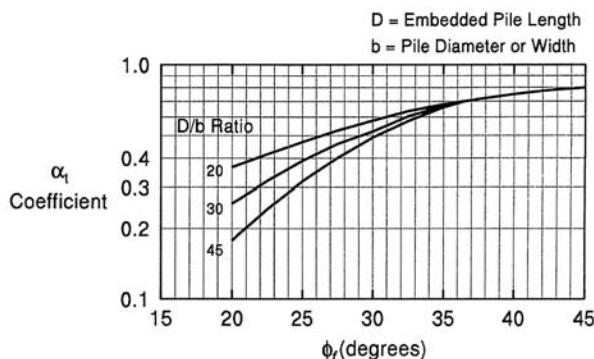

$\alpha_t$  = coefficient from Figure 10.7.3.8.6f-7 (dim)

$N'_q$  = bearing capacity factor from Figure 10.7.3.8.6f-8

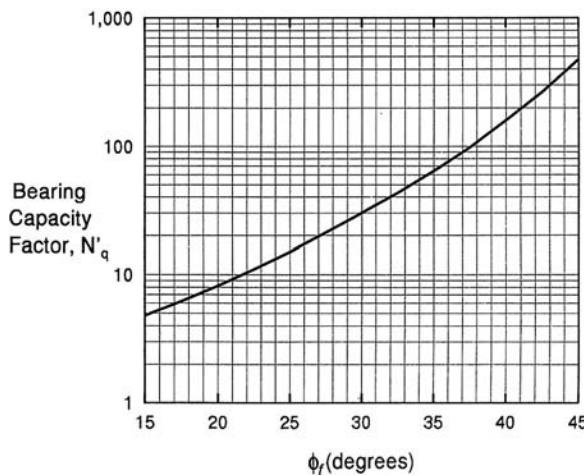

$\sigma'_v$  = effective overburden stress at pile tip (ksf)  
 $\leq 3.2$  ksf

$q_L$  = limiting unit tip resistance from Figure 10.7.3.8.6f-9

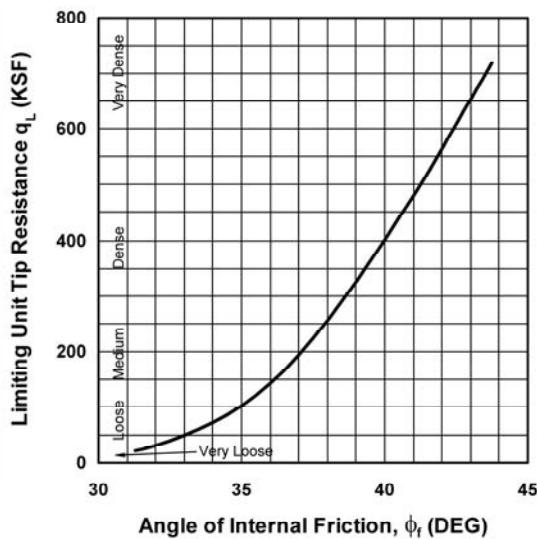

If the friction angle,  $\phi_f$ , is estimated from average, corrected SPT blow counts,  $N_{160}$ , the  $N_{160}$  values should be averaged over the zone from the pile tip to two diameters below the pile tip.

**Figure 10.7.3.8.6f-7— $\alpha_t$  Coefficient (Hannigan et al., 2005 modified after Bowles, 1977)**

**Figure 10.7.3.8.6f-8—Bearing Capacity Factor,  $N'_q$**   
(Hannigan et al., 2005 modified after Bowles, 1977)

**Figure 10.7.3.8.6f-9—Limiting Unit Pile Tip Resistance**  
(Hannigan et al., 2005 after Meyerhof, 1976)

*10.7.3.8.6g—Using SPT or CPT in Cohesionless Soils*

*C10.7.3.8.6g*

These methods shall be applied only to sands and nonplastic silts.

The nominal unit tip resistance for the Meyerhof method, in ksf, for piles driven to a depth  $D_b$  into a cohesionless soil stratum shall be taken as:

$$q_p = \frac{0.8(N_{160})D_b}{D} \leq q_\ell \quad (10.7.3.8.6g-1)$$

In-situ tests are widely used in cohesionless soils because obtaining good quality samples of cohesionless soils is very difficult. In-situ test parameters may be used to estimate the tip resistance and skin friction of piles.

Two frequently used in-situ test methods for predicting pile axial resistance are the standard penetration test (SPT) method (Meyerhof, 1976) and the cone penetration test (CPT) method (Nottingham and Schmertmann, 1975).

where:

- $N1_{60}$  = representative SPT blow count near the pile tip corrected for overburden pressure as specified in Article 10.4.6.2.4 (blows/ft)
- $D$  = pile width or diameter (ft)
- $D_b$  = depth of penetration in bearing strata (ft)
- $q_\ell$  = limiting tip resistance taken as eight times the value of  $N1_{60}$  for sands and six times the value of  $N1_{60}$  for nonplastic silt (ksf)

The nominal skin friction of piles in cohesionless soils for the Meyerhof method, in ksf, shall be taken as:

- For driven displacement piles:

$$q_s = \frac{\bar{N}1_{60}}{25} \quad (10.7.3.8.6g-2)$$

- For nondisplacement piles, e.g., steel H-piles:

$$q_s = \frac{\bar{N}1_{60}}{50} \quad (10.7.3.8.6g-3)$$

where:

- $q_s$  = unit skin friction for driven piles (ksf)

$$\bar{N}1_{60} = \text{average corrected SPT-blow count along the pile side (blows/ft)}$$

Tip resistance,  $q_p$ , for the Nottingham and Schmertmann method, in ksf, shall be determined as shown in Figure 10.7.3.8.6g-1.

In which:

$$q_p = \frac{q_{c1} + q_{c2}}{2} \quad (10.7.3.8.6g-4)$$

where:

- $q_{c1}$  = average  $q_c$  over a distance of  $yD$  below the pile tip (path a-b-c); sum  $q_c$  values in both the downward (path a-b) and upward (path b-c) directions; use actual  $q_c$  values along path a-b and the minimum path rule along path b-c; compute  $q_{c1}$  for  $y$ -values from 0.7 to 4.0 and use the minimum  $q_{c1}$  value obtained (ksf)

Displacement piles, which have solid sections or hollow sections with a closed end, displace a relatively large volume of soil during penetration. Nondisplacement piles usually have relatively small cross-sectional areas, e.g., steel H-piles and open-ended pipe piles that have not yet plugged. Plugging occurs when the soil between the flanges in a steel H-pile or the soil in the cylinder of an open-ended steel pipe pile adheres fully to the pile and moves down with the pile as it is driven.

CPT may be used to determine:

- The cone penetration resistance,  $q_c$ , which may be used to determine the tip resistance of piles, and
- Sleeve friction,  $f_s$ , which may be used to determine the skin friction resistance.

$q_{c2}$  = average  $q_c$  over a distance of  $8D$  above the pile tip (path c-e); use the minimum path rule as for path b-c in the  $q_{c1}$ , computations; ignore any minor "x" peak depressions if in sand but include in minimum path if in clay (ksf)

The minimum average cone resistance between 0.7 and four pile diameters below the elevation of the pile tip shall be obtained by a trial and error process, with the use of the minimum-path rule. The minimum-path rule shall also be used to find the value of cone resistance for the soil for a distance of eight pile diameters above the tip. The two results shall be averaged to determine the pile tip resistance.

The nominal skin friction resistance of piles for this method, in kips, shall be taken as:

$$R_s = K_{s,c} \left[ \sum_{i=1}^{N_1} \left( \frac{L_i}{8D_i} \right) f_{si} a_{si} h_i + \sum_{i=1}^{N_2} f_{si} a_{si} h_i \right] \quad (10.7.3.8.6g-5)$$

where:

$K_{s,c}$  = correction factors:  $K_c$  for clays and  $K_s$  for sands from Figure 10.7.3.8.6g-2 (dim)

$L_i$  = depth to middle of length interval at the point considered (ft)

$D_i$  = pile width or diameter at the point considered (ft)

$f_{si}$  = unit local sleeve friction resistance from CPT at the point considered (ksf)

$a_{si}$  = pile perimeter at the point considered (ft)

$h_i$  = length interval at the point considered (ft)

$N_1$  = number of intervals between the ground surface and a point  $8D$  below the ground surface

$N_2$  = number of intervals between  $8D$  below the ground surface and the tip of the pile

This process is described in Nottingham and Schmertmann (1975).

For a pile of constant cross-section (nontapered), Eq. 10.7.3.8.6g-5 can be written as:

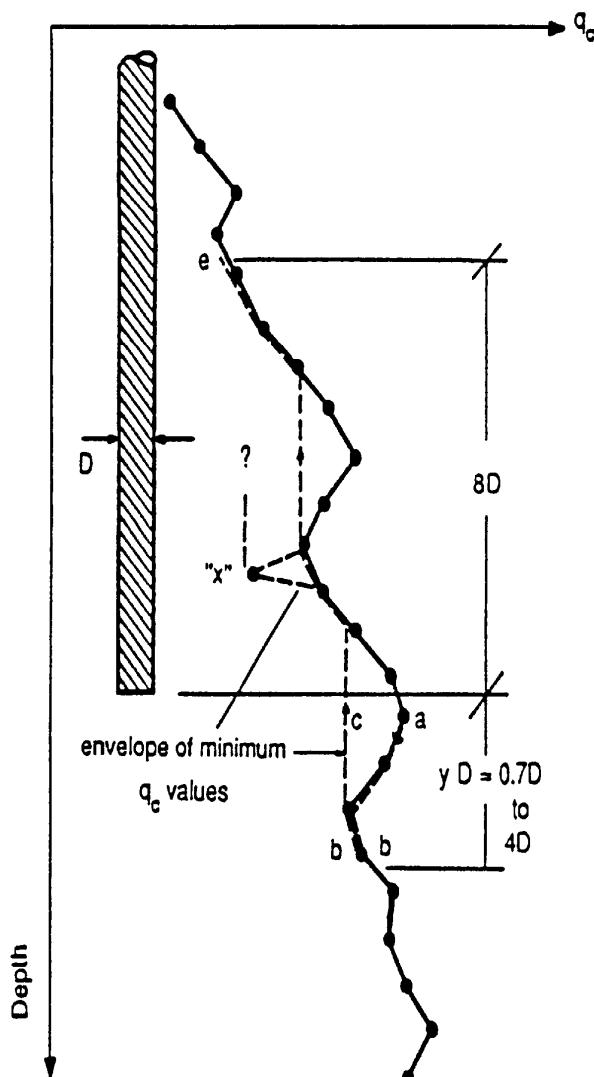

$$R_s = K_{s,c} \left[ \frac{a_s}{8D} \sum_{i=1}^{N_1} L_i f_{si} h_i + a_s \sum_{i=1}^{N_2} f_{si} h_i \right] \quad (C10.7.3.8.6g-1)$$

If, in addition to the pile being prismatic,  $f_s$  is approximately constant at depths below  $8D$ , Eq. C10.7.3.8.6g-1 can be simplified to:

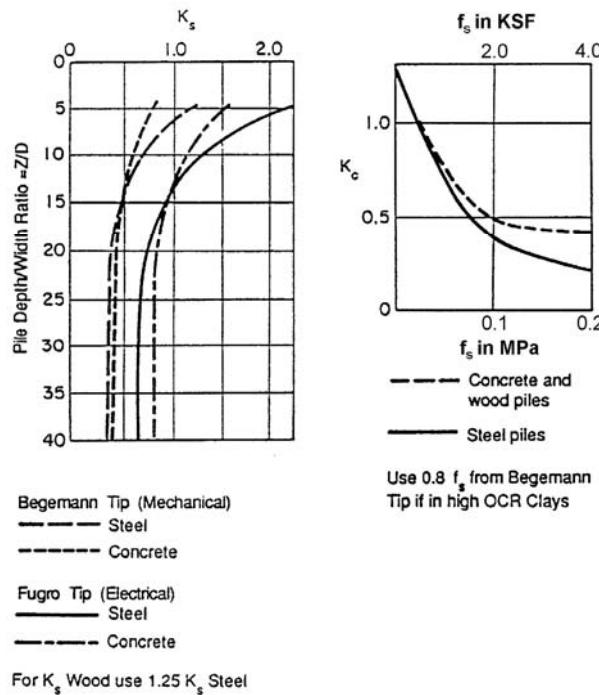

$$R_s = K_{s,c} [a_s f_s (Z - 4D)] \quad (C10.7.3.8.6g-2)$$

where:

$Z$  = total embedded pile length (ft)

**Figure 10.7.3.8.6g-1—Pile End-Bearing Computation Procedure after Nottingham and Schmertmann (1975)**

**Figure 10.7.3.8.6g-2 —Side Friction Correction Factors  $K_s$  and  $K_c$  after Nottingham and Schmertmann (1975)**

#### 10.7.3.9—Resistance of Pile Groups in Compression

For pile groups in clay, the nominal axial resistance of the pile group shall be taken as the lesser of:

- The sum of the individual nominal resistances of each pile in the group, or
- The nominal resistance of an equivalent pier consisting of the piles and the block of soil within the area bounded by the piles.

If the cap is not in firm contact with the ground and if the soil at the surface is soft, the individual resistance of each pile shall be multiplied by an efficiency factor  $\eta$ , taken as:

- $\eta = 0.65$  for a center-to-center spacing of 2.5 diameters,
- $\eta = 1.0$  for a center-to-center spacing of 6.0 diameters.

For intermediate spacings, the value of  $\eta$  may be determined by linear interpolation.

#### C10.7.3.9

The equivalent pier approach checks for block failure and is generally only applicable for pile groups within cohesive soils. For pile groups in sand, the sum of the nominal resistances of the individual piles always controls the group resistance.

When analyzing the equivalent pier, the full shear strength of the soil should be used to determine the friction resistance. The total base area of the equivalent pier should be used to determine the end bearing resistance.

In cohesive soils, the resistance of a pile group depends on whether the cap is in firm contact with the ground beneath. If the cap is in firm contact, the soil between the pile and the pile group behave as a unit.

At small pile spacings, a block type failure mechanism may prevail, whereas individual pile failure may occur at larger pile spacings. It is necessary to check for both failure mechanisms and design for the case that yields the minimum capacity.

For a pile group of width  $X$ , length  $Y$ , and depth  $Z$ , as shown in Figure C10.7.3.9-1, the bearing capacity for block failure, in kips, is given by:

If the cap is in firm contact with the ground, no reduction in efficiency shall be required. If the cap is not in firm contact with the ground and if the soil is stiff, no reduction in efficiency shall be required.

The bearing capacity of pile groups in cohesionless soil shall be the sum of the resistance of all the piles in the group. The efficiency factor,  $\eta$ , shall be 1.0 where the pile cap is or is not in contact with the ground for a center-to-center pile spacing of 2.5 diameters or greater. The resistance factor is the same as that for single piles, as specified in Table 10.5.5.2.3-1.

For pile groups in clay or sand, if a pile group is tipped in a strong soil deposit overlying a weak deposit, the block bearing resistance shall be evaluated with consideration to pile group punching as a group into the underlying weaker layer. The methods in Article 10.6.3.1.2a of determining bearing resistance of a spread footing in a strong layer overlying a weaker layer shall apply, with the notional footing located as shown in Article 10.7.2.3.

$$Q_g = (2X + 2Y)Z\bar{S}_u + XYN_c S_u \quad (\text{C10.7.3.9-1})$$

in which:

for  $\frac{Z}{X} \leq 2.5$ :

$$N_c = 5 \left( 1 + \frac{0.2X}{Y} \right) \left( 1 + \frac{0.2Z}{X} \right) \quad (\text{C10.7.3.9-2})$$

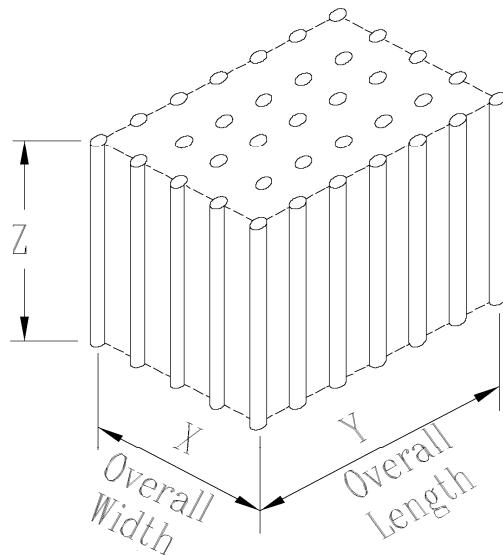

for  $\frac{Z}{X} > 2.5$ :

$$N_c = 7.5 \left( 1 + \frac{0.2X}{Y} \right) \quad (\text{C10.7.3.9-3})$$

where:

$\bar{S}_u$  = average undrained shear strength along the depth of penetration of the piles (ksf)

$S_u$  = undrained shear strength at the base of the group (ksf)

**Figure C10.7.3.9-1—Pile Group Acting as a Block Foundation**

### 10.7.3.10—Uplift Resistance of Single Piles

Uplift on single piles shall be evaluated when tensile forces are present. The factored nominal tensile resistance of the pile due to soil failure shall be greater than the factored pile loads.

The uplift resistance of a single pile should be estimated in a manner similar to that for estimating the skin friction resistance of piles in compression specified in Article 10.7.3.8.6.

Factored uplift resistance in kips shall be taken as:

$$R_R = \varphi R_n = \varphi_{up} R_s \quad (10.7.3.10-1)$$

where:

$R_s$  = nominal uplift resistance due to side resistance (kips)

$\varphi_{up}$  = resistance factor for uplift resistance specified in Table 10.5.5.2.3-1

Uplift resistance of single piles may be determined by static load test. If a static uplift test is to be performed, it shall follow the procedures specified in [ASTM D3689](#).

The pile load test(s) should be used to calibrate the static analysis method, i.e., back calculate soil properties, to adjust the calculated uplift resistance for variations in the stratigraphy. The minimum penetration criterion to obtain the desired uplift resistance should be based on the calculated uplift resistance using the pile load test results.

### 10.7.3.11—Uplift Resistance of Pile Groups

The nominal uplift resistance of pile groups shall be evaluated when the foundation is subjected to uplift loads.

Pile group factored uplift resistance, in kips, shall be taken as:

$$R_R = \varphi R_n = \varphi_{ug} R_{ug} \quad (10.7.3.11-1)$$

where:

$\varphi_{ug}$  = resistance factor specified in Table 10.5.5.2.3-1

$R_{ug}$  = nominal uplift resistance of the pile group (kips)

### C10.7.3.10

The factored load effect acting on any pile in a group may be estimated using the traditional elastic strength of materials procedure for a cross-section under thrust and moment. The cross-sectional properties should be based on the pile as a unit area.

Note that the resistance factor for uplift already is reduced to 80 percent of the resistance factor for static skin friction resistance. Therefore, the skin friction resistance estimated based on Article 10.7.3.8.6 does not need to be reduced to account for uplift effects on skin friction.

Static uplift tests should be evaluated using a modified Davisson Method as described in Hannigan et al. (2005).

### C10.7.3.11

A net uplift force can act on the foundation. An example of such a load is the construction load induced during the erection of concrete segmental girder bridges.

The uplift resistance,  $R_{ug}$ , of a pile group shall be taken as the lesser of:

- The sum of the individual pile uplift resistance, or
- The uplift resistance of the pile group considered as a block.

For pile groups in cohesionless soil, the weight of the block that will be uplifted shall be determined using a spread of load of  $1H$  in  $4V$  from the base of the pile group taken from Figure 10.7.3.11-1. Buoyant unit weights shall be used for soil below the groundwater level.

In cohesive soils, the block used to resist uplift in undrained shear shall be taken from Figure 10.7.3.11-2. The nominal group uplift resistance may be taken as:

$$R_n = R_{ug} = (2XZ + 2YZ)\bar{S}_u + W_g \quad (10.7.3.11-2)$$

where:

$X$  = width of the group, as shown in Figure 10.7.3.11-2 (ft)

$Y$  = length of the group, as shown in Figure 10.7.3.11-2 (ft)

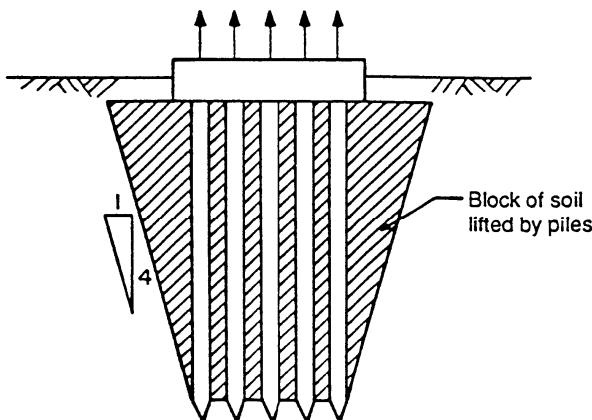

$Z$  = depth of the block of soil below pile cap taken from Figure 10.7.3.11-2 (ft)

$\bar{S}_u$  = average undrained shear strength along the sides of the pile group (ksf)

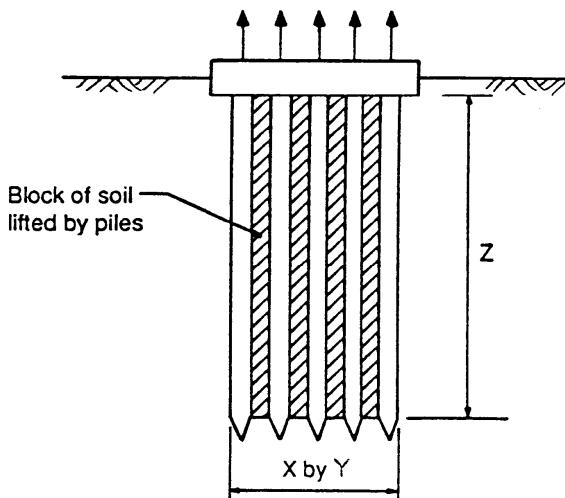

$W_g$  = weight of the block of soil, piles, and pile cap (kips)

The resistance factor for the nominal group uplift resistance,  $R_{ug}$ , determined as the sum of the individual pile resistance, shall be taken as the same as that for the uplift resistance of single piles as specified in Table 10.5.5.2.3-1.

The resistance factor for the uplift resistance of the pile group considered as a block shall be taken as specified in Table 10.5.5.2.3-1 for pile groups in clay and in sand.

**Figure 10.7.3.11-1—Uplift of Group of Closely Spaced Piles in Cohesionless Soils after Tomlinson (1987)**

**Figure 10.7.3.11-2—Uplift of Group of Piles in Cohesive Soils after Tomlinson (1987)**

#### 10.7.3.12—Nominal Horizontal Resistance of Pile Foundations

The nominal resistance of pile foundations to horizontal loads shall be evaluated based on both geomaterial and structural properties. The horizontal soil resistance along the piles should be modeled using  $P-y$  curves developed for the soils at the site.

The applied loads shall be factored loads and they must include both horizontal and axial loads. The analysis may be performed on a representative single pile with the appropriate pile top boundary condition or on the entire pile group. The  $P-y$  curves shall be modified for group effects. The  $P$ -multipliers in Table 10.7.2.4-1 should be used to modify the curves. If the pile cap will always be embedded, the  $P-y$  horizontal resistance of the soil on the cap face may be included in the horizontal resistance.

#### C10.7.3.12

Pile foundations are subjected to horizontal loads due to wind, traffic loads, bridge curvature, stream flow, vessel or traffic impact and earthquake. Batter piles are sometimes used but they are somewhat more expensive than vertical piles and vertical piles are more effective against dynamic loads.

Additional details regarding methods of analysis using  $P-y$  curves, both for single piles and pile groups, are provided in Article 10.7.2.4. As an alternative to  $P-y$  analysis, strain wedge theory may be used (see Article 10.7.2.4).

When this analysis is performed, the loads are factored since the strength limit state is under consideration, but the resistances as represented by the  $P-y$  curves are not factored since they already represent the ultimate condition.

The minimum penetration of the piles below ground (see Article 10.7.6) required in the contract should be established such that fixity is obtained. For this determination, the loads applied to the pile are factored as specified in Section 3, and a soil resistance factor of 1.0 shall be used as specified in Table 10.5.5.2.3-1.

If fixity cannot be obtained, additional piles should be added, larger diameter piles used if feasible to drive them to the required depth, or a wider spacing of piles in the group should be considered to provide the necessary lateral resistance. Batter piles may be added to provide the lateral resistance needed, unless downdrag is anticipated. If downdrag is anticipated, batter piles should not be used. The design procedure, if fixity cannot be obtained, should take into consideration the lack of fixity of the pile.

Lateral resistance of single piles may be determined by static load test. If a static lateral load test is to be performed, it shall follow the procedures specified in [ASTM D3966](#).

### 10.7.3.13—Pile Structural Resistance

#### 10.7.3.13.1—Steel Piles

The nominal compressive resistance in the structural limit state for piles loaded in compression shall be as specified in Article 6.9.4.1 for noncomposite piles and Article 6.9.5.1 for composite piles. If the pile is fully embedded,  $\lambda$  shall be taken as 0.

The nominal axial resistance of horizontally unsupported noncomposite piles that extend above the ground surface in air or water shall be determined from Eqs. 6.9.4.1.1-1 or 6.9.4.1.1-2. The nominal axial resistance of horizontally unsupported composite piles that extend above the ground surface in air or water shall be determined from Eqs. 6.9.5.1-1 or 6.9.5.1-2.

The effective length of laterally unsupported piles should be determined based on the provisions in Article 10.7.3.13.4.

The resistance factors for the compression limit state are specified in Article 6.5.4.2.

#### 10.7.3.13.2—Concrete Piles

The nominal axial compression resistance for concrete piles and prestressed concrete piles shall be as specified in Article 5.7.4.4.

The nominal axial compression resistance for concrete piles that are laterally unsupported in air or water shall be determined using the procedures given in Articles 5.7.4.3 and 4.5.3.2. The effective length of laterally unsupported piles should be determined based on the provisions in Article 10.7.3.13.4.

The resistance factor for the compression limit state for concrete piles shall be that given in Article 5.5.4.2.1 for concrete loaded in axial compression.

The strength limit state for lateral resistance is only structural (see Sections 5 and 6 for structural limit state design requirements), though the determination of pile fixity is the result of soil-structure interaction. A failure of the soil does not occur; the soil will continue to displace at constant or slightly increasing resistance. Failure occurs when the pile reaches the structural limit state, and this limit state is reached, in the general case, when the nominal combined bending and axial resistance is reached.

If the lateral resistance of the soil in front of the pile cap is included in the horizontal resistance of the foundation, the effect of soil disturbance resulting from construction of the pile cap should be considered. In such cases, the passive resistance may need to be reduced to account for the effects of disturbance.

For information on analysis and interpretation of load tests, see Article 10.7.2.4.

#### C10.7.3.13.1

Composite members refer to steel pipe piles that are filled with concrete.

The effective length given in Article 10.7.3.13.4 is an empirical approach to determining effective length. Computer methods are now available that can determine the axial resistance of a laterally unsupported compression member using a  $P-\Delta$  analysis that includes a numerical representation of the lateral soil resistance (Williams et al., 2003). These methods are preferred over the empirical approach in Article 10.7.3.13.4.

#### C10.7.3.13.2

Article 5.7.4 includes specified limits on longitudinal reinforcement, spirals and ties. Methods are given for determining nominal axial compression resistance but they do not include the nominal axial compression resistance of prestressed members. Article C5.7.4.1 notes that compression members are usually prestressed only where they are subjected to high levels of flexure. Therefore, a method of determining nominal axial compression resistance is not given.

Article 5.7.4.5 specifically permits an analysis based on equilibrium and strain compatibility. Methods are also available for performing a stability analysis (Williams et al., 2003).

**10.7.3.13.3—Timber Piles**

The nominal axial compression resistance for timber piles shall be as specified in Article 8.8.2. The methods presented there include both laterally supported and laterally unsupported members.

The effective length of laterally unsupported piles should be determined based on the provisions in Article 10.7.3.13.4.

**10.7.3.13.4—Buckling and Lateral Stability**

In evaluating stability, the effective length of the pile shall be equal to the laterally unsupported length, plus an embedded depth to fixity.

The potential for buckling of unsupported pile lengths and the determination of stability under lateral loading should be evaluated by methods that consider soil-structure interaction as specified in Article 10.7.3.12.

For preliminary design, the depth to fixity below the ground, in feet, may be taken as:

- For clays:

$$1.4 [E_p l_w / E_s]^{0.25} \quad (10.7.3.13.4-1)$$

- For sands:

$$1.8 [E_p l_w / n_h]^{0.2} \quad (10.7.3.13.4-2)$$

where:

$E_p$  = modulus of elasticity of pile (ksi)

$l_w$  = weak axis moment of inertia for pile ( $\text{ft}^4$ )

$E_s$  = soil modulus for clays =  $0.465 S_u$  (ksi)

$S_u$  = undrained shear strength of clays (ksf)

$n_h$  = rate of increase of soil modulus with depth for sands as specified in Table C10.4.6.3-2 (ksi/ft)

**10.7.4—Extreme Event Limit State**

The provisions of Article 10.5.5.3 shall apply.

For the applicable factored loads, including those specified in Article 10.7.1.6, for each extreme event limit state, the pile foundations shall be designed to have adequate factored axial and lateral resistance. For seismic design, all soil within and above the liquefiable zone, if the soil is liquefiable, shall not be considered to contribute axial compressive resistance. Downdrag resulting from liquefaction induced settlement shall be determined as specified in Article 3.11.8 and included in the loads applied to the foundation. Static downdrag loads should not be combined with seismic downdrag loads due to liquefaction.

**C10.7.3.13.3**

Article 8.5.2.3 requires that a reduction factor for long term loads of 0.75 be multiplied times the resistance factor for Strength Load Combination IV.

**C10.7.3.13.4**

This procedure is taken from Davisson and Robinson (1965) and should only be used for preliminary design.

In Eqs. 10.7.3.13.4-1 and 10.7.3.13.4-2, the loading condition has been assumed to be axial load only, and the piles are assumed to be fixed at their ends. Because the equations give depth to fixity from the ground line, the Engineer must determine the boundary conditions at the top of the pile to determine the total unbraced length of the pile. If other loading or pile tip conditions exist, see Davisson and Robinson (1965).

The effect of pile spacing on the soil modulus has been studied by Prakash and Sharma (1990), who found that, at pile spacings greater than 8 times the pile width, neighboring piles have no effect on the soil modulus or buckling resistance. However, at a pile spacing of three times the pile width, the effective soil modulus is reduced to 25 percent of the value applicable to a single pile. For intermediate spacings, modulus values may be estimated by interpolation.

**C10.7.4**

See Article C10.5.5.3.3.

The pile foundation shall also be designed to resist the horizontal force resulting from lateral spreading, if applicable, or the liquefiable soil shall be improved to prevent liquefaction and lateral spreading. For lateral soil resistance of the pile foundation, the  $P-y$  curve soil parameters should be reduced to account for liquefaction. To determine the amount of reduction, the duration of strong shaking and the ability of the soil to fully develop a liquefied condition during the period of strong shaking should be considered.

When designing for scour, the pile foundation design shall be conducted as described in Article 10.7.3.6, except that the check flood and resistance factors consistent with Article 10.5.5.3.2 shall be used.

#### 10.7.5—Corrosion and Deterioration

The effects of corrosion and deterioration from environmental conditions shall be considered in the selection of the pile type and in the determination of the required pile cross-section.

As a minimum, the following types of deterioration shall be considered:

- Corrosion of steel pile foundations, particularly in fill soils, low pH soils, and marine environments;
- Sulfate, chloride, and acid attack of concrete pile foundations; and
- Decay of timber piles from wetting and drying cycles or from insects or marine borers.

The following soil or site conditions should be considered as indicative of a potential pile deterioration or corrosion situation:

- Resistivity less than 2,000 ohm-cm,
- pH less than 5.5,
- pH between 5.5 and 8.5 in soils with high organic content,
- Sulfate concentrations greater than 1,000 ppm,
- Landfills and cinder fills,
- Soils subject to mine or industrial drainage,

#### C10.7.5

Resistivity, pH, chloride content, and sulfate concentration values have been adapted from those in Fang (1991) and Tomlinson (1987).

Some states use a coal tar epoxy paint system as a protective coating with good results.

The criterion for determining the potential for deterioration varies widely. An alternative set of recommendations is given by Elias (1990).

A field electrical resistivity survey or resistivity testing and pH testing of soil and groundwater samples may be used to evaluate the corrosion potential.

The deterioration potential of steel piles may be reduced by several methods, including protective coatings, concrete encasement, cathodic protection, use of special steel alloys, or increased steel area. Protective coatings should be resistant to abrasion and have a proven service record in the corrosive environment identified. Protective coatings should extend into noncorrosive soils a few feet because the lower portion of the coating is more susceptible to abrasion loss during installation.

Concrete encasement through the corrosive zone may also be used. The concrete mix should be of low permeability and placed properly. Steel piles protected by concrete encasement should be coated with a dielectric coating near the base of the concrete jacket.

The use of special steel alloys of nickel, copper, and potassium may also be used for increased corrosion resistance in the atmosphere or splash zone of marine piling.

Sacrificial steel area may also be used for corrosion resistance. This technique over sizes the steel section so that the available section after corrosion meets structural requirements.

- Areas with a mixture of high resistivity soils and low resistivity high alkaline soils, and
- Insects (wood piles).

The following water conditions should be considered as indicative of a potential pile deterioration or corrosion situation:

- Chloride content greater than 500 ppm,
- Sulfate concentration greater than 500 ppm,
- Mine or industrial runoff,
- High organic content,
- pH less than 5.5,
- Marine borers, and
- Piles exposed to wet/dry cycles.

When chemical wastes are suspected, a full chemical analysis of soil and groundwater samples shall be considered.

Deterioration of concrete piles can be reduced by design procedures. These include use of a dense impermeable concrete, sulfate resisting Portland cement, increased steel cover, air-entrainment, reduced chloride content in the concrete mix, cathodic protection, and epoxy-coated reinforcement. Piles that are continuously submerged are less subject to deterioration. ACI 318, Section 4.5.2, provides maximum water-cement ratio requirements for special exposure conditions. ACI 318, Section 4.5.3, lists the appropriate types of cement for various types of sulfate exposure.

For prestressed concrete, ACI 318 recommends a maximum water-soluble chloride ion of 0.06 percent by weight of cement.

Cathodic protection of reinforcing and prestressing steel may be used to protect concrete from corrosion effects. This process induces electric flow from the anode to the cathode of the pile and reduces corrosion. An external DC power source may be required to drive the current. However, cathodic protection requires electrical continuity between all steel and that necessitates bonding the steel for electric connection. This bonding is expensive and usually precludes the use of cathodic protection of concrete piles.

Epoxy coating of pile reinforcement has been found in some cases to be useful in resisting corrosion. It is important to ensure that the coating is continuous and free of holidays.

More detail on design for corrosion is contained in Hannigan et al. (2005).

#### **10.7.6—Determination of Minimum Pile Penetration**

The minimum pile penetration, if required for the particular site conditions and loading, shall be based on the maximum depth needed to meet the following requirements as applicable:

- Single and pile group settlement (service limit state)
- Lateral deflection (service limit state)
- Uplift (strength limit state)
- Depth into bearing soils needed to resist downdrag loads resulting from static consolidation stresses on soft soil or downdrag loads due to liquefaction (strength and extreme event limit state, respectively)
- Depth into bearing soils needed to provide adequate pile axial (compression and uplift) and lateral resistance after scour (strength and extreme event limit states)
- Nominal soil shear resistance and fixity for resisting the applied lateral loads to the foundation (strength limit state)

#### **C10.7.6**

A minimum pile penetration should only be specified if necessary to ensure that all of the applicable limit states are met. A minimum pile penetration should not be specified solely to meet axial compression resistance, i.e., bearing, unless field verification of the pile nominal bearing resistance is not performed as described in Article 10.7.3.8.

- Axial uplift, and lateral resistance to resist extreme event limit state loads

The contract documents should indicate the minimum pile penetration, if applicable, as determined above. The contract documents should also include the required nominal axial compressive resistance,  $R_{ndr}$  as specified in Article 10.7.7 and the method by which this resistance will be verified, if applicable, such that the resistance factor(s) used for design are consistent with the construction field verification methods of nominal axial compressive pile resistance.

#### **10.7.7—Determination of $R_{ndr}$ Used to Establish Contract Driving Criteria for Bearing**

The value of  $R_{ndr}$  used for the construction of the pile foundation to establish the driving criteria to obtain the design bearing resistance shall be the value that meets or exceeds the following limit states, as applicable:

- Strength limit state compression resistance specified in Article 10.7.3.8
- Strength limit state compression resistance, including downdrag specified in Article 10.7.3.7
- Strength limit state compression resistance, accounting for scour specified in Article 10.7.3.6
- Extreme event limit state compression resistance for seismic specified in Article 10.7.4
- Extreme event limit state compression resistance for scour specified in Article 10.7.4

#### **10.7.8—Drivability Analysis**

The establishment of the installation criteria for driven piles should include a drivability analysis. Except as specified herein, the drivability analysis shall be performed by the Engineer using a wave equation analysis, and the driving stresses ( $\sigma_{dr}$ ) anywhere in the pile determined from the analysis shall be less than the following limits:

Steel Piles, compression and tension:

$$\sigma_{dr} = 0.9\varphi_{da}f_y \quad (10.7.8-1)$$

where:

$f_y$  = yield strength of the steel (ksi)

#### **C10.7.8**

Wave equation analyses should be conducted during design using a range of likely hammer/pile combinations, considering the soil and installation conditions at the foundation site. See Article 10.7.3.8.4 for additional considerations for conducting wave equation analyses. These analyses should be used to assess feasibility of the proposed foundation system and to establish installation criteria with regard to driving stresses to limit driving stresses to acceptable levels. For routine pile installation applications, e.g., smaller diameter, low nominal resistance piles, the development of installation criteria with regard to the limitation of driving stresses, e.g., minimum or maximum ram weight, hammer size, maximum acceptable driving resistance, etc., may be based on local experience,

$\varphi_{da}$  = resistance factor as specified in Table 10.5.5.2.3-1

Concrete piles:

- n compression:

$$\sigma_{dr} = \varphi_{da} 0.85 f'_c \quad (10.7.8-2)$$

- n tension, considering only the steel reinforcement:

$$\sigma_{dr} = 0.7 \varphi_{da} f_y \quad (10.7.8-3)$$

where:

$f'_c$  = unconfined compressive strength of the concrete (ksi)

$f_y$  = yield strength of the steel reinforcement (ksi)

Prestressed concrete piles, normal environments:

- n compression:

$$\sigma_{dr} = \varphi_{da} (0.85 f'_c - f_{pe}) \quad (10.7.8-4)$$

- n tension:

$$\sigma_{dr} = \varphi_{da} (0.095 \sqrt{f'_c} + f_{pe}) \quad (10.7.8-5)$$

where:

$f_{pe}$  = effective prestressing stress in concrete (ksi)

Prestressed concrete piles, severe corrosive environments:

- n tension:

$$\sigma_{dr} = \varphi_{da} f_{pe} \quad (10.7.8-6)$$

Timber piles, in compression and tension:

$$\sigma_{dr} = \varphi_{da} (3F_{co}) \quad (10.7.8-7)$$

where:

$F_{co}$  = base resistance of wood in compression parallel to the grain as specified in Article 8.4.1.3 (ksi)

rather than conducting a detailed wave equation analysis that is project specific. Local experience could include previous drivability analysis results and actual pile driving experience that are applicable to the project specific situation at hand. Otherwise, a project specific drivability study should be conducted.

Drivability analyses may also be conducted as part of the project construction phase. When conducted during the construction phase, the drivability analysis shall be conducted using the contractor's proposed driving system. This information should be supplied by the contractor. This drivability analysis should be used to determine if the contractor's proposed driving system is capable of driving the pile to the maximum resistance anticipated without exceeding the factored structural resistance available, i.e.,  $\sigma_{dr}$ .

In addition to this drivability analysis, the best approach to controlling driving stresses during pile installation is to conduct dynamic testing with signal matching to verify the accuracy of the wave equation analysis results. Note that if a drivability analysis is conducted using the wave equation for acceptance of the contractor's proposed driving system, but a different method is used to develop driving resistance, i.e., blow count, criterion to obtain the specified nominal pile resistance, e.g., a driving formula, the difference in the methods regarding the predicted driving resistance should be taken into account when evaluating the contractor's driving system. For example, the wave equation analysis could indicate that the contractor's hammer can achieve the desired bearing resistance, but the driving formula could indicate the driving resistance at the required nominal bearing is too high. Such differences should be considered when setting up the driving system acceptance requirements in the contract documents.

The selection of a blow count limit is difficult because it can depend on the site soil profile, the pile type, and possibly hammer manufacturer limitations to prevent hammer damage. In general, blow counts greater than 10–15 blows per in. should be used with care, particularly with concrete or timber piles. In cases where the driving is easy until near the end of driving, a higher blow count may sometimes be satisfactory, but if a high blow count is required over a large percentage of the depth, even ten blows per in. may be too large.

This drivability analysis shall be based on the maximum driving resistance needed:

- To obtain minimum penetration requirements specified in Article 10.7.6,
- To overcome resistance of soil that cannot be counted upon to provide axial or lateral resistance throughout the design life of the structure, e.g., material subject to scour, or material subject to downdrag, and
- To obtain the required nominal bearing resistance.

### **10.7.9—Test Piles**

Test piles should be driven at several locations on the site to establish order length. If dynamic measurements are not taken, these test piles should be driven after the driving criteria have been established.

If dynamic measurements during driving are taken, both order lengths and driving criteria should be established after the test pile(s) are driven. Dynamic measurements obtained during test pile driving, signal matching analyses, and wave equation analyses should be used to determine the driving criteria (bearing requirements) as specified in Articles 10.7.3.8.2, 10.7.3.8.3, and 10.7.3.8.4.

## **10.8—DRILLED SHAFTS**

### **10.8.1—General**

#### **10.8.1.1—Scope**

The provisions of this Section shall apply to the design of drilled shafts. Throughout these provisions, the use of the term “drilled shaft” shall be interpreted to mean a shaft constructed using either drilling (open hole or with drilling slurry) or casing plus excavation equipment and technology.

These provisions shall also apply to shafts that are constructed using casing advancers that twist or rotate casings into the ground concurrent with excavation rather than drilling.

The provisions of this Section shall not be taken as applicable to drilled piles, e.g., augercast piles, installed with continuous flight augers that are concreted as the auger is being extracted.

### **C10.7.9**

Test piles are sometimes known as Indicator Piles. It is common practice to drive test piles at the beginning of the project to establish pile order lengths and/or to evaluate site variability whether or not dynamic measurements are taken.

#### **C10.8.1.1**

Drilled shafts may be an economical alternative to spread footing or pile foundations, particularly when spread footings cannot be founded on suitable soil or rock strata within a reasonable depth or when driven piles are not viable. Drilled shafts may be an economical alternative to spread footings where scour depth is large. Drilled shafts may also be considered to resist high lateral or axial loads, or when deformation tolerances are small. For example, a movable bridge is a bridge where it is desirable to keep deformations small.

Drilled shafts are classified according to their primary mechanism for deriving load resistance either as floating (friction) shafts, i.e., shafts transferring load primarily by side resistance, or end-bearing shafts, i.e., shafts transferring load primarily by tip resistance.

It is recommended that the shaft design be reviewed for constructability prior to advertising the project for bids.

### 10.8.1.2—Shaft Spacing, Clearance, and Embedment into Cap

If the center-to-center spacing of drilled shafts is less than 4.0 diameters, the interaction effects between adjacent shafts shall be evaluated. If the center-to-center spacing of drilled shafts is less than 6.0 diameters, the sequence of construction should be specified in the contract documents.

Shafts used in groups should be located such that the distance from the side of any shaft to the nearest edge of the cap is not less than 12.0 in. Shafts shall be embedded sufficiently into the cap to develop the required structural resistance.

### 10.8.1.3—Shaft Diameter and Enlarged Bases

If the shaft is to be manually inspected, the shaft diameter should not be less than 30.0 in. The diameter of columns supported by shafts should be smaller than or equal to the diameter of the drilled shaft.

In stiff cohesive soils, an enlarged base (bell, or underream) may be used at the shaft tip to increase the tip bearing area to reduce the unit end bearing pressure or to provide additional resistance to uplift loads.

Where the bottom of the drilled hole is dry, cleaned and inspected prior to concrete placement, the entire base area may be taken as effective in transferring load.

### 10.8.1.4—Battered Shafts

Battered shafts should be avoided. Where increased lateral resistance is needed, consideration should be given to increasing the shaft diameter or increasing the number of shafts.

### C10.8.1.2

Larger spacing may be required to preserve shaft excavation stability or to prevent communication between shafts during excavation and concrete placement.

Shaft spacing may be decreased if casing construction methods are required to maintain excavation stability and to prevent interaction between adjacent shafts.

### C10.8.1.3

Nominal shaft diameters used for both geotechnical and structural design of shafts should be selected based on available diameter sizes.

If the shaft and the column are the same diameter, it should be recognized that the placement tolerance of drilled shafts is such that it will likely affect the column location. The shaft and column diameter should be determined based on the shaft placement tolerance, column and shaft reinforcing clearances, and the constructability of placing the column reinforcing in the shaft. A horizontal construction joint in the shaft at the bottom of the column reinforcing will facilitate constructability. Making allowance for the tolerance where the column connects with the superstructure, which could affect column alignment, can also accommodate this shaft construction tolerance.

In drilling rock sockets, it is common to use casing through the soil zone to temporarily support the soil to prevent cave-in, allow inspection and to produce a seal along the soil-rock contact to minimize infiltration of groundwater into the socket. Depending on the method of excavation, the diameter of the rock socket may need to be sized at least 6 in. smaller than the nominal casing size to permit seating of casing and insertion of rock drilling equipment.

Where practical, consideration should be given to extension of the shaft to a greater depth to avoid the difficulty and expense of excavation for enlarged bases.

### C10.8.1.4

Due to problems associated with hole stability during excavation, installation, and with removal of casing during installation of the rebar cage and concrete placement, construction of battered shafts is very difficult.

### 10.8.1.5—Drilled Shaft Resistance

Drilled shafts shall be designed to have adequate axial and structural resistances, tolerable settlements, and tolerable lateral displacements.

The axial resistance of drilled shafts shall be determined through a suitable combination of subsurface investigations, laboratory and/or in-situ tests, analytical methods, and load tests, with reference to the history of past performance. Consideration shall also be given to:

- The difference between the resistance of a single shaft and that of a group of shafts;
- The resistance of the underlying strata to support the load of the shaft group;
- The effects of constructing the shaft(s) on adjacent structures;
- The possibility of scour and its effect;
- The transmission of forces, such as downdrag forces, from consolidating soil;
- Minimum shaft penetration necessary to satisfy the requirements caused by uplift, scour, downdrag, settlement, liquefaction, lateral loads and seismic conditions;
- Satisfactory behavior under service loads;
- Drilled shaft nominal structural resistance; and
- Long-term durability of the shaft in service, i.e., corrosion and deterioration.

Resistance factors for shaft axial resistance for the strength limit state shall be as specified in Table 10.5.5.2.4-1.

The method of construction may affect the shaft axial and lateral resistance. The shaft design parameters shall take into account the likely construction methodologies used to install the shaft.

### C10.8.1.5

The drilled shaft design process is discussed in detail in *Drilled Shafts: Construction Procedures and Design Methods* (O'Neill and Reese, 1999).

The performance of drilled shaft foundations can be greatly affected by the method of construction, particularly side resistance. The designer should consider the effects of ground and groundwater conditions on shaft construction operations and delineate, where necessary, the general method of construction to be followed to ensure the expected performance. Because shafts derive their resistance from side and tip resistance, which is a function of the condition of the materials in direct contact with the shaft, it is important that the construction procedures be consistent with the material conditions assumed in the design. Softening, loosening, or other changes in soil and rock conditions caused by the construction method could result in a reduction in shaft resistance and an increase in shaft displacement. Therefore, evaluation of the effects of the shaft construction procedure on resistance should be considered an inherent aspect of the design. Use of slurries, varying shaft diameters, and post grouting can also affect shaft resistance.

Soil parameters should be varied systematically to model the range of anticipated conditions. Both vertical and lateral resistance should be evaluated in this manner.

Procedures that may affect axial or lateral shaft resistance include, but are not limited to, the following:

- Artificial socket roughening, if included in the design nominal axial resistance assumptions.
- Removal of temporary casing where the design is dependent on concrete-to-soil adhesion.
- The use of permanent casing.
- Use of tooling that produces a uniform cross-section where the design of the shaft to resist lateral loads cannot tolerate the change in stiffness if telescoped casing is used.

It should be recognized that the design procedures provided in these Specifications assume compliance to construction specifications that will produce a high quality shaft. Performance criteria should be included in the construction specifications that require:

- Shaft bottom cleanout criteria,
- Appropriate means to prevent side wall movement or failure (caving) such as temporary casing, slurry, or a combination of the two,
- Slurry maintenance requirements including minimum slurry head requirements, slurry testing requirements, and maximum time the shaft may be left open before concrete placement.

If for some reason one or more of these performance criteria are not met, the design should be reevaluated and the shaft repaired or replaced as necessary.

### **10.8.1.6—Determination of Shaft Loads**

#### *10.8.1.6.1—General*

The factored loads to be used in shaft foundation design shall be as specified in Section 3. Computational assumptions that shall be used in determining individual shaft loads are also specified in Section 3.

#### *C10.8.1.6.1*

The specification and determination of top of cap loads is discussed extensively in Section 3. It should be noted that Article 3.6.2.1 states that dynamic load allowance need not be applied to foundation elements that are below the ground surface. Therefore, if shafts extend above the ground surface to act as columns the dynamic load allowance should be included in evaluating the structural resistance of that part of the shaft above the ground surface. The dynamic load allowance may be ignored in evaluating the geotechnical resistance.

#### *10.8.1.6.2—Downdrag*

The provisions of Articles 10.7.1.6.2 and 3.11.8 shall apply.

#### *C10.8.1.6.2*

See commentary to Articles 10.7.1.6.2 and 3.11.8.

Downdrag loads may be estimated using the  $\alpha$ -method, as specified in Article 10.8.3.5.1b, for calculating negative shaft resistance. As with positive shaft resistance, the top 5.0 ft and a bottom length taken as one shaft diameter should be assumed to not contribute to downdrag loads.

When using the  $\alpha$ -method, an allowance should be made for a possible increase in the undrained shear strength as consolidation occurs. Downdrag loads may also come from cohesionless soils above settling cohesive soils, requiring granular soil friction methods be used in such zones to estimate downdrag loads.

#### *10.8.1.6.3—Uplift*

The provisions in Article 10.7.1.6.3 shall apply.

#### *C10.8.1.6.3*

See commentary to Article C10.7.1.6.3.

### **10.8.2—Service Limit State Design**

#### **10.8.2.1—Tolerable Movements**

The requirements of Article 10.5.2.1 shall apply.

#### **C10.8.2.1**

See commentary to Article 10.5.2.1.

#### **10.8.2.2—Settlement**

##### *10.8.2.2.1—General*

The settlement of a drilled shaft foundation involving either single-drilled shafts or groups of drilled shafts shall not exceed the movement criteria selected in accordance with Article 10.5.2.1.

ILLUSTRATION BY JEFFREY L. BROWN

*10.8.2.2.2—Settlement of Single-Drilled Shaft*

The settlement of single-drilled shafts shall be estimated in consideration of:

- Short-term settlement,
- Consolidation settlement if constructed in cohesive soils, and
- Axial compression of the shaft.

The normalized load-settlement curves shown in Figures 10.8.2.2.2-1 through 10.8.2.2.2-4 should be used to limit the nominal shaft axial resistance computed as specified for the strength limit state in Article 10.8.3 for service limit state tolerable movements. Consistent values of normalized settlement shall be used for limiting the base and side resistance when using these Figures. Long-term settlement should be computed according to Article 10.7.2 using the equivalent footing method and added to the short-term settlements estimated using Figures 10.8.2.2.2-1 through 10.8.2.2.2-4.

Other methods for evaluating shaft settlements that may be used are found in O'Neill and Reese (1999).

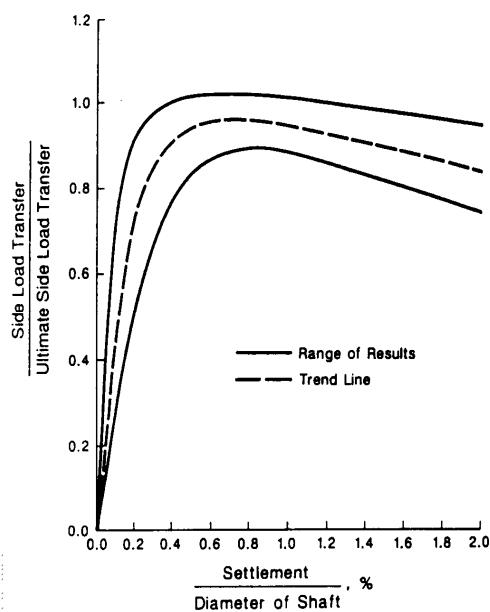

*C10.8.2.2.2*

O'Neill and Reese (1999) have summarized load-settlement data for drilled shafts in dimensionless form, as shown in Figures 10.8.2.2.2-1 through 10.8.2.2.2-4. These curves do not include consideration of long-term consolidation settlement for shafts in cohesive soils. Figures 10.8.2.2.2-1 and 10.8.2.2.2-2 show the load-settlement curves in side resistance and in end bearing for shafts in cohesive soils. Figures 10.8.2.2.2-3 and 10.8.2.2.2-4 are similar curves for shafts in cohesionless soils. These curves should be used for estimating short-term settlements of drilled shafts.

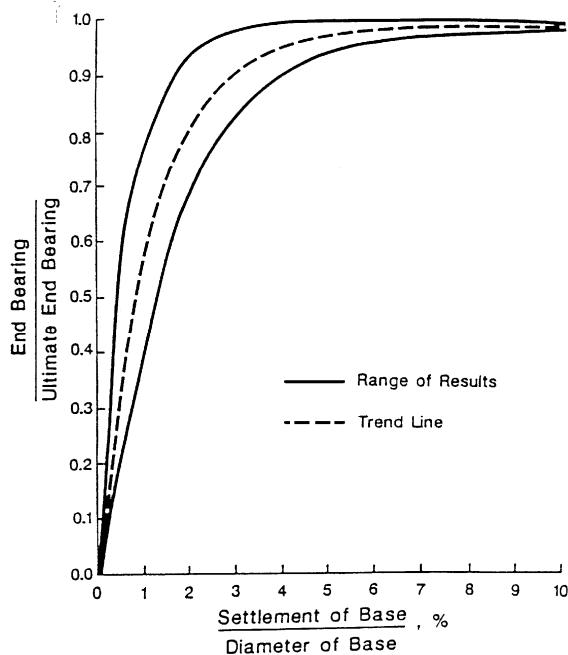

The designer should exercise judgment relative to whether the trend line, one of the limits, or some relation in between should be used from Figures 10.8.2.2.2-1 through 10.8.2.2.2-4.

The values of the load-settlement curves in side resistance were obtained at different depths, taking into account elastic shortening of the shaft. Although elastic shortening may be small in relatively short shafts, it may be substantial in longer shafts. The amount of elastic shortening in drilled shafts varies with depth. O'Neill and Reese (1999) have described an approximate procedure for estimating the elastic shortening of long-drilled shafts.

Settlements induced by loads in end bearing are different for shafts in cohesionless soils and in cohesive soils. Although drilled shafts in cohesive soils typically have a well-defined break in a load-displacement curve, shafts in cohesionless soils often have no well-defined failure at any displacement. The resistance of drilled shafts in cohesionless soils continues to increase as the settlement increases beyond five percent of the base diameter. The shaft end bearing  $R_p$  is typically fully mobilized at displacements of two to five percent of the base diameter for shafts in cohesive soils. The unit end bearing resistance for the strength limit state (see Article 10.8.3.3) is defined as the bearing pressure required to cause vertical deformation equal to five percent of the shaft diameter, even though this does not correspond to complete failure of the soil beneath the base of the shaft.

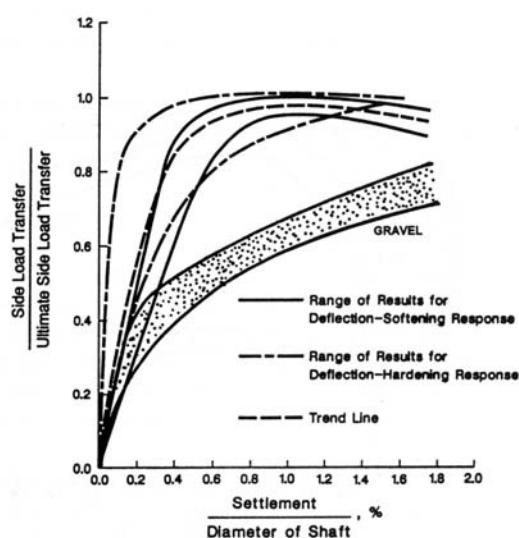

**Figure 10.8.2.2.2-1** Normalized Load Transfer in Side Resistance versus Settlement in Cohesive Soils (from O'Neill and Reese, 1999)

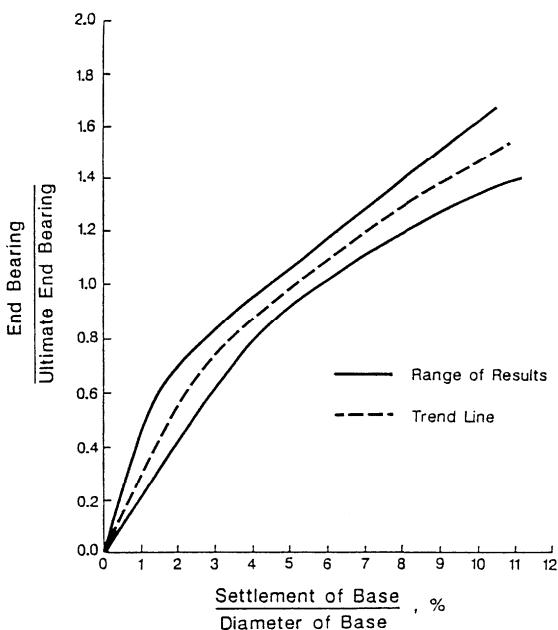

**Figure 10.8.2.2.2-2**—Normalized Load Transfer in End Bearing versus Settlement in Cohesive Soils (from O'Neill and Reese, 1999)

The curves in Figures 10.8.2.2.2-1 and 10.8.2.2.2-3 also show the settlements at which the side resistance is mobilized. The shaft skin friction  $R_s$  is typically fully mobilized at displacements of 0.2 percent to 0.8 percent of the shaft diameter for shafts in cohesive soils. For shafts in cohesionless soils, this value is 0.1 percent to 1.0 percent.

**Figure 10.8.2.2.3—Normalized Load Transfer in Side Resistance versus Settlement in Cohesionless Soils (from O'Neill and Reese, 1999)**

**Figure 10.8.2.2.4—Normalized Load Transfer in End Bearing versus Settlement in Cohesionless Soils (from O'Neill and Reese, 1999)**

#### 10.8.2.3—Intermediate Geo Materials (IGMs)

For detailed settlement estimation of shafts in IGMs, the procedures provided by O'Neill and Reese (1999) should be used.

The deflection-softening response typically applies to cemented or partially cemented soils, or other soils that exhibit brittle behavior, having low residual shear strengths at larger deformations. Note that the trend line for sands is a reasonable approximation for either the deflection-softening or deflection-hardening response.

#### C10.8.2.3

IGMs are defined by O'Neill and Reese (1999) as follows:

- *Cohesive IGM*—clay shales or mudstones with an  $S_u$  of 5 to 50 ksf, and
- *Cohesionless*—granular tills or granular residual soils with  $N_{160}$  greater than 50 blows/ft.

**10.8.2.2.4—Group Settlement**

The provisions of Article 10.7.2.3 shall apply. Shaft group effect shall be considered for groups of 2 shafts or more.

**C10.8.2.2.4**

See commentary to Article 10.7.2.3.

O'Neill and Reese (1999) summarize various studies on the effects of shaft group behavior. These studies were for groups that consisted of  $1 \times 2$  to  $3 \times 3$  shafts. These studies suggest that group effects are relatively unimportant for shaft center-to-center spacing of  $5D$  or greater.

**10.8.2.3—Horizontal Movement of Shafts and Shaft Groups**

The provisions of Articles 10.5.2.1 and 10.7.2.4 shall apply.

**C10.8.2.3**

See commentary to Articles 10.5.2.1 and 10.7.2.4.

**10.8.2.4—Settlement Due to Downdrag**

The provisions of Article 10.7.2.5 shall apply.

**C10.8.2.4**

See commentary to Article 10.7.2.5.

**10.8.2.5—Lateral Squeeze**

The provisions of Article 10.7.2.6 shall apply.

**C10.8.2.5**

See commentary to Article 10.7.2.6.

**10.8.3—Strength Limit State Design****10.8.3.1—General**

The nominal shaft resistances that shall be considered at the strength limit state include:

- Axial compression resistance,
- Axial uplift resistance,
- Punching of shafts through strong soil into a weaker layer,
- Lateral geotechnical resistance of soil and rock stratum,
- Resistance when scour occurs,
- Axial resistance when downdrag occurs, and
- Structural resistance of shafts.

**10.8.3.2—Groundwater Table and Buoyancy**

The provisions of Article 10.7.3.5 shall apply.

**C10.8.3.2**

See commentary to Article 10.7.3.5.

**10.8.3.3—Scour**

The provisions of Article 10.7.3.6 shall apply.

**C10.8.3.3**

See commentary to Article 10.7.3.6.

**10.8.3.4—Downdrag**

The provisions of Article 10.7.3.7 shall apply.

**C10.8.3.4**

See commentary to Article 10.7.3.7.

### 10.8.3.5—Nominal Axial Compression Resistance of Single Drilled Shafts

The factored resistance of drilled shafts,  $R_R$ , shall be taken as:

$$R_R = \varphi R_n = \varphi_{qp} R_p + \varphi_{qs} R_s \quad (10.8.3.5-1)$$

in which:

$$R_p = q_p A_p \quad (10.8.3.5-2)$$

$$R_s = q_s A_s \quad (10.8.3.5-3)$$

where:

$R_p$  = nominal shaft tip resistance (kips)

$R_s$  = nominal shaft side resistance (kips)

$\varphi_{qp}$  = resistance factor for tip resistance specified in Table 10.5.5.2.4-1

$\varphi_{qs}$  = resistance factor for shaft side resistance specified in Table 10.5.5.2.4-1

$q_p$  = unit tip resistance (ksf)

$q_s$  = unit side resistance (ksf)

$A_p$  = area of shaft tip ( $\text{ft}^2$ )

$A_s$  = area of shaft side surface ( $\text{ft}^2$ )

The methods for estimating drilled shaft resistance provided in this Article should be used. Shaft strength limit state resistance methods not specifically addressed in this Article for which adequate successful regional or national experience is available may be used, provided adequate information and experience is also available to develop appropriate resistance factors.

### C10.8.3.5

The nominal axial compression resistance of a shaft is derived from the tip resistance and/or shaft side resistance, i.e., skin friction. Both the tip and shaft resistances develop in response to foundation displacement. The maximum values of each are unlikely to occur at the same displacement, as described in Article 10.8.2.2.2.

For consistency in the interpretation of both static load tests (Article 10.8.3.5.6) and the normalized curves of Article 10.8.2.2.2, it is customary to establish the failure criterion at the strength limit state at a gross deflection equal to five percent of the base diameter for drilled shafts.

O'Neill and Reese (1999) identify several methods for estimating the resistance of drilled shafts in cohesive and granular soils, intermediate geomaterials, and rock. The most commonly used methods are provided in this Article. Methods other than the ones provided in detail in this Article may be used provided that adequate local or national experience with the specific method is available to have confidence that the method can be used successfully and that appropriate resistance factors can be determined. At present, it must be recognized that these resistance factors have been developed using a combination of calibration by fitting to previous allowable stress design (ASD) practice and reliability theory (see Allen, 2005, for additional details on the development of resistance factors for drilled shafts). Such methods may be used as an alternative to the specific methodology provided in this Article, provided that:

- The method selected consistently has been used with success on a regional or national basis.
- Significant experience is available to demonstrate that success.
- As a minimum, calibration by fitting to allowable stress design is conducted to determine the appropriate resistance factor, if inadequate measured data are available to assess the alternative method using reliability theory. A similar approach as described by Allen (2005) should be used to select the resistance factor for the alternative method.

#### 10.8.3.5.1—Estimation of Drilled Shaft Resistance in Cohesive Soils

##### 10.8.3.5.1a—General

Drilled shafts in cohesive soils should be designed by total and effective stress methods for undrained and drained loading conditions, respectively.

## 10.8.3.5.1b—Side Resistance

The nominal unit side resistance,  $q_s$ , in ksf, for shafts in cohesive soil loaded under undrained loading conditions by the  $\alpha$ -Method shall be taken as:

$$q_s = \alpha S_u \quad (10.8.3.5.1b-1)$$

in which:

$$\alpha = 0.55 \text{ for } \frac{S_u}{p_a} \leq 1.5 \quad (10.8.3.5.1b-2)$$

$$\alpha = 0.55 - 0.1(S_u/p_a - 1.5) \quad (10.8.3.5.1b-3)$$

for  $1.5 \leq S_u/p_a \leq 2.5$

where:

$S_u$  = undrained shear strength (ksf)

$\alpha$  = adhesion factor (dim)

$p_a$  = atmospheric pressure (= 2.12 ksf)

The following portions of a drilled shaft, illustrated in Figure 10.8.3.5.1b-1, should not be taken to contribute to the development of resistance through skin friction:

- At least the top 5.0 ft of any shaft;
- For straight shafts, a bottom length of the shaft taken as the shaft diameter;
- Periphery of belled ends, if used; and
- Distance above a belled end taken as equal to the shaft diameter.

When permanent casing is used, the side resistance shall be adjusted with consideration to the type and length of casing to be used, and how it is installed.

Values of  $\alpha$  for contributing portions of shafts excavated dry in open or cased holes should be as specified in Eqs. 10.8.3.5.1b-2 and 10.8.3.5.1b-3.

## C10.8.3.5.1b

The  $\alpha$ -method is based on total stress. For effective stress methods for shafts in clay, see O'Neill and Reese (1999).

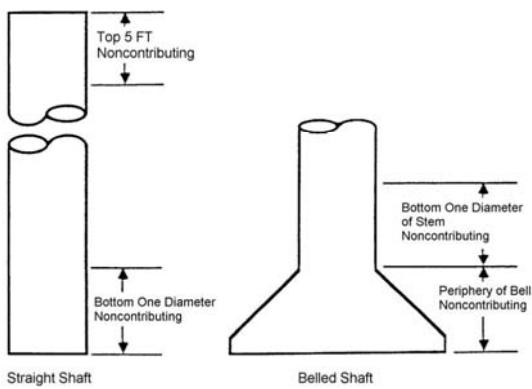

The adhesion factor is an empirical factor used to correlate the results of full-scale load tests with the material property or characteristic of the cohesive soil. The adhesion factor is usually related to  $S_u$  and is derived from the results of full-scale pile and drilled shaft load tests. Use of this approach presumes that the measured value of  $S_u$  is correct and that all shaft behavior resulting from construction and loading can be lumped into a single parameter. Neither presumption is strictly correct, but the approach is used due to its simplicity.

Steel casing will generally reduce the side resistance of a shaft. No specific data is available regarding the reduction in skin friction resulting from the use of permanent casing relative to concrete placed directly against the soil. Side resistance reduction factors for driven steel piles relative to concrete piles can vary from 50 to 75 percent, depending on whether the steel is clean or rusty, respectively (Potyondy, 1961). Greater reduction in the side resistance may be needed if oversized cutting shoes or splicing rings are used.

If open-ended pipe piles are driven full depth with an impact hammer before soil inside the pile is removed, and left as a permanent casing, driven pile static analysis methods may be used to estimate the side resistance as described in Article 10.7.3.8.6.

The upper 5.0 ft of the shaft is ignored in estimating  $R_n$ , to account for the effects of seasonal moisture changes, disturbance during construction, cyclic lateral loading, and low lateral stresses from freshly placed concrete. The lower 1.0-diameter length above the shaft tip or top of enlarged base is ignored due to the development of tensile cracks in the soil near these regions of the shaft and a corresponding reduction in lateral stress and side resistance.

Bells or underreams constructed in stiff fissured clay often settle sufficiently to result in the formation of a gap above the bell that will eventually be filled by slumping soil. Slumping will tend to loosen the soil immediately above the bell and decrease the side resistance along the lower portion of the shaft.

**Figure 10.8.3.5.1b-1—Explanation of Portions of Drilled Shafts Not Considered in Computing Side Resistance (O'Neill and Reese, 1999)**

The value of  $\alpha$  is often considered to vary as a function of  $S_u$ . Values of  $\alpha$  for drilled shafts are recommended as shown in Eqs. 10.8.3.5.1b-2 and 10.8.3.5.1b-3, based on the results of back-analyzed, full-scale load tests. This recommendation is based on eliminating the upper 5.0 ft and lower 1.0 diameter of the shaft length during back-analysis of load test results. The load tests were conducted in insensitive cohesive soils. Therefore, if shafts are constructed in sensitive clays, values of  $\alpha$  may be different than those obtained from Eqs. 10.8.3.5.1b-2 and 10.8.3.5.1b-3. Other values of  $\alpha$  may be used if based on the results of load tests.

The depth of 5.0 ft at the top of the shaft may need to be increased if the drilled shaft is installed in expansive clay, if scour deeper than 5.0 ft is anticipated, if there is substantial groundline deflection from lateral loading, or if there are other long-term loads or construction factors that could affect shaft resistance.

A reduction in the effective length of the shaft contributing to side resistance has been attributed to horizontal stress relief in the region of the shaft tip, arising from development of outward radial stresses at the toe during mobilization of tip resistance. The influence of this effect may extend for a distance of  $1B$  above the tip (O'Neill and Reese, 1999). The effectiveness of enlarged bases is limited when  $L/D$  is greater than 25.0 due to the lack of load transfer to the tip of the shaft.

The values of  $\alpha$  obtained from Eqs. 10.8.3.5.1b-2 and 10.8.3.5.1b-3 are considered applicable for both compression and uplift loading.

#### 10.8.3.5.1c—Tip Resistance

For axially loaded shafts in cohesive soil, the nominal unit tip resistance,  $q_p$ , by the total stress method as provided in O'Neill and Reese (1999) shall be taken as:

$$q_p = N_c S_u \leq 80.0 \quad (10.8.3.5.1c-1)$$

in which:

$$N_c = 6 \left[ 1 + 0.2 \left( \frac{Z}{D} \right) \right] \leq 9 \quad (10.8.3.5.1c-2)$$

where:

$D$  = diameter of drilled shaft (ft)

$Z$  = penetration of shaft (ft)

$S_u$  = undrained shear strength (ksf)

#### C10.8.3.5.1c

These equations are for total stress analysis. For effective stress methods for shafts in clay, see O'Neill and Reese (1999).

The limiting value of 80.0 ksf for  $q_p$  is not a theoretical limit but a limit based on the largest measured values. A higher limiting value may be used if based on the results of a load test, or previous successful experience in similar soils.

The value of  $S_u$  should be determined from the results of in-situ and/or laboratory testing of undisturbed samples obtained within a depth of 2.0 diameters below the tip of the shaft. If the soil within 2.0 diameters of the tip has  $S_u < 0.50$  ksf, the value of  $N_c$  should be multiplied by 0.67.

*10.8.3.5.2—Estimation of Drilled Shaft Resistance in Cohesionless Soils*

*10.8.3.5.2a—General*

Shafts in cohesionless soils should be designed by effective stress methods for drained loading conditions or by empirical methods based on in-situ test results.

*C10.8.3.5.2a*

The factored resistance should be determined in consideration of available experience with similar conditions.

Although many field load tests have been performed on drilled shafts in clays, very few have been performed on drilled shafts in sands. The shear strength of cohesionless soils can be characterized by an angle of internal friction,  $\phi_f$ , or empirically related to its *SPT* blow count,  $N$ . Methods of estimating shaft resistance and end bearing are presented below. Judgment and experience should always be considered.

*10.8.3.5.2b—Side Resistance*

The nominal axial resistance of drilled shafts in cohesionless soils by the  $\beta$ -method shall be taken as:

$$q_s = \beta \sigma'_v \leq 4.0 \text{ for } 0.25 \leq \beta \leq 1.2 \quad (10.8.3.5.2b-1)$$

in which, for sandy soils:

- for  $N_{60} \geq 15$ :

$$\beta = 1.5 - 0.135\sqrt{z} \quad (10.8.3.5.2b-2)$$

- for  $N_{60} < 15$ :

$$\beta = \frac{N_{60}}{15} (1.5 - 0.135\sqrt{z}) \quad (10.8.3.5.2b-3)$$

*C10.8.3.5.2b*

O'Neill and Reese (1999) provide additional discussion of computation of shaft side resistance and recommend allowing  $\beta$  to increase to 1.8 in gravels and gravelly sands, however, they recommend limiting the unit side resistance to 4.0 ksf in all soils.

O'Neill and Reese (1999) proposed a method for uncemented soils that uses a different approach in that the shaft resistance is independent of the soil friction angle or the *SPT* blow count. According to their findings, the friction angle approaches a common value due to high shearing strains in the sand caused by stress relief during drilling.

where:

$\sigma'_v$  = vertical effective stress at soil layer mid-depth (ksf)

$\beta$  = load transfer coefficient (dim)

$z$  = depth below ground, at soil layer mid-depth (ft)

$N_{60}$  = average *SPT* blow count (corrected only for hammer efficiency) in the design zone under consideration (blows/ft)

Higher values may be used if verified by load tests.

For gravelly sands and gravels, Eq. 10.8.3.5.2b-4 should be used for computing  $\beta$  where  $N_{60} \geq 15$ . If  $N_{60} < 15$ , Eq. 10.8.3.5.2b-3 should be used.

$$\beta = 2.0 - 0.06(z)^{0.75} \quad (10.8.3.5.2b-4)$$

When permanent casing is used, the side resistance shall be adjusted with consideration to the type and length of casing to be used, and how it is installed.

The detailed development of Eq. 10.8.3.5.2b-4 is provided in O'Neill and Reese (1999).

Steel casing will generally reduce the side resistance of a shaft. No specific data is available regarding the reduction in skin friction resulting from the use of permanent casing relative concrete placed directly against the soil. Side resistance reduction factors for driven steel piles relative to concrete piles can vary from 50 to 75 percent, depending on whether the steel is clean or rusty, respectively (Potyondy, 1961). Casing reduction factors of 0.6 to 0.75 are commonly used. Greater reduction in the side resistance may be needed if oversized cutting shoes or splicing rings are used.

If open-ended pipe piles are driven full depth with an impact hammer before soil inside the pile is removed, and left as a permanent casing, driven pile static analysis methods may be used to estimate the side resistance as described in Article 10.7.3.8.6.

#### 10.8.3.5.2c—Tip Resistance

The nominal tip resistance,  $q_p$ , in ksf, for drilled shafts in cohesionless soils by the O'Neill and Reese (1999) method shall be taken as:

$$\text{for } N_{60} \leq 50, q_p = 1.2N_{60} \quad (10.8.3.5.2c-1)$$

where:

$N_{60}$  = average SPT blow count (corrected only for hammer efficiency) in the design zone under consideration (blows/ft)

The value of  $q_p$  in Eq. 10.8.3.5.2c-1 should be limited to 60 ksf, unless greater values can be justified through load test data.

Cohesionless soils with SPT- $N_{60}$  blow counts greater than 50 shall be treated as intermediate geomaterial (IGM) and the tip resistance, in ksf, taken as:

$$q_p = 0.59 \left[ N_{60} \left( \frac{p_a}{\sigma'_v} \right) \right]^{0.8} \quad (10.8.3.5.2c-2)$$

where:

$p_a$  = atmospheric pressure (= 2.12 ksf)

$\sigma'_v$  = vertical effective stress at the tip elevation of the shaft (ksf)

#### C10.8.3.5.2c

O'Neill and Reese (1999) provide additional discussion regarding the computation of nominal tip resistance.

See O'Neill and Reese (1999) for background on IGMs.

$N_{60}$  should be limited to 100 in Eq. 10.8.3.5.2c-2 if higher values are measured.

#### 10.8.3.5.3—Shafts in Strong Soil Overlying Weaker Compressible Soil

Where a shaft is tipped in a strong soil layer overlying a weaker layer, the base resistance shall be reduced if the shaft base is within a distance of  $1.5B$  of the top of the weaker layer. A weighted average should be used that varies linearly from the full base resistance in the overlying strong layer at a distance of  $1.5B$  above the top of the weaker layer to the base resistance of the weaker layer at the top of the weaker layer.

#### 10.8.3.5.4—Estimation of Drilled Shaft Resistance in Rock

##### 10.8.3.5.4a—General

Drilled shafts in rock subject to compressive loading shall be designed to support factored loads in:

- Side-wall shear comprising skin friction on the wall of the rock socket; or
- End bearing on the material below the tip of the drilled shaft; or
- A combination of both.

The difference in the deformation required to mobilize skin friction in soil and rock versus what is required to mobilize end bearing shall be considered when estimating axial compressive resistance of shafts embedded in rock. Where end bearing in rock is used as part of the axial compressive resistance in the design, the contribution of skin friction in the rock shall be reduced to account for the loss of skin friction that occurs once the shear deformation along the shaft sides is greater than the peak rock shear deformation, i.e., once the rock shear strength begins to drop to a residual value.

##### C10.8.3.5.3

The distance of  $1.5B$  represents the zone of influence for general bearing capacity failure based on bearing capacity theory for deep foundations.

##### C10.8.3.5.4a

Methods presented in this Article to calculate drilled shaft axial resistance require an estimate of the uniaxial compressive strength of rock core. Unless the rock is massive, the strength of the rock mass is most frequently controlled by the discontinuities, including orientation, length, and roughness, and the behavior of the material that may be present within the discontinuity, e.g., gouge or infilling. The methods presented are semi-empirical and are based on load test data and site-specific correlations between measured resistance and rock core strength.

Design based on side-wall shear alone should be considered for cases in which the base of the drilled hole cannot be cleaned and inspected or where it is determined that large movements of the shaft would be required to mobilize resistance in end bearing.

Design based on end-bearing alone should be considered where sound bedrock underlies low strength overburden materials, including highly weathered rock. In these cases, however, it may still be necessary to socket the shaft into rock to provide lateral stability.

Where the shaft is drilled some depth into sound rock, a combination of sidewall shear and end bearing can be assumed (*Kulhawy and Goodman, 1980*).

If the rock is degradable, use of special construction procedures, larger socket dimensions, or reduced socket resistance should be considered.

For drilled shafts installed in karstic formations, exploratory borings should be advanced at each drilled shaft location to identify potential cavities. Layers of compressible weak rock along the length of a rock socket and within approximately three socket diameters or more below the base of a drilled shaft may reduce the resistance of the shaft.

For rock that is stronger than concrete, the concrete shear strength will control the available side friction, and the strong rock will have a higher stiffness, allowing significant end bearing to be mobilized before the side wall shear strength reaches its peak value. Note that concrete typically reaches its peak shear strength at about 250 to 400 microstrain (for a 10-ft long rock socket, this is approximately 0.5 in. of deformation at the top of the rock socket). If strains or deformations greater than the value at the peak shear stress are anticipated to mobilize the desired end bearing in the rock, a residual value for the skin friction can still be used. Article 10.8.3.5.4d provides procedures for computing a residual value of the skin friction based on the properties of the rock and shaft.

#### *10.8.3.5.4b—Side Resistance*

For drilled shafts socketed into rock, shaft resistance, in ksf, may be taken as (Horvath and Kenney, 1979):

$$q_s = 0.65\alpha_E p_a \left( q_u / p_a \right)^{0.5} < 7.8 p_a \left( f'_c / p_a \right)^{0.5} \quad (10.8.3.5.4b-1)$$

where:

$q_u$  = uniaxial compressive strength of rock (ksf)

$p_a$  = atmospheric pressure (= 2.12 ksf)

$\alpha_E$  = reduction factor to account for jointing in rock as provided in Table 10.8.3.5.4b-1

$f'_c$  = concrete compressive strength (ksi)

**Table 10.8.3.5.4b-1—Estimation of  $\alpha_E$  (O'Neill and Reese, 1999)**

$E_m/E_i$	$\alpha_E$
1.0	1.0
0.5	0.8
0.3	0.7
0.1	0.55
0.05	0.45

#### *C10.8.3.5.4b*

Eq. 10.8.3.5.4b-1 applies to the case where the side of the rock socket is considered to be smooth or where the rock is drilled using a drilling slurry. Significant additional shaft resistance may be achieved if the borehole is specified to be artificially roughened by grooving. Methods to account for increased shaft resistance due to borehole roughness are provided in Section 11 of O'Neill and Reese (1999).

Eq. 10.8.3.5.4b-1 should only be used for intact rock. When the rock is highly jointed, the calculated  $q_s$  should be reduced to arrive at a final value for design. The procedure is as follows:

- Step 1. Evaluate the ratio of rock mass modulus to intact rock modulus, i.e.,  $E_m/E_i$ , using Table C10.4.6.5-1.
- Step 2. Evaluate the reduction factor,  $\alpha_E$ , using Table 10.8.3.5.4b-1.
- Step 3. Calculate  $q_s$  according to Eq. 10.8.3.5.4b-1.

**10.8.3.5.4c—Tip Resistance**

End-bearing for drilled shafts in rock may be taken as follows:

- If the rock below the base of the drilled shaft to a depth of  $2.0B$  is either intact or tightly jointed, i.e., no compressible material or gouge-filled seams, and the depth of the socket is greater than  $1.5B$  (O'Neill and Reese, 1999):

$$q_p = 2.5q_u \quad (10.8.3.5.4c-1)$$

- If the rock below the base of the shaft to a depth of  $2.0B$  is jointed, the joints have random orientation, and the condition of the joints can be evaluated as:

$$q_p = \left[ \sqrt{s} + \sqrt{(m - \sqrt{s}) + s} \right] q_u \quad (10.8.3.5.4c-2)$$

where:

$s, m$  = fractured rock mass parameters and are specified in Table 10.4.6.4-4

$q_u$  = unconfined compressive strength of rock (ksf)

**10.8.3.5.4d—Combined Side and Tip Resistance**

Design methods that consider the difference in shaft movement required to mobilize skin friction in rock versus what is required to mobilize end bearing, such as the methodology provided by O'Neill and Reese (1999), shall be used to estimate axial compressive resistance of shafts embedded in rock.

**C10.8.3.5.4c**

If end bearing in the rock is to be relied upon, and wet construction methods are used, bottom clean-out procedures such as airlifts should be specified to ensure removal of loose material before concrete placement.

The use of Eq. 10.8.3.5.4c-1 also requires that there are no solution cavities or voids below the base of the drilled shaft.

For further information see O'Neill and Reese (1999).

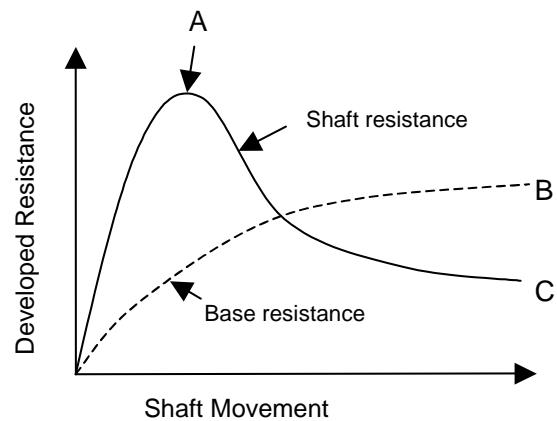

Eq. 10.8.3.5.4c-2 is a lower bound solution for bearing resistance for a drilled shaft bearing on or socketed in a fractured rock mass. This method is appropriate for rock with joints that are not necessarily oriented preferentially and the joints may be open, closed, or filled with weathered material. Load testing will likely indicate higher tip resistance than that calculated using Eq. 10.8.3.5.4c-2. Resistance factors for this method have not been developed and must therefore be estimated by the designer.

**C10.8.3.5.4d**

Typically, the axial compression load on a shaft socketed into rock is carried solely in shaft side resistance until a total shaft movement on the order of 0.4 in. occurs.

Designs which consider combined effects of side friction and end-bearing of a drilled shaft in rock require that side friction resistance and end bearing resistance be evaluated at a common value of axial displacement, since maximum values of side friction and end-bearing are not generally mobilized at the same displacement.

Where combined side friction and end-bearing in rock is considered, the designer needs to evaluate whether a significant reduction in side resistance will occur after the peak side resistance is mobilized. As indicated in Figure C10.8.3.5.4d-1, when the rock is brittle in shear, much shaft resistance will be lost as vertical movement increases to the value required to develop the full value of  $q_p$ . If the rock is ductile in shear, i.e., deflection softening does not occur, then the side resistance and end-bearing resistance can be added together directly. If the rock is brittle, however, adding them directly may be unconservative. Load testing or laboratory shear strength testing, e.g., direct shear testing, may be used to evaluate whether the rock is brittle or ductile in shear.

**Figure C10.8.3.5.4d-1—Deflection Softening Behavior of Drilled Shafts under Compression Loading (after O’Neill and Reese, 1999).**

The method used to evaluate combined side friction and end-bearing at the strength limit state requires the construction of a load-vertical deformation curve. To accomplish this, calculate the total load acting at the head of the drilled shaft,  $Q_{T1}$ , and vertical movement,  $w_{T1}$ , when the nominal shaft side resistance (Point A on Figure C10.8.3.5.4d-1) is mobilized. At this point, some end bearing is also mobilized. For detailed computational procedures for estimating shaft resistance in rock, considering the combination of side and tip resistance, see O’Neill and Reese (1999).

#### 10.8.3.5.5—Estimation of Drilled Shaft Resistance in Intermediate Geo Materials (IGMs)

For detailed base and side resistance estimation procedures for shafts in IGMs, the procedures provided by O’Neill and Reese (1999) should be used.

#### 10.8.3.5.6—Shaft Load Test

When used, load tests shall be conducted in representative soil conditions using shafts constructed in a manner and of dimensions and materials similar to those planned for the production shafts. The load test shall follow the procedures specified in ASTM D1143. The loading procedure should follow the Quick Load Test Method, unless detailed longer-term load-settlement data is needed, in which case the standard loading procedure should be used.

The nominal resistance shall be determined according to the failure definition of either:

- “Plunging” of the drilled shaft, or
- A gross settlement or uplift of five percent of the diameter of the shaft if plunging does not occur.

#### C10.8.3.5.5

See Article 10.8.2.2.3 for a definition of an IGM.

For convenience, since a common situation is to tip the shaft in a cohesionless IGM, the equation for tip resistance in a cohesionless IGM is provided in Article C10.8.3.5.2c.

#### C10.8.3.5.6

For a larger project where many shafts are to be used, it may be cost-effective to perform a full-scale load test on a drilled shaft during the design phase of a project to confirm response to load.

Load tests should be conducted following prescribed written procedures that have been developed from accepted standards and modified, as appropriate, for the conditions at the site. The Quick Test Procedure is desirable because it avoids problems that frequently arise when performing a static test that cannot be started and completed within an eight-hour period. Tests that extend over a longer period are difficult to perform due to the limited number of experienced personnel that are usually available. The Quick Test has proven to be easily

The resistance factors for axial compressive resistance or axial uplift resistance shall be taken as specified in Table 10.5.5.2.4-1.

Regarding the use of shaft load test data to determine shaft resistance, the load test results should be applied to production shafts that are not load tested by matching the static resistance prediction to the load test results. The calibrated static analysis method should then be applied to adjacent locations within the site to determine the shaft tip elevation required, in consideration of variations in the geologic stratigraphy and design properties at each production shaft location. The definition of a site and number of load tests required to account for site variability shall be as specified in Article 10.5.5.2.3.

performed in the field, and the results usually are satisfactory. However, if the formation in which the shaft is installed may be subject to significant creep settlement, alternative procedures provided in [ASTM D1143](#) should be considered.

Load tests are conducted on full-scale drilled shaft foundations to provide data regarding nominal axial resistance, load-displacement response, and shaft performance under the design loads, and to permit assessment of the validity of the design assumptions for the soil conditions at the test shaft(s).

Tests can be conducted for compression, uplift, lateral loading, or for combinations of loading. Full-scale load tests in the field provide data that include the effects of soil, rock, and groundwater conditions at the site; the dimensions of the shaft; and the procedures used to construct the shaft.

The results of full-scale load tests can differ even for apparently similar ground conditions. Therefore, care should be exercised in generalizing and extrapolating the test results to other locations.

For large diameter shafts, where conventional reaction frames become unmanageably large, load testing using Osterberg load cells may be considered. Additional discussion regarding load tests is provided in O'Neill and Reese (1999). Alternatively, smaller diameter shafts may be load tested to represent the larger diameter shafts (but no less than one-half the full scale production shaft diameter), provided that appropriate measures are taken to account for potential scale effects when extrapolating the results to the full scale production shafts.

Plunging occurs when a steady increase in movement results from incrementally small increases in load, e.g., 2.0 kips.

### 10.8.3.6—Shaft Group Resistance

#### 10.8.3.6.1—General

Reduction in resistance from group effects shall be evaluated.

#### C10.8.3.6.1

In addition to the overlap effects discussed below, drilling of a hole for a shaft less than three shaft diameters from an existing shaft reduces the effective stresses against both the side and base of the existing shaft. As a result, the capacities of individual drilled shafts within a group tend to be less than the corresponding capacities of isolated shafts.

If casing is advanced in front of the excavation heading, this reduction need not be made.

#### 10.8.3.6.2—Cohesive Soil

The provisions of Article 10.7.3.9 shall apply.

The resistance factor for the group resistance of an equivalent pier or block failure provided in Table 10.5.5.2.4-1 shall apply where the cap is, or is not, in contact with the ground.

The resistance factors for the group resistance calculated using the sum of the individual drilled shaft resistances are the same as those for the single-drilled shaft resistances.

#### C10.8.3.6.2

The efficiency of groups of drilled shafts in cohesive soil may be less than that of the individual shaft due to the overlapping zones of shear deformation in the soil surrounding the shafts.

**10.8.3.6.3—Cohesionless Soil**

Regardless of cap contact with the ground, the individual nominal resistance of each shaft should be reduced by a factor  $\eta$  for an isolated shaft taken as:

- $\eta = 0.65$  for a center-to-center spacing of 2.5 diameters,
- $\eta = 1.0$  for a center-to-center spacing of 4.0 diameters or more.

For intermediate spacings, the value of  $\eta$  may be determined by linear interpolation.

**C10.8.3.6.3**

The bearing resistance of drilled shaft groups in sand is less than the sum of the individual shafts due to overlap of shear zones in the soil between adjacent shafts and loosening of the soil during construction. The recommended reduction factors are based in part on theoretical considerations and on limited load test results. See O'Neill and Reese (1999) for additional details and a summary of group load test results. It should be noted that most of the available group load test results were obtained for sands above the water table and for relatively small groups, e.g., groups of 3–9 shafts. For larger shaft groups, or for shaft groups of any size below the water table, more conservative values of  $\eta$  should be considered.

**10.8.3.6.4—Shaft Groups in Strong Soil Overlying Weak Soil**

For shaft groups that are collectively tipped within a strong soil layer overlying a soft, cohesive layer, block bearing resistance shall be evaluated in accordance with Article 10.7.3.9.

**10.8.3.7—Uplift Resistance****10.8.3.7.1—General**

Uplift resistance shall be evaluated when upward loads act on the drilled shafts. Drilled shafts subjected to uplift forces shall be investigated for resistance to pullout, for their structural strength, and for the strength of their connection to supported components.

**10.8.3.7.2—Uplift Resistance of Single Drilled Shaft**

The uplift resistance of a single straight-sided drilled shaft should be estimated in a manner similar to that for determining side resistance for drilled shafts in compression, as specified in Article 10.8.3.3.

In determining the uplift resistance of a belled shaft, the side resistance above the bell should conservatively be neglected if the resistance of the bell is considered, and it can be assumed that the bell behaves as an anchor.

**C10.8.3.7.2**

The resistance factors for uplift are lower than those for axial compression. One reason for this is that drilled shafts in tension unload the soil, thus reducing the overburden effective stress and hence the uplift side resistance of the drilled shaft. Empirical justification for uplift resistance factors is provided in Article C10.5.5.2.3, and in Allen (2005).

The factored nominal uplift resistance of a belled drilled shaft in a cohesive soil,  $R_R$ , in kips, should be determined as:

$$R_R = \varphi R_n = \varphi_{up} R_{sbell} \quad (10.8.3.7.2-1)$$

in which:

$$R_{sbell} = q_{s\ bell} A_u \quad (10.8.3.7.2-2)$$

where:

$$q_{sbell} = N_u S_u \text{ (ksf)}$$

$$A_u = \pi(D_p^2 - D^2)/4 \text{ (ft}^2\text{)}$$

$$N_u = \text{uplift adhesion factor (dim)}$$

$$D_p = \text{diameter of the bell (ft)}$$

$$D_b = \text{depth of embedment in the founding layer (ft)}$$

$$D = \text{shaft diameter (ft)}$$

$$S_u = \text{undrained shear strength averaged over a distance of 2.0 bell diameters } (2D_p) \text{ above the base (ksf)}$$

$$\varphi_{up} = \text{resistance factor specified in Table 10.5.5.2.4-1}$$

If the soil above the founding stratum is expansive,  $S_u$  should be averaged over the lesser of either  $2.0D_p$  above the bottom of the base or over the depth of penetration of the drilled shaft in the founding stratum.

The value of  $N_u$  may be assumed to vary linearly from 0.0 at  $D_b/D_p = 0.75$  to a value of 8.0 at  $D_b/D_p = 2.5$ , where  $D_b$  is the depth below the founding stratum. The top of the founding stratum should be taken at the base of zone of seasonal moisture change.

#### 10.8.3.7.3—Group Uplift Resistance

The provisions of Article 10.7.3.11 shall apply.

#### 10.8.3.7.4—Uplift Load Test

The provisions of Article 10.7.3.10 shall apply.

#### 10.8.3.8—Nominal Horizontal Resistance of Shaft and Shaft Groups

The provisions of Article 10.7.3.12 apply.

The design of horizontally loaded drilled shafts shall account for the effects of interaction between the shaft and ground, including the number of shafts in the group.

For shafts used in groups, the drilled shaft head shall be fixed into the cap.

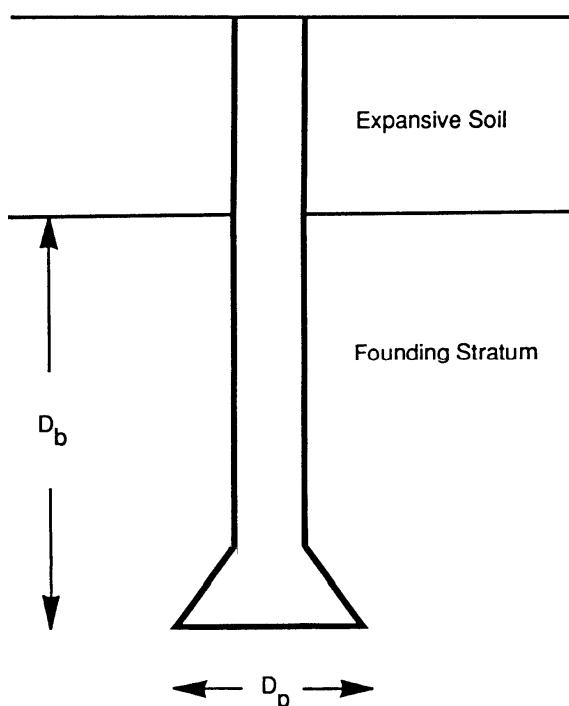

Figure C10.8.3.7.2-1—Uplift of a Belled Drilled Shaft

The assumed variation of  $N_u$  is based on Yazdanbod et al. (1987).

This method does not include the uplift resistance contribution due to soil suction and the weight of the shaft.

#### C10.8.3.7.4

See commentary to Article 10.7.3.10.

#### C10.8.3.8

See commentary to Article 10.7.3.12.

#### **10.8.3.9—Shaft Structural Resistance**

#### **10.8.3.9.1—General**

The structural design of drilled shafts shall be in accordance with the provisions of Section 5 for the design of reinforced concrete.

#### *10.8.3.9.2—Buckling and Lateral Stability*

The provisions of Article 10.7.3.13.4 shall apply.

#### *10.8.3.9.3—Reinforcement*

Where the potential for lateral loading is insignificant, drilled shafts may be reinforced for axial loads only. Those portions of drilled shafts that are not supported laterally shall be designed as reinforced concrete columns in accordance with Article 5.7.4. Reinforcing steel shall extend a minimum of 10.0 ft below the plane where the soil provides fixity.

Where the potential for lateral loading is significant, the unsupported portion of the shaft shall be designed in accordance with Articles 5.10.11 and 5.13.4.6.

The minimum spacing between longitudinal bars, as well as between transverse bars or spirals, shall be sufficient to allow free passage of the concrete through the cage and into the annulus between the cage and the borehole wall.

### C10.8.3.9.2

See commentary to Article 10.7.3.13.4.

### C10.8.3.9.3

Shafts constructed using generally accepted procedures are not normally stressed to levels such that the allowable concrete stress is exceeded. Exceptions include:

- Shafts with sockets in hard rock,
  - Shafts subjected to lateral loads,
  - Shafts subjected to uplift loads from expansive soils or direct application of uplift loads, and
  - Shafts with unreinforced bells.

Maintenance of the spacing of reinforcement and the maximum aggregate size requirements are important to ensure that the high-slump concrete mixes normally used for drilled shafts can flow readily between the steel bars during concrete placement. See Article 5.13.4.5.2 for specifications regarding the minimum clear spacing required between reinforcing cage bars.

A shaft can be considered laterally supported:

- Below the zone of liquefaction or seismic loads,
  - In rock, or
  - 5.0 ft below the ground surface or the lowest anticipated scour elevation.

Laterally supported does not mean fixed. Fixity would occur somewhat below this location and depends on the stiffness of the supporting soil.

The out-to-out dimension of the assembled reinforcing cage should be sufficiently smaller than the diameter of the drilled hole to ensure free flow of concrete around the reinforcing as the concrete is placed. See Article 5.13.4.

See commentary to Article 10.7.5 regarding assessment of corrosivity. In addition, consideration should be given to the ability of the concrete and steel shell to bond together.

The minimum requirements to consider the steel  
to be load carrying shall be as specified in  
Article 5.13.4.5.2.

Transverse reinforcement may be constructed as

Seismic provisions shall be in accordance with Article 5-12.4.1.

**10.8.3.9.5—Concrete**

The maximum aggregate size, slump, wet or dry placement, and necessary design strength should be considered when specifying shaft concrete. The concrete selected should be capable of being placed and adequately consolidated for the anticipated construction condition, and shaft details should be specified. The maximum size aggregate shall meet the requirements of Article 10.8.3.9.3.

**C10.8.3.9.5**

When concrete is placed in shafts, vibration is often not possible except for the uppermost cross-section. Vibration should not be used for high slump concrete.

**10.8.3.9.6—Reinforcement into Superstructure**

Sufficient reinforcement shall be provided at the junction of the shaft with the shaft cap or column to make a suitable connection. The embedment of the reinforcement into the cap shall comply with the provision for cast-in-place piles in Section 5.

**10.8.3.9.7—Enlarged Bases**

Enlarged bases shall be designed to ensure that the plain concrete is not overstressed. The enlarged base shall slope at a side angle not greater than 30 degrees from the vertical and have a bottom diameter not greater than three times the diameter of the shaft. The thickness of the bottom edge of the enlarged base shall not be less than 6.0 in.

**10.8.4—Extreme Event Limit State****C10.8.4**

The provisions of Article 10.5.5.3 and 10.7.4 shall apply.

See commentary to Articles 10.5.5.3 and 10.7.4.

**10.9—MICROPILES****10.9.1—General****C10.9.1**

The provisions of Article 10.7.1 shall apply, except as noted herein.

Micropiles shall be classified by type based on their method of installation as follows:

- Type A micropiles are constructed by placing a sand-cement mortar or neat cement grout in the pile under a gravity head only;
- Type B micropiles are constructed by injecting a neat cement grout under pressure (typically 6–21 ksf) into the drilled hole while the temporary drill casing or auger is withdrawn;
- Type C micropiles are grouted as for Type A, followed 15–25 min after primary grouting by injection of additional grout under pressure (typically greater than 21 ksf) via a preplaced sleeved grout pipe.

Micropiles should be considered:

- Where footings cannot be founded on rock, stiff cohesive, or granular foundation material at a reasonable expense;
- At locations where soil conditions would normally permit the use of spread footings, but the potential for erosion exists;
- At locations where pile foundations must penetrate rock;
- At locations where difficult subsurface conditions (e.g., cobbles, boulders, debris fill, running sands) would hinder installation of driven piles or drilled shafts;
- At locations where difficult access or limited headroom preclude use of other deep foundation systems;

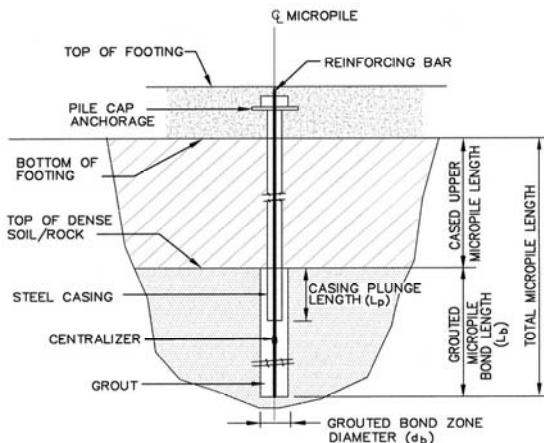

- Type D micropiles are grouted similar to Type C, but the primary grout is allowed to harden before injecting the secondary grout under pressure (typically 42–170 ksf) with a packer to achieve treatment of specific pile intervals or material horizons; or
- Type E micropiles are constructed by drilling with grout injection through a continuous-thread, hollow-core steel bar. The grout injection serves to flush cuttings, achieve grout penetration into the ground and stabilize the drill hole. Often the initial grout has a high water to cement ratio and is then replaced with a thicker structural grout near the completion of drilling.

Primary grout, where it provides direct load transfer along the micropile to the surrounding ground, shall be Portland cement-based grout injected into the micropile hole before or after reinforcement installation.

Post grouting, also known as regROUTing or secondary grouting, shall be taken as the injection of additional Portland cement grout into the bond length of the micropile after set up of primary grout to enhance the grout–ground bond.

- At locations where foundations must bridge over or penetrate subsurface voids;
- Where vibration limits preclude conventional pile driving operations or access by drilled shaft rigs; or
- When underpinning or retrofitting existing foundations.

A typical detail for a composite reinforced micropile is illustrated in Figure C10.9.1-1.

**Figure C10.9.1-1—Typical Detail of Composite Reinforced Micropile (After Sabatini, et al., 2005)**

#### 10.9.1.1—Scope

The provisions of this Article shall apply to the design of micropiles.

The provisions of this section shall not be taken as applicable to drilled piles, e.g., augercast piles, installed with continuous flight augers that are concreted as the auger is being extracted.

#### 10.9.1.2—Minimum Micropile Spacing, Clearance, and Embedment into Cap

Center-to-center pile spacing should not be less than 30.0 in. or 3.0 pile diameters, whichever is greater. Otherwise, the provisions of Article 10.7.1.2 shall apply.

#### 10.9.1.3—Micropiles through Embankment Fill

Micropiles extending through embankments shall penetrate a minimum of 10.0 ft into original ground, unless the required nominal axial and lateral resistance occurs at a lesser penetration below the embankment within bedrock or other suitable support materials.

#### 10.9.1.4—Battered Micropiles

The provisions of Article 10.7.1.4 shall apply.

#### C10.9.1.3

If compressible soils are located beneath the embankment, micropiles should be installed after embankment settlement is complete, if possible, to minimize or eliminate downdrag forces.

#### C10.9.1.4

See Article C10.7.1.4.

**10.9.1.5—Micropile Design Requirements**

Micropile design shall address the following issues as appropriate:

- Nominal axial resistance to be specified in the contract and size of micropile group required to provide adequate support, with consideration of how nominal axial micropile resistance will be determined in the field;
- Group interaction;
- Pile quantity estimation from estimated pile penetration required to meet nominal axial resistance and other design requirements;
- Minimum pile penetration necessary to satisfy the requirements caused by uplift, scour, downdrag, settlement, liquefaction, lateral loads, and seismic conditions;
- Foundation deflection to meet the established movement and associated structure performance criteria;
- Pile foundation nominal structural resistance; and
- Long-term durability of the micropile in service, i.e. corrosion and deterioration.

**10.9.1.6—Determination of Micropile Loads**

The provisions of Article 10.7.1.6 shall apply.

*10.9.1.6.1—Downdrag*

The provisions of Articles 10.7.1.6.2 and 3.11.8 shall apply.

*10.9.1.6.2—Uplift Due to Expansive Soils*

The provisions in Article 10.7.1.6.3 shall apply.

*10.9.1.6.3—Nearby Structures*

The provisions of Article 10.7.1.6.4 shall apply.

**10.9.2—Service Limit State Design****10.9.2.1—General**

The provisions of Article 10.7.2.1 shall apply.

**10.9.2.2—Tolerable Movements**

The provisions of Articles 10.5.2.1 and 10.5.2.2 shall apply.

**C10.9.1.5**

The micropile design process is discussed in detail in *Micropile Design and Construction* (Sabatini, et al., 2005).

**C10.9.1.6**

See Article C10.7.1.6.

*C10.9.1.6.1*

See Articles C10.7.1.6.2 and C3.11.8.

*C10.9.1.6.2*

See Article C10.7.1.6.3.

**C10.9.2.1**

See Article C10.7.2.1.

**C10.9.2.2**

See Articles C10.5.2.1 and C10.5.2.2.

**10.9.2.3—Settlement**

The provisions of Article 10.7.2.3 shall apply.

**C10.9.2.3**

See Article C10.7.2.3.

Methods for calculating the settlement of micropiles are discussed in Sabatini, et al. (2005).

*10.9.2.3.1—Micropile Groups in Cohesive Soil*

The provisions of Article 10.7.2.3.1 shall apply.

*C10.9.2.3.1*

See Article 10.7.2.3.1.

*10.9.2.3.2—Micropile Groups in Cohesionless Soil*

The provisions of Article 10.7.2.3.2 shall apply.

*C10.9.2.3.2*

See Article C10.7.2.3.2.

**10.9.2.4—Horizontal Micropile Foundation Movement**

The provisions of Articles 10.5.2.1 and 10.7.2.4 shall apply.

**C10.9.2.4**

See Articles C10.5.2.1 and C10.7.2.4.

**10.9.2.5—Settlement Due to Downdrag**

The provisions of Article 10.7.2.5 shall apply.

**C10.9.2.5**

See Article C10.7.2.5.

**10.9.2.6—Lateral Squeeze**

The provisions of Article 10.7.2.6 shall apply.

**C10.9.2.6**

See Article C10.7.2.6.

**10.9.3—Strength Limit State Design****10.9.3.1—General****C10.9.3.1**

For strength limit state design, the following shall be determined:

- Loads and performance requirements;
- Micropile dimensions and nominal axial micropile resistance;
- Size and configuration of the micropile group to provide adequate foundation support;
- Estimated micropile length to be used in the construction contract documents to provide a basis for bidding;
- A minimum micropile penetration, if required, for the particular site conditions and loading, determined based on the maximum (deepest) penetration needed to meet all of the applicable requirements identified in Article 10.7.6; and
- The nominal structural resistance of the micropile and/or micropile group.

A minimum micropile penetration should only be specified if needed to insure that uplift, lateral stability, depth to resist downdrag, depth to resist scour, and depth for structural lateral resistance are met for the strength limit state, in addition to similar requirements for the service and extreme event limit states. See Article C10.7.6 for additional details.

Punching of micropiles through strong soil into a weaker layer is not likely for micropiles designed for a resistance by bond transfer only.

**10.9.3.2—Ground Water Table and Bouyancy**

The provisions of Article 10.7.3.4 shall apply.

**C10.9.3.2**

See Article C10.7.3.4.

**10.9.3.3—Scour**

The provisions of Article 10.7.3.5 shall apply.

**C10.9.3.3**

See Article C10.7.3.5.

**10.9.3.4—Downdrag**

The provisions of Article 10.7.3.6 shall apply.

**C10.9.3.4**

See Article C10.7.3.6.

**10.9.3.5—Nominal Axial Compression Resistance of a Single Micropile***10.9.3.5.1—General*

Micropiles shall be designed to resist failure of the bonded length in soil and rock, or for micropiles bearing on rock, failure of the rock at the micropile tip.

The factored resistance of a micropile,  $R_R$ , shall be taken as:

$$R_R = \varphi R_n = \varphi_{qp} R_p + \varphi_{qs} R_s \quad (10.9.3.5.1-1)$$

in which:

$$R_p = q_p A_p \quad (10.9.3.5.1-2)$$

$$R_s = q_s A_s \quad (10.9.3.5.1-3)$$

where:

$R_p$  = nominal tip resistance (kips)

$R_s$  = nominal grout-to-ground bond resistance (kips)

$\varphi_{qp}$  = resistance factor for tip resistance specified in Table 10.5.5.2.5-1

$\varphi_{qs}$  = resistance factor for grout-to-ground bond resistance specified in Table 10.5.5.2.5-1

$q_p$  = unit tip resistance (ksf)

$q_s$  = unit grout-to-ground bond resistance (ksf)

$A_p$  = area of micropile tip ( $\text{ft}^2$ )

$A_s$  = area of grout-to-ground bond surface ( $\text{ft}^2$ )

*C10.9.3.5.1*

Micropiles are typically designed based on bond into soil and rock neglecting tip resistance due to their relatively small diameter and high grout-to-ground bond resistance. Tip resistance may be considered for micropiles bearing on hard rock although the axial capacity for this case is often controlled by the structural resistance of the micropile.

Both the tip and bond resistances develop in response to foundation displacement. The maximum values of each are unlikely to occur at the same displacement. The bond resistance is typically fully mobilized at displacements of about 0.1 to 0.4 in. The tip capacity, however, is mobilized after the micropile settles about six percent of its diameter (Jeon and Kulhawy, 2001), and is generally neglected in the design of micropiles in soil.

The methods for estimating micropile axial resistance provided in this article should be used. Micropile strength limit state resistance methods not specifically addressed in this Article for which adequate successful regional or national experience is available may be used, provided adequate information and experience is also available to develop appropriate resistance factors.

For final design, micropile resistance shall be verified through the performance of micropile load tests as described in Article 10.9.3.5.4. The resistance factors for micropiles shall be taken as specified in Table 10.5.5.2.5-1.

*10.9.3.5.2—Estimation of Grout-to-Ground Bond Resistance*

The nominal grout-to-ground bond resistance over the bonded length of a micropile,  $R_s$ , in kips shall be taken as:

$$R_s = \pi d_b \alpha_b L_b \quad (10.9.3.5.2-1)$$

where:

$d_b$  = diameter of micropile drill hole through bonded length (ft)

$\alpha_b$  = nominal micropile grout-to-ground bond strength (ksf)

$L_b$  = micropile bonded length (ft)

For final design, micropile capacity shall be verified through the performance of micropile load tests as described in Article 10.9.3.5.4.

*C10.9.3.5.2*

The value of nominal unit grout-to-ground bond strength, either estimated empirically or determined through load testing, is typically taken as the average value over the entire bond length.

Micropile grout-to-ground bond strength is influenced by soil and rock conditions, method of micropile drilling and installation, and grouting pressure. The final micropile geotechnical design should be performed by a specialty contractor qualified to perform micropile design and construction. As a guide, Table C10.9.3.5.2-1 may be used to estimate the nominal (ultimate) unit grout-to-ground bond strength for Types A, B, C, D, and E micropiles bonded into soil and/or rock for preliminary design.

For preliminary design, the grout-to-ground bond resistance of micropiles may be based on the results of micropile load tests; estimated based on a review of geologic and boring data, soil and rock samples, laboratory testing, and previous experience; or estimated using published soil/rock-grout bond guidelines.

**Table C10.9.3.5.2-1—Summary of Typical  $\alpha_b$  Values (Grout-to-Ground Bond) for Preliminary Micropile Design (modified after Sabatini, et al., 2005)**

Soil/Rock Description	Typical Range of Grout-to-Ground Bond Nominal Resistance for Micropile Types <sup>(1)</sup> (ksf)				
	Type A	Type B	Type C	Type D	Type E
Silt & Clay (some sand) (soft medium plastic)	0.7–1.4	0.7–2.0	0.7–2.5	0.7–3.0	0.7–2.0
Silt & Clay (some sand) (stiff, dense to very dense)	0.7–2.5	1.4–4.0	2.0–4.0	2.0–4.0	1.4–4.0
Sand (some silt) (fine, loose-medium dense)	1.4–3.0	1.4–4.0	2.0–4.0	2.0–5.0	1.4–5.0
Sand (some silt, gravel) (fine-coarse, medium-very dense)	2.0–4.5	2.5–7.5	3.0–7.5	3.0–8.0	2.5–7.5
Gravel (some sand) (medium-very dense)	2.0–5.5	2.5–7.5	3.0–7.5	3.0–8.0	2.5–7.5
Glacial Till (silt, sand, gravel) (medium-very dense, cemented)	2.0–4.0	2.0–6.5	2.5–6.5	2.5–7.0	2.0–6.5
Soft Shales (fresh-moderate fracturing, little to no weathering)	4.3–11.5	N/A	N/A	N/A	N/A
Slates and Hard Shales (fresh-moderate fracturing, little to no weathering)	10.8–28.8	N/A	N/A	N/A	N/A
Limestone (fresh-moderate fracturing, little to no weathering)	21.6–43.2	N/A	N/A	N/A	N/A
Sandstone (fresh-moderate fracturing, little to no weathering)	10.8–36.0	N/A	N/A	N/A	N/A
Granite and Basalt (fresh-moderate fracturing, little to no weathering)	28.8–87.7	N/A	N/A	N/A	N/A

<sup>(1)</sup> Refer to Article 10.9.1 for description of micropile types.

#### 10.9.3.5.3—Estimation of Micropile Tip Resistance in Rock

The methods used for design of micropiles bearing on rock shall consider the presence, orientation, and condition of discontinuities, weathering profiles, and other similar profiles as they apply at a particular site. The designer shall judge the competency of a rock mass in accordance with the provisions of Article 10.4.6.4.

For micropiles founded on competent rock, tip resistance may be estimated in accordance with the provisions of Article 10.8.3.5.4c.

#### C10.9.3.5.3

Micropiles are generally designed based on bond into rock rather than tip resistance. Tip resistance is generally considered only for micropiles bearing on competent rock.

For micropiles founded on competent rock, the rock is usually so sound that the structural capacity will govern the design.

Weak rock includes some shales and mudstones or poor-quality weathered rocks. The term “weak” has no generally accepted, quantitative definition; therefore, judgment and experience are required to make this determination.

**10.9.3.5.4—Micropile Load Test**

The load test shall follow the procedures specified in [ASTM D1143](#) for compression and [ASTM D3689](#) for tension. The loading procedure should follow the Quick Load Test Method, unless detailed longer-term load-settlement data is needed, in which case the standard loading procedure should be used. Unless specified otherwise by the Engineer, the pile axial resistance shall be determined from the test data using the Davisson Method as presented in Article 10.7.3.8.2.

The number of load tests required to account for site variability shall be as specified in Article 10.5.5.2.2. The number of test micropiles required should be increased in nonuniform subsurface conditions.

In addition, proof tests loaded to the required factored load shall be performed on one pile per substructure unit or five percent of the piles, whichever is greater, unless specified otherwise by the Engineer.

The resistance factors for axial compressive resistance or axial uplift resistance shall be taken as specified in Table 10.5.5.2.5-1.

**C10.9.3.5.4**

See Article C10.8.3.5.6.

Load Tests on micropiles are performed to determine micropile installation characteristics, evaluate micropile capacity with depth, and establish micropile bond lengths.

During the performance of ASTM tests, the Contractor may perform several load cycles on the test micropile for diagnostic purposes.

Test micropiles may not be required where previous experience exists with the same micropile type and ultimate micropile capacity in similar subsurface conditions. However, load tests can differ even for apparently similar ground conditions. Therefore, care should be exercised in generalizing and extrapolating the test results to other locations.

Test micropiles are frequently planned for each substructure.

With approval of the Engineer, the number of load tests and proof tests can be reduced based on:

- Previous micropile load tests in similar ground using similar methods, or
- Site-specific tests showing much higher than required factored resistance or consistent proof test.

**C10.9.3.6****10.9.3.6—Resistance of Micropile Groups in Compression**

Reduction in resistance from group effects shall be evaluated in accordance with the provisions of Article 10.7.3.9.

**10.9.3.7—Nominal Uplift Resistance of a Single Micropile**

Uplift resistance shall be evaluated when upward loads act on the micropiles. Micropiles subjected to uplift forces shall be investigated for resistance to pullout, for their structural strength, and for the strength of their connection to supported components.

**10.9.3.8—Nominal Uplift Resistance of Micropile Groups**

The provisions of Article 10.7.3.11 shall apply.

See Article C10.7.3.9.

**C10.9.3.7**

Resistance factors in Article 10.5.5.2.5 assume a tension load test is performed. In the event that tension load tests are not performed, the resistance factor for presumptive values may be used or the tension resistance estimated as 50 percent of the compression resistance.

**C10.9.3.8**

Group uplift resistance in rock should consider the depth of soil overburden, rock discontinuity spacing and condition, and rock mass shear strength, as well as bond between micropiles and rock.

### 10.9.3.9—Nominal Horizontal Resistance of Micropiles and Micropile Groups

The provisions of Article 10.7.3.12 apply.

The design of horizontally loaded micropiles shall account for the effects of interaction between the micropiles and ground, including the number and spacing of micropiles in the group.

For micropiles used in groups, the micropile head shall be embedded into the cap and the degree of fixity shall be considered in the design.

### C10.9.3.9

See Article C10.7.3.12.

### 10.9.3.10—Structural Resistance

#### 10.9.3.10.1—General

The structural design of micropiles shall be in accordance with the provisions of Section 5 for the design of reinforced concrete and Section 6 for the design of steel.

The cased and uncased length of each micropile shall be designed to resist the forces distributed to the micropile based on the micropile inclination and spacing.

The resistance factors for structural design shall be as specified in Table 10.5.5.2.5-2.

#### C10.9.3.10.1

Articles 5.6.3.4, 5.7.4, 5.7.6, 5.13.4, and 6.15 provide specific provisions applicable to design of concrete and steel micropiles.

The design of micropiles supporting axial compression load only requires an allowance for unintended eccentricity. This has been accounted for by use of the equations in Article 5.7.4.4 for reinforced concrete columns that already contain an eccentricity allowance.

#### 10.9.3.10.2—Axial Compressive Resistance

The upper cased section of a micropile subjected to compression loading shall be designed structurally to support the full factored load on the micropile. The lower uncased section of a micropile subjected to compression loading shall be designed structurally to support the maximum full factored load on the micropile less the load transferred to the surrounding ground from the cased portion of the pile in the plunge length (if used), as described in Article 10.9.3.10.4.

For micropiles extending through a weak upper soil layer, extending above ground, subject to scour, extending through mines/caves, or extending through soil that may liquefy, the effect of any laterally unsupported length shall be considered in the determination of axial compression resistance.

The factored structural resistance of a micropile to axial compression loading,  $R_C$ , in kips may be taken as:

$$R_C = \phi_C R_n \quad (10.9.3.10.2-1)$$

where:

$\phi_C$  = resistance factor specified in Table 10.5.5.2.5-2 for structural resistance of micropiles in axial compression

$R_n$  = nominal axial compression resistance of micropile specified in Articles 10.9.3.10.2a and 10.9.3.10.2b (kips)

*10.9.3.10.2a—Cased Length*

The factored structural resistance of the upper cased length of a micropile having no unsupported length and loaded in compression,  $R_{CC}$ , in kips may be taken as:

$$R_{CC} = \varphi_{CC} R_n \quad (10.9.3.10.2a-1)$$

for which:

$$R_n = 0.85 [ 0.85 f'_c A_g + f_y (A_b + A_c) ] \quad (10.9.3.10.2a-2)$$

where:

$\varphi_{CC}$  = resistance factor specified in Table 10.5.5.2.5-2 for structural resistance of the cased section of a micropile subjected to compression loading

$f'_c$  = specified compressive strength of micropile grout at 28 days unless another age is specified (ksi)

$A_g$  = cross-sectional area of grout within micropile (in.<sup>2</sup>)

$f_y$  = specified minimum yield strength of reinforcement bar or steel casing, or stress in steel reinforcement bar or casing at a strain of 0.003, whichever is less (ksi)

$A_b$  = cross-sectional area of steel reinforcing bar (in.<sup>2</sup>)

$A_c$  = cross-sectional area of steel casing (in.<sup>2</sup>)

*10.9.3.10.2b—Uncased Length*

The factored structural resistance of the lower, uncased length of a micropile having no unsupported length and loaded in compression,  $R_{CU}$ , in kips may be taken as:

$$R_{CU} = \varphi_{CU} R_n \quad (10.9.3.10.2b-1)$$

for which:

$$R_n = 0.85 [ 0.85 f'_c A_g + f_y A_b ] \quad (10.9.3.10.2b-2)$$

where:

$\varphi_{CU}$  = resistance factor specified in Table 10.5.5.2.5-2 for structural resistance of the uncased section of a micropile subjected to compression loading

$f'_c$  = specified compressive strength of micropile grout at 28 days unless another age is specified (ksi)

*C10.9.3.10.2a*

The design compressive stress in the steel is limited to the stress at which the strain equals 0.003 to maintain compatibility with the strain in the grout.

$A_g$  = cross-sectional area of grout within micropile (in.<sup>2</sup>)

$f_y$  = specified minimum yield strength of reinforcement bar or stress in steel reinforcement bar at a strain of 0.003, whichever is less (ksi)

$A_b$  = cross-sectional area of steel reinforcing bar (in.<sup>2</sup>)

#### 10.9.3.10.3—Axial Tension Resistance

The upper cased section of a micropile subjected to tension loading shall be designed structurally to support the full factored load on the micropile. The lower uncased section of a micropile subjected to tension loading shall be designed structurally to support the maximum full factored load on the micropile less the load transferred to the surrounding ground from the cased portion of the micropile in the plunge length, as described in Article 10.9.3.10.4.

The factored structural resistance of a micropile subjected to tension,  $R_T$ , may be taken as:

$$R_T = \varphi_T R_n \quad (10.9.3.10.3-1)$$

where:

$\varphi_T$  = resistance factor specified in Table 10.5.5.2.5-2 for structural resistance of a micropile subjected to tension loading (dim)

$R_n$  = nominal axial tension resistance of micropile specified in Articles 10.9.3.10.3a and 10.9.3.10.3b

#### 10.9.3.10.3a—Cased Length

The factored structural resistance of the upper cased length of a micropile subjected to tension loading,  $R_{TC}$ , in kips may be taken as:

$$R_{TC} = \varphi_{TC} R_n \quad (10.9.3.10.3a-1)$$

for which:

$$R_n = f_y (A_b + A_{ct}) \quad (10.9.3.10.3a-2)$$

where:

$\varphi_{TC}$  = resistance factor specified in Table 10.5.5.2.5-2 for structural resistance of the cased section of a micropile subjected to tension loading (dim)

$f_y$  = specified minimum yield strength of reinforcement bar or steel casing, whichever is less (ksi)

$A_b$  = cross-sectional area of steel reinforcing bar (in.<sup>2</sup>)

$A_{ct}$  = cross-sectional area of steel casing considering reduction for threads (in.<sup>2</sup>)

#### C10.9.3.10.3a

The design compressive stress in the steel is limited to the stress at which the strain equals 0.003 to maintain compatibility with the strain in the grout.

### 10.9.3.10.3b—Uncased Length

The factored structural resistance of the lower uncased length of a micropile subjected to tension loading,  $R_{TU}$ , in kips may be taken as:

$$R_{TU} = \varphi_{TU} R_n \quad (10.9.3.10.3b-1)$$

for which:

$$R_n = f_y A_b \quad (10.9.3.10.3b-2)$$

where:

$\varphi_{TU}$  = resistance factor specified in Table 10.5.5.2.5-2 for structural resistance of the uncased section of a micropile subjected to tension loading (dim)

$f_y$  = specified minimum yield strength of reinforcement bar (kip)

$A_b$  = cross-sectional area of steel reinforcing bar ( $\text{in.}^2$ )

### 10.9.3.10.4—Plunge Length Transfer Load

The factored axial load transferred to the ground through the plunge length of the cased portion of a micropile,  $P_t$ , in kips, may be taken as:

$$P_t = \varphi [\pi d_b a_b L_p] \quad (10.9.3.10.4-1)$$

where:

$\varphi$  = resistance factor specified in Table 10.5.5.2.5-1 for geotechnical bearing or uplift resistance, as appropriate, of a single micropile

$d_b$  = diameter of micropile drill hole through bonded length (ft)

$a_b$  = nominal micropile grout-to-ground bond strength (ksf)

$L_p$  = micropile casing plunge length (ft)

If load transfer through the plunge length of the cased portion of a micropile is considered to reduce the load on the lower uncased portion of the micropile, the factored axial load on the uncased portion of the micropile in compression or tension,  $P_u$ , in kips, may be taken as:

$$P_u = Q - P_t \quad (10.9.3.10.4-2)$$

where:

$$\begin{aligned} Q &= \sum \eta_i \gamma_i Q_i \\ &= \text{total factored axial load on micropile (kips)} \end{aligned}$$

### C10.9.3.10.4

An optional procedure for construction of a composite reinforced micropile includes insertion of the pile casing into the top of the grouted bond zone to effect a transition between the upper cased portion to the lower uncased portion of a micropile. The length of casing inserted into the bond zone by the plunge length is shown in Figure C10.9.1-1. As a result, a portion of the factored axial load on a micropile is transferred to the surrounding ground by the cased portion of the pile, reducing the load that must be supported by the weaker uncased portion of the pile. The reduction in load applied to the uncased length is termed the transfer load  $P_t$ .

$P_t$  = plunge length transfer load from Eq. 10.9.3.10.4-1 (kips)

#### 10.9.3.10.5—Grout-to-Steel Bond

Casing-to-grout bond shall be checked and reinforcement bar development length shall be checked in accordance with the provisions of Section 5.

#### C10.9.3.10.5

Grout-to-steel bond does not typically govern micropile design, except for overlap of reinforcing bars into upper casing.

The bond between the cement grout and the reinforcing steel is the mechanism for transfer of the pile load from the reinforcing steel to the ground. Typical ultimate bond values range from 0.15 to 0.25 ksi for smooth bars and pipe, and 0.30 to 0.50 ksi for deformed bars (Armour, et al., 2000). Refer to Section 5 for bar development requirements.

As is the case with any reinforcement, the surface condition will affect the attainable bond. A film of rust may be beneficial, but the presence of loose debris or lubricant or paint is not desirable. Normal methods for the handling and storage of reinforcing bars apply to micropile construction. For the permanent casing that is also used to drill the hole, cleaning of the casing surface can occur during drilling, particularly in granular soils.

#### 10.9.3.10.6—Buckling and Lateral Stability

The provisions of Article 10.7.3.13.4 shall apply.

#### 10.9.3.10.7—Reinforcement into Superstructure

Sufficient reinforcement shall be provided at the junction of the micropile with the micropile footing or column to make a suitable connection. The embedment of the reinforcement into the cap shall comply with the provision for cast-in-place piles in Section 5.

### 10.9.4—Extreme Event Limit State

The provisions of Articles 10.5.5.3 and 10.7.4 shall apply.

### 10.9.5—Corrosion and Deterioration

The provisions of Article 10.7.5 shall apply.

### C10.9.4

See Articles C10.5.5.3 and C10.7.4.

### C10.9.5

Corrosion protection methods and design presented in Article C10.7.5 apply to micropiles as well. In addition, other micropile specific design options including plastic encapsulation of central reinforcing bars is provided in Sabatini (2005).

## APPENDIX A10—SEISMIC ANALYSIS AND DESIGN OF FOUNDATIONS

### A10.1—INVESTIGATION

Slope instability, liquefaction, fill settlement, and increases in lateral earth pressure have often been major factors contributing to bridge damage in earthquakes. These earthquake hazards may be significant design factors for peak earthquake accelerations in excess of 0.1 g and should form part of a site-specific investigation if the site conditions and the associated acceleration levels and design concepts suggest that such hazards may be of importance.

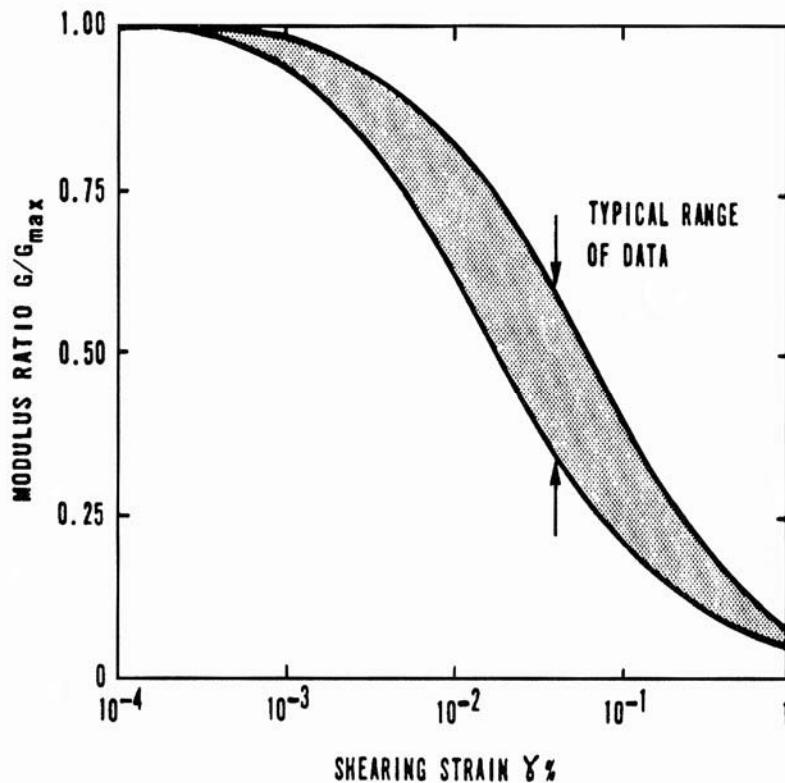

### A10.2—FOUNDATION DESIGN

The commonly accepted practice for the seismic design of foundations is to utilize a pseudo-static approach, where earthquake-induced foundation loads are determined from the reaction forces and moments necessary for structural equilibrium. Although traditional bearing capacity design approaches are also applied, with appropriate capacity reduction factors if a margin of safety against “failure” is desired, a number of factors associated with the dynamic nature of earthquake loading should always be borne in mind.

Under cyclic loading at earthquake frequencies, the strength capable of being mobilized by many soils is greater than the static strength. For unsaturated cohesionless soils, the increase may be about ten percent, whereas for cohesive soils, a 50 percent increase could occur. However, for softer saturated clays and saturated sands, the potential for strength and stiffness degradation under repeated cycles of loading must also be recognized. For bridges classified as Zone 2, the use of static soil strengths for evaluating ultimate foundation capacity provides a small implicit measure of safety and, in most cases, strength and stiffness degradation under repeated loading will not be a problem because of the smaller magnitudes of seismic events. However, for bridges classified as Zones 3 and 4, some attention should be given to the potential for stiffness and strength degradation of site soils when evaluating ultimate foundation capacity for seismic design.

As earthquake loading is transient in nature, “failure” of soil for a short time during a cycle of loading may not be significant. Of perhaps greater concern is the magnitude of the cyclic foundation displacement or rotation associated with soil yield, as this could have a significant influence on structural displacements or bending moments and shear distributions in columns and other members.

As foundation compliance influences the distribution of forces or moments in a structure and affects computation of the natural period, equivalent stiffness factors for foundation systems are often required. In many cases, use is made of various analytical solutions that are available for footings or piles where it is assumed that soil behaves in an elastic medium. In using these formulae, it should be recognized that equivalent elastic moduli for soils are a function of strain amplitude, and for seismic loads modulus values could be significantly less than those appropriate for low levels of seismic loading. Variation of shear modulus with shearing strain amplitude in the case of sands is shown in Figure A10.2-1. Additional discussion of this topic can be found in the *AASHTO Guide Specifications for LRFD Seismic Design*.

**Figure A10.2-1—Variation of Shear Modulus with Shearing Strain for Sands**

On the basis of field and experimental observations, it is becoming more widely recognized that transient foundation uplift or rocking during earthquake loading, resulting in separation of the foundation from the subsoil, is acceptable provided that appropriate design precautions are taken (Taylor and Williams, 1979). Experimental studies suggest that rotational yielding beneath rocking foundation can provide a useful form of energy dissipation. However, care must be taken to avoid significant induced vertical deformations accompanying possible soil yield during earthquake rocking as well as excessive pier movement. These could lead to design difficulties with relative displacements.

*Lateral Loading of Piles*—Most of the well-known solutions for computing the lateral stiffness of vertical piles are based on the assumption of elastic behavior and utilize equivalent cantilever beam concepts (Davisson and Gill, 1960), the beam on an elastic Inkler foundation method (Matlock and Reese, 1960), or elastic continuum solutions (Poulos, 1971). However, the use of methods incorporating nonlinear subgrade reaction behavior that allows for soil failure may be important for high lateral loading of piles in soft clay and sand. Such a procedure is encompassed in the American Petroleum Institute (API) recommendations for offshore platform design. The method utilizes nonlinear subgrade reaction or  $P-y$  curves for sands and clays that have been developed experimentally from field loading tests.

The general features of the API analysis in the case of sands are illustrated in Figure A10.2-2. Under large loads, a passive failure zone develops near the pile head. Test data indicate that the ultimate resistance,  $p_u$ , for lateral loading is reached for pile deflections,  $y_u$ , of about  $3d/80$ , where  $d$  is the pile diameter. Note that most of the lateral resistance is mobilized over a depth of about  $5d$ . The API method also recognizes degradation in lateral resistance with cyclic loading, although in the case of saturated sands, the degradation postulated does not reflect pore water pressure increases. The degradation in lateral resistance due to earthquake-induced, free-field pore water pressure increases in saturated sands has been described by Finn and Martin (1979). A numerical method that allows the use of API  $P-y$  curves to compute pile stiffness characteristics forms the basis of the computer program BMCOL 76 described by Bogard and Matlock (1977).

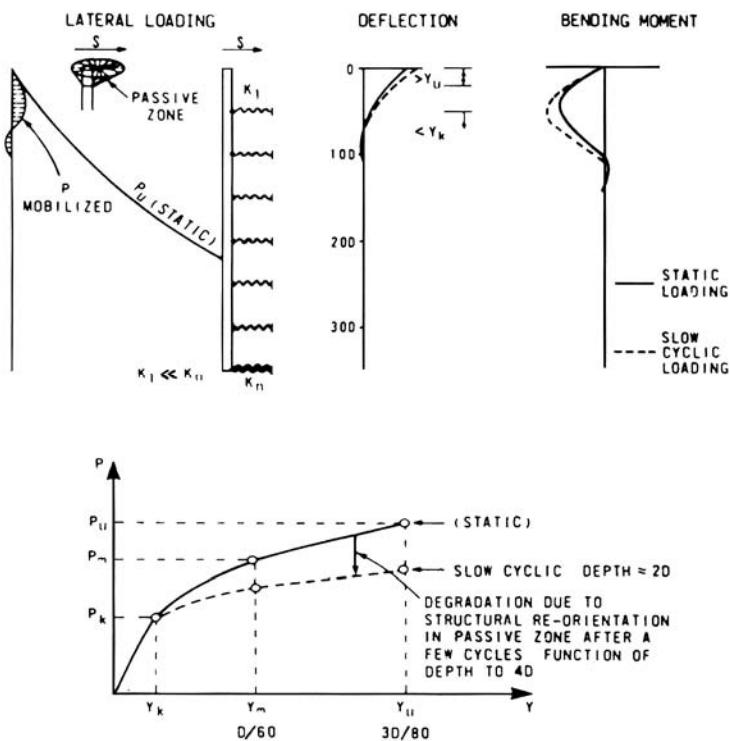

Figure A10.2-2—Lateral Loading of Piles in Sand Using API Criteria

The influence of group action on pile stiffness is a somewhat controversial subject. Solutions based on elastic theory can be misleading where yield near the pile head occurs. Experimental evidence tends to suggest that group action is not significant for pile spacings greater than  $4d$  to  $6d$ .

For batter pile systems, the computation of lateral pile stiffness is complicated by the stiffness of the piles in axial compression and tension. It is also important to recognize that bending deformations in batter pile groups may generate high reaction forces on the pile cap.

It should be noted that although battered piles are economically attractive for resisting horizontal loads, such piles are very rigid in the lateral direction if arranged so that only axial loads are induced. Hence, large relative lateral displacements of the more flexible surrounding soil may occur during the free-field earthquake response of the site (particularly if large changes in soil stiffness occur over the pile length), and these relative displacements may in turn induce high pile bending moments. For this reason, more flexible vertical pipe systems where lateral load is resisted by bending near the pile heads are recommended. However, such pile systems must be designed to be ductile because large lateral displacements may be necessary to resist the lateral load. A compromise design using battered piles spaced some distance apart may provide a system that has the benefits of limited flexibility and the economy of axial load resistance to lateral load.

**Soil-Pile Interaction**—The use of pile stiffness characteristics to determine earthquake-induced pile bending moments based on a pseudo-static approach assumes that moments are induced only by lateral loads arising from inertial effects on the bridge structure. However, it must be remembered that the inertial loads are generated by interaction of the free-field earthquake ground motion with the piles and that the free-field displacements themselves can influence bending moments. This is illustrated in an idealized manner in Figure A10.2-3. The free-field earthquake displacement time histories provide input into the lateral resistance interface elements, which in turn transfer motion to the pile. Near the pile heads, bending moments will be dominated by the lateral interaction loads generated by inertial effects on the bridge structure. At greater depth (e.g., greater than  $10d$ ), where soil stiffness progressively increases with respect to pile stiffness, the pile will be constrained to deform in a manner similar to that of the free field, and pile bending moments become a function of the curvatures induced by free-field displacements.

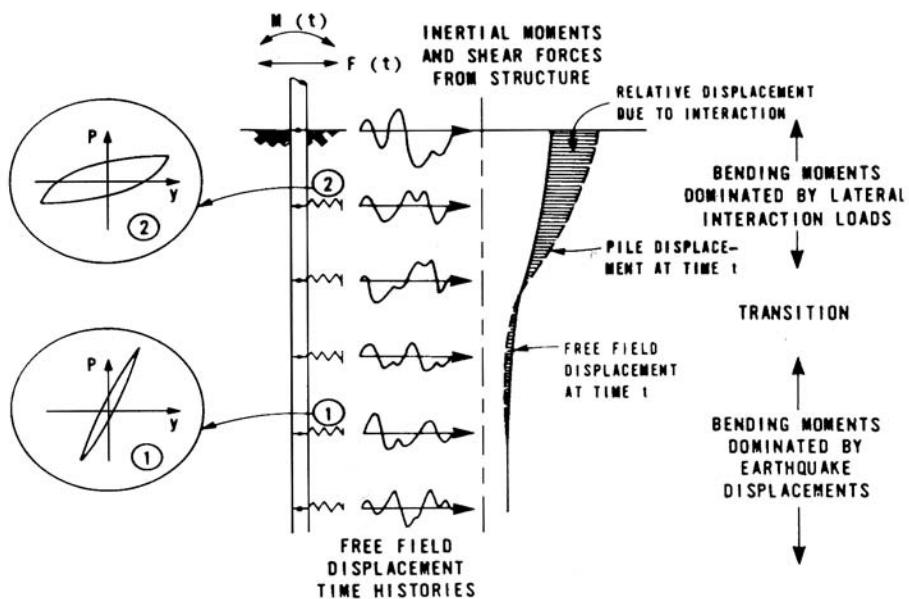

Figure A10.2-3—Mechanism of Soil-Pile Interaction during Seismic Loading

To illustrate the nature of free-field displacements, reference is made to Figure A10.2-4, which represents a 200-ft deep cohesionless soil profile subjected to the El Centro earthquake. The free-field response was determined using a nonlinear, one-dimensional response analysis. From the displacement profiles shown at specific times, curvatures can be computed and pile bending moments calculated if it is assumed that the pile is constrained to displace in phase with the free-field response.

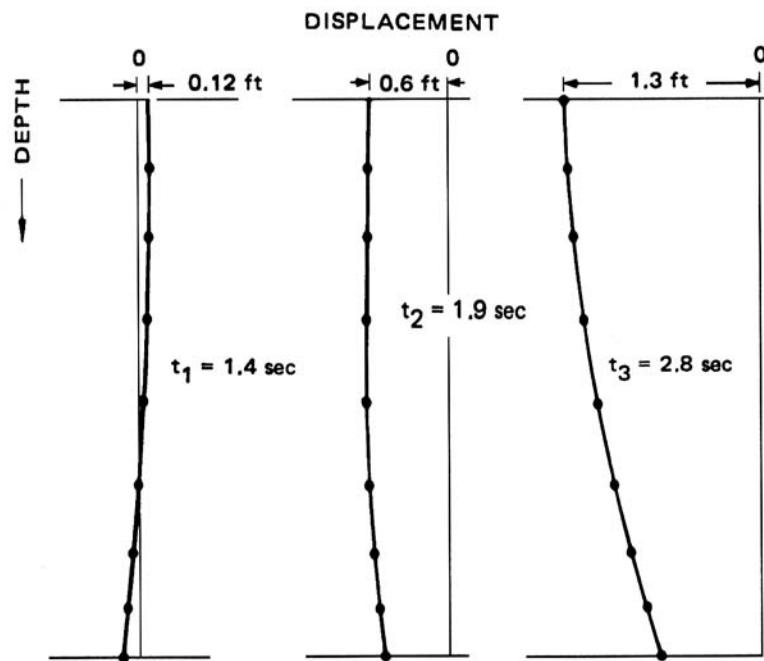

Figure A10.2-4—Typical Earthquake Displacement Profiles

Large curvatures could develop at interfaces between soft and rigid soils and, clearly, in such cases emphasis should be placed on using flexible ductile piles. Margason (1979) suggests that curvatures of up to  $6 \times 10^{-4}$  in.<sup>-1</sup> could be induced by strong earthquakes, but these should pose no problem to well-designed steel or prestressed concrete piles.

Studies incorporating the complete soil-pile structure interaction system, as presented in Figure A10.2-3, have been described by Penzien (1970) for a bridge piling system in a deep soft clay. A similar but somewhat simpler soil-pile structure interaction system (SPASM) to that used by Penzien has been described by Matlock et al. (1978). The model used is, in effect, a dynamic version of the previously mentioned BMCOL program.

### A10.3—SPECIAL PILE REQUIREMENTS

The uncertainties of ground and bridge response characteristics lead to the desirability of providing tolerant pile and foundation systems. Toughness under induced curvature and shears is required, and hence piles such as steel H-sections and concrete filled steel-cased piles are favored for highly seismic areas. Unreinforced concrete piles are brittle in nature, so nominal longitudinal reinforcing is specified to reduce this hazard. The reinforcing steel should be extended into the footing to tie elements together and to assist in load transfer from the pile to the pile cap.

Experience has shown that reinforced concrete piles tend to hinge or shatter immediately below the pile cap. Hence, tie spacing is reduced in this area so that the concrete is better confined. Driven precast piles should be constructed with considerable spiral confining steel to ensure good shear strength and tolerance of yield curvatures should these be imparted by the soil or structural response. Clearly, it is desirable to ensure that piles do not fail below ground level and that flexural yielding in the columns is forced to occur above ground level. The additional pile design requirements imposed on piles for bridges classified as Zones 3 and 4, for which earthquake loading is more severe, reflect a design philosophy aimed at minimizing below-ground damage that is not easily inspected following a major earthquake.

## SECTION 11

# ABUTMENTS, PIERS, AND WALLS

### 11.1—SCOPE

This Section provides requirements for design of abutments and walls. Conventional retaining walls, nongravity cantilevered walls, anchored walls, mechanically stabilized earth (MSE) walls, and prefabricated modular walls are considered.

### 11.2—DEFINITIONS

*Abutment*—A structure that supports the end of a bridge span, and provides lateral support for fill material on which the roadway rests immediately adjacent to the bridge. In practice, different types of abutments may be used. These include:

- *Stub Abutment*—Stub abutments are located at or near the top of approach fills, with a backwall depth sufficient to accommodate the structure depth and bearings which sit on the bearing seat.
- *Partial-Depth Abutment*—Partial-depth abutments are located approximately at middepth of the front slope of the approach embankment. The higher backwall and wingwalls may retain fill material, or the embankment slope may continue behind the backwall. In the latter case, a structural approach slab or end span design must bridge the space over the fill slope, and curtain walls are provided to close off the open area. Inspection access should be provided for this situation.
- *Full-Depth Abutment*—Full-depth abutments are located at the approximate front toe of the approach embankment, restricting the opening under the structure.
- *Integral Abutment*—Integral abutments are rigidly attached to the superstructure and are supported on a spread or deep foundations capable of permitting necessary horizontal movements.

*Anchored Wall*—An earth retaining system typically composed of the same elements as nongravity cantilevered walls, and that derive additional lateral resistance from one or more tiers of anchors.

*Mechanically Stabilized Earth Wall*—A soil-retaining system, employing either strip or grid-type, metallic, or polymeric tensile reinforcements in the soil mass, and a facing element that is either vertical or nearly vertical.

*Nongravity Cantilever Wall*—A soil-retaining system that derives lateral resistance through embedment of vertical wall elements and supports retained soil with facing elements. Vertical wall elements may consist of discrete elements, e.g., piles, drilled shafts or auger-cast piles spanned by a structural facing, e.g., lagging, panels or shotcrete. Alternatively, the vertical wall elements and facing may be continuous, e.g., sheet piles, diaphragm wall panels, tangent-piles, or tangent drilled shafts.

*Pier*—That part of a bridge structure that provides intermediate support to the superstructure. Different types of piers may be used. These include:

- *Solid Wall Piers*—Solid wall piers are designed as columns for forces and moments acting about the weak axis and as piers for those acting about the strong axis. They may be pinned, fixed or free at the top, and are conventionally fixed at the base. Short, stubby types are often pinned at the base to eliminate the high moments which would develop due to fixity. Earlier, more massive designs were considered gravity types.
- *Double Wall Piers*—Double wall piers consist of two separate walls, spaced in the direction of traffic, to provide support at the continuous soffit of concrete box superstructure sections. These walls are integral with the superstructure and must also be designed for the superstructure moments which develop from live loads and erection conditions.

- *Bent Piers*—Bent-type piers consist of two or more transversely spaced columns of various solid cross-sections, and these types are designed for frame action relative to forces acting about the strong axis of the pier. They are usually fixed at the base of the pier and are either integral with the superstructure or with a pier cap at the top. The columns may be supported on a spread- or pile-supported footing, or a solid wall shaft, or they may be extensions of the piles or shaft above the ground line.
- *Single-Column Piers*—Single-column piers, often referred to as “T” or “Hammerhead” piers, are usually supported at the base by a spread-, drilled shaft- or pile-supported footing, and may be either integral with, or provide independent support for, the superstructure. Their cross-section can be of various shapes and the column can be prismatic or flared to form the pier cap or to blend with the sectional configuration of the superstructure cross-section. This type of pier can avoid the complexities of skewed supports if integrally framed into the superstructure and their appearance reduces the massiveness often associated with superstructures.
- *Tubular Piers*—A hollow core section which may be of steel, reinforced concrete or prestressed concrete, of such cross-section to support the forces and moments acting on the elements. Because of their vulnerability to lateral loadings, tubular piers shall be of sufficient wall thickness to sustain the forces and moments for all loading situations as are appropriate. Prismatic configurations may be sectionally precast or prestressed as erected.

*Prefabricated Modular Wall*—A soil-retaining system employing interlocking soil-filled timber, reinforced concrete, or steel modules or bins to resist earth pressures by acting as gravity retaining walls.

*Rigid Gravity and Semi-Gravity (Conventional) Retaining Wall*—A structure that provides lateral support for a mass of soil and that owes its stability primarily to its own weight and to the weight of any soil located directly above its base.

In practice, different types of rigid gravity and semi-gravity retaining walls may be used. These include:

- A *gravity* wall depends entirely on the weight of the stone or concrete masonry and of any soil resting on the masonry for its stability. Only a nominal amount of steel is placed near the exposed faces to prevent surface cracking due to temperature changes.
- A *semi-gravity* wall is somewhat more slender than a gravity wall and requires reinforcement consisting of vertical bars along the inner face and dowels continuing into the footing. It is provided with temperature steel near the exposed face.
- A *cantilever* wall consists of a concrete stem and a concrete base slab, both of which are relatively thin and fully reinforced to resist the moments and shears to which they are subjected.
- A *counterfort* wall consists of a thin concrete face slab, usually vertical, supported at intervals on the inner side by vertical slabs or counterforts that meet the face slab at right angles. Both the face slab and the counterforts are connected to a base slab, and the space above the base slab and between the counterforts is backfilled with soil. All the slabs are fully reinforced.

## 11.3—NOTATION

### 11.3.1—General

$A_c$	= cross-sectional area of reinforcement unit (in. <sup>2</sup> ) (11.10.6.4.1)
$A_m$	= maximum wall acceleration coefficient at the centroid (11.10.7.1)
$A_S$	= peak seismic ground acceleration coefficient modified by short-period site factor (11.6.5) (C11.8.6) (11.10.7.1)
$B$	= wall base width (ft) (11.10.2)
$b$	= unit width of reinforcement; width of bin module (ft) (11.10.6.4.1) (11.11.5.1)
$b_f$	= width of applied footing load (ft) (11.10.10.2)
$C$	= overall reinforcement surface area geometry factor (dim.) (11.10.6.3.2)
$CR_{cr}$	= long-term connection strength reduction factor to account for reduced ultimate strength resulting from connection (dim.) (11.10.6.4.4b)

$CR_u$	= short-term connection strength reduction factor to account for reduced ultimate strength resulting from the connection (dim.) (11.10.6.4.4b)
$C_u$	= coefficient of uniformity (dim.) (11.10.6.3.2)
$D$	= design embedment depth of vertical element (ft); diameter of bar or wire (in.) (11.10.6.3.2) (C11.8.4.1)
$D^*$	= diameter of bar or wire corrected for corrosion loss (ft) (11.10.6.4.1)
$D_o$	= embedment for which net passive pressure is sufficient to provide moment equilibrium (ft) (C11.8.4.1)
$D_{60}/D_{10}$	= uniformity coefficient of soil defined as ratio of the particle size of soil that is 60 percent finer in size to the particle size of soil that is ten percent finer in size (dim.) (11.10.6.3.2)
$d$	= diameter of anchor drill hole (ft); the lateral wall displacement (in.); fill above wall (ft) (C11.6.5) (11.9.4.2) (11.10.8)
$E_c$	= thickness of metal reinforcement at end of service life (mil.) (11.10.6.4.1)
$E_n$	= nominal thickness of steel reinforcement at construction (mil.) (11.10.6.4.2a)
$E_s$	= sacrificial thickness of metal expected to be lost by uniform corrosion during service life (mil.) (11.10.6.4.2a)
$E_{AE}$	= total active static and seismic force (kips/ft) (A11.1.1.1)
$E_{PE}$	= total passive static and seismic force (kips/ft) (A11.1.1.1)
$e$	= eccentricity of load from centerline of foundation (ft) (11.10.8)
$F_T$	= resultant force of active lateral earth pressure (kips/ft) (11.6.3.2)
$F_y$	= minimum yield strength of steel (ksi) (11.10.6.4.3a)
$F^*$	= reinforcement pullout friction factor (dim.) (11.10.6.3.2)
$G_u$	= distance from center of gravity of a horizontal segmental facing block unit, including aggregate fill, measured from the front of the unit (ft) (11.10.6.4.4b)
$H$	= height of wall (ft) (11.9.1)
$H_h$	= hinge height for segmental facing (ft) (11.10.6.4.4b)
$H_u$	= segmental facing block unit height (ft) (11.10.6.4.4b)
$H_1$	= equivalent wall height (ft) (11.10.6.3.1)
$h$	= vertical distance between ground surface and wall base at the back of wall heel (ft) (11.6.3.2)
$h_i$	= height of reinforced soil zone contributing horizontal load to reinforcement at level $i$ (ft) (11.10.6.2.1)
$i_b$	= slope of facing base downward into backfill (degrees) (11.10.6.4.4b)
$k_a$	= active earth pressure coefficient (dim.) (11.8.4.1)
$k_{af}$	= active earth pressure coefficient of backfill (dim.) (11.10.5.2)
$k_h$	= horizontal seismic acceleration coefficient (dim.) (11.8.6)
$k_v$	= vertical seismic acceleration coefficient (dim.) (A11.1.1.1)
$k_{AE}$	= seismic active pressure coefficient (dim.) (A11.1.1.1)
$k_{PE}$	= seismic passive pressure coefficient (dim.) (A11.1.1.1)
$k_r$	= horizontal earth pressure coefficient of reinforced fill (dim.) (11.10.5.2)
$L$	= spacing between vertical elements or facing supports (ft); length of reinforcing elements in an MSE wall and correspondingly its foundation (ft) (11.8.5.2) (11.10.2)
$L_a$	= length of reinforcement in active zone (ft) (11.10.2)
$L_b$	= anchor bond length (ft) (11.9.4.2)
$L_e$	= length of reinforcement in resistance zone (ft) (11.10.2)
$L_{ei}$	= effective reinforcement length for layer $i$ (ft) (11.10.7.2)
$MARV$	= minimum average roll value (11.10.6.4.3b)
$M_{max}$	= maximum bending moment in vertical wall element or facing (kip-ft or kip-ft/ft) (11.8.5.2)
$N$	= normal component of resultant on base of foundation (kips/ft) (11.6.3.2)
$P_{AE}$	= dynamic horizontal thrust (kips/ft) (11.10.7.1)
$P_b$	= pressure inside bin module (ksf) (11.10.5.1)
$P_H$	= lateral force due to superstructure or other concentrated loads (kips/ft) (11.10.10.1)
$P_i$	= factored horizontal force per mm of wall transferred to soil reinforcement at level $i$ ; internal inertial force, due to the weight of the backfill within the active zone (kips/ft) (11.10.6.2.1) (11.10.7.2)
$P_{IR}$	= horizontal inertial force (kips/ft) (11.10.7.1)
$P_{ir}$	= horizontal inertial force caused by acceleration of reinforced backfill (kips/ft) (11.10.7.1)
$P_{is}$	= internal inertial force caused by acceleration of sloping surcharge (kips/ft) (11.10.7.1)
$P_r$	= ultimate soil reinforcement pullout resistance per unit of reinforcement width (kips/ft) (11.10.6.3.2)
$P_v$	= load on strip footing (kips/ft) (11.10.10.1)
$P'_v$	= load on isolated rectangular footing or point load (kips) (11.10.10.1)
$p$	= average lateral pressure, including earth, surcharge and water pressure, acting on the section of wall element being considered (ksf) (11.9.5.2)

$Q_n$	= nominal (ultimate) anchor resistance (kips) (11.9.4.2)
$Q_R$	= factored anchor resistance (kips) (11.9.4.2)
$q_s$	= surcharge pressure (ksf) (11.10.5.2)
$q_{max}$	= maximum unit soil pressure on base of foundation (ksf) (11.6.3.2)
$R$	= resultant force at base of wall (kips/ft) (11.6.3.2)
$R_{BH}$	= basal heave ratio (C11.9.3.1)
$R_c$	= reinforcement coverage ratio (dim.) (11.10.6.3.2)
$R_n$	= nominal resistance (kips or kips/ft) (11.5.4)
$R_R$	= factored resistance (kips or kips/ft) (11.5.4)
$RF$	= combined strength reduction factor to account for potential long-term degradation due to installation damage, creep and chemical/biological aging of geosynthetic reinforcements (dim.) (11.10.6.4.2b)
$RF_c$	= combined strength reduction factor for long-term degradation of geosynthetic reinforcement facing connection (dim.) (11.10.6.4.4b)
$RF_{CR}$	= strength reduction factor to prevent long-term creep rupture of reinforcement (dim.) (11.10.6.4.3b)
$RF_D$	= strength reduction factor to prevent rupture of reinforcement due to chemical and biological degradation (dim.) (11.10.6.4.3b)
$RF_{ID}$	= strength reduction factor to account for installation damage to reinforcement (dim.) (11.10.6.4.3b)
$S_h$	= horizontal reinforcement spacing (ft) (11.10.6.4.1)
$S_t$	= spacing between transverse grid elements (in.) (11.10.6.3.2)
$S_u$	= undrained shear strength (ksf) (11.9.5.2)
$S_v$	= vertical spacing of reinforcements (ft) (11.10.6.2.1)
$S_{rs}$	= ultimate reinforcement tensile resistance required to resist static load component (kips/ft) (11.10.7.2)
$S_{rt}$	= ultimate reinforcement tensile resistance required to resist transient load component (kips/ft) (11.10.7.2)
$T_{ac}$	= nominal long-term reinforcement/facing connection design strength (kips/ft) (11.10.6.4.1)
$T_{at}$	= nominal long-term reinforcement design strength (kips/ft) (11.10.6.4.1)
$T_{crc}$	= creep reduced connection strength per unit of reinforcement width determined from the stress rupture envelope at the specified design life as produced from a series of long-term connection creep tests (kips/ft) (11.10.6.4.4b)
$T_{lot}$	= ultimate wide width tensile strength per unit of reinforcement width ( <a href="#">ASTM D4595</a> or <a href="#">D6637</a> ) for the reinforcement material lot used for the connection strength testing (kips/ft) (11.10.6.4.4b)
$T_{md}$	= factored incremental dynamic inertia force (kips/ft) (11.10.7.2)
$T_{ultconn}$	= ultimate connection strength per unit of reinforcement width (kips/ft) (11.10.6.4.4b)
$T_{ult}$	= ultimate tensile strength of reinforcement (kips/ft) (11.10.6.4.3b)
$T_{max}$	= applied load to reinforcement (kips/ft) (11.10.6.2.1)
$T_o$	= factored tensile load at reinforcement/facing connection (kips/ft) (11.10.6.2.2)
$t$	= thickness of transverse elements (in.) (11.10.6.3.2)
$T_{total}$	= total load on reinforcement layer (static & dynamic) per unit width of wall (kips/ft) (11.10.7.2)
$V_1$	= weight of soil carried by wall heel, not including weight of soil surcharge (kips/ft) (11.6.3.2)
$V_2$	= weight of soil surcharge directly above wall heel (kips/ft) (11.6.3.2)
$W_u$	= unit width of segmental facing (ft) (11.10.2.3.2)
$W_1$	= weight of wall stem (kips/ft) (11.6.3.2)
$W_2$	= weight of wall footing or base (kips/ft) (11.6.3.2)
$x$	= spacing between vertical element supports (ft) (11.9.5.2)
$Z$	= depth below effective top of wall or to reinforcement (ft) (11.10.6.2.1)
$Z_p$	= depth of soil at reinforcement layer at beginning of resistance zone for pullout calculation (ft) (11.10.6.2.1)
$\alpha$	= scale effect correction factor (dim.) (11.10.6.3.2)
$\beta$	= inclination of ground slope behind face of wall (degrees) (11.5.5)
$\gamma_{EQ}$	= load factor for earthquake loading in Article 3.4.1 (dim.) (11.6.5)
$\gamma_P$	= load factor for vertical earth pressure in Article 3.4.1 (dim.) (11.10.6.2.1)
$\gamma_s$	= soil unit weight (kcf)
$\gamma'_s$	= effective soil unit weight (kcf) (C11.8.4.1)
$\gamma_r$	= unit weight of reinforced fill (kcf) (11.10.5.2)
$\gamma_f$	= unit weight of backfill (kcf) (11.10.5.2)
$\Delta\sigma_H$	= horizontal stress on reinforcement from concentrated horizontal surcharge (ksf); traffic barrier impact stress applied over reinforcement tributary area (ksf) (11.10.6.2.1) (11.10.10.2)
$\Delta\sigma_v$	= vertical stress due to footing load (ksf) (11.10.8)
$\delta$	= wall-backfill interface friction angle (degrees) (11.5.5)
$\delta_{max}$	= maximum displacement (ft) (11.10.4.2)

$\delta_R$	= relative displacement coefficient (11.10.4.2)
$\theta$	= wall batter from horizontal (degrees) (11.10.6.2.1)
$\rho$	= soil-reinforcement angle of friction (degrees) (11.10.5.3)
$\phi$	= resistance factor (11.5.4)
$\phi_f$	= internal friction angle of foundation or backfill soil (degrees) (11.10.2)
$\phi_r$	= internal friction angle of reinforced fill (degrees) (11.10.5.2)
$\phi'_f$	= effective internal friction angle of soil (degrees) (11.8.4.1)
$\sigma_H$	= factored horizontal stress at reinforcement level (ksf) (11.10.6.2.1)
$\sigma_{Hmax}$	= maximum stress in soil reinforcement in abutment zones (11.10.8)
$\sigma_v$	= vertical stress in soil (ksf) (11.10.6.2.1)
$\sigma_{VI}$	= vertical soil stress over effective base width (ksf) (11.10.8)
$\tau_n$	= nominal anchor bond stress (ksf) (11.9.4.2)
$\omega$	= wall batter due to setback of segmental facing units (degrees) (11.10.6.4.4b)

## 11.4—SOIL PROPERTIES AND MATERIALS

### 11.4.1—General

Backfill materials should be granular, free-draining materials. Where walls retain in-situ cohesive soils, drainage shall be provided to reduce hydrostatic water pressure behind the wall.

### C11.4.1

Much of the knowledge and experience with MSE structures has been with select, cohesionless backfill as specified in Section 7 of *AASHTO LRFD Bridge Construction Specifications*. Hence, knowledge about internal stress distribution, pullout resistance and failure surface shape is constrained and influenced by the unique engineering properties of granular soils. While cohesive soils have been successfully used, problems including excessive deformation and complete collapse have also occurred. Most of these problems have been attributed to poor drainage. Drainage requirements for walls constructed with poor draining soils are provided in Elias et al. (2001).

### 11.4.2—Determination of Soil Properties

The provisions of Articles 2.4 and 10.4 shall apply.

## 11.5—LIMIT STATES AND RESISTANCE FACTORS

### 11.5.1—General

Design of abutments, piers and walls shall satisfy the criteria for the service limit state specified in Article 11.5.2, and for the strength limit state specified in Article 11.5.3.

### C11.5.1

Abutments, piers and retaining walls shall be designed to withstand lateral earth and water pressures, including any live and dead load surcharge, the self weight of the wall, temperature and shrinkage effects, and earthquake loads in accordance with the general principles specified in this Section.

Earth retaining structures shall be designed for a service life based on consideration of the potential long-term effects of material deterioration, seepage, stray currents and other potentially deleterious environmental factors on each of the material components comprising the structure. For most applications, permanent retaining walls should be designed for a minimum service life of 75 years. Retaining wall applications defined as temporary shall be considered to have a service life of 36 months or less.

A greater level of safety and/or longer service life, i.e., 100 years, may be appropriate for walls which support bridge abutments, buildings, critical utilities, or other facilities for which the consequences of poor performance or failure would be severe.

Permanent structures shall be designed to retain an aesthetically pleasing appearance, and be essentially maintenance free throughout their design service life.

### 11.5.2—Service Limit States

Abutments, piers, and walls shall be investigated for excessive vertical and lateral displacement, and overall stability, at the service limit state. Tolerable vertical and lateral deformation criteria for retaining walls shall be developed based on the function and type of wall, anticipated service life, and consequences of unacceptable movements to the wall and any potentially affected nearby structures, i.e., both structural and aesthetic. Overall stability shall be evaluated using limit equilibrium methods of analysis.

The provisions of Articles 10.6.2.2, 10.7.2.2, and 10.8.2.1 shall apply to the investigation of vertical wall movements. For anchored walls, deflections shall be estimated in accordance with the provisions of Article 11.9.3.1. For MSE walls, deflections shall be estimated in accordance with the provisions of Article 11.10.4.

Design of walls to be essentially maintenance free does not preclude the need for periodic inspection of the wall to assess its condition throughout its design life.

#### C11.5.2

Vertical wall movements are primarily the result of soil settlement beneath the wall. For gravity and semigravity walls, lateral movement results from a combination of differential vertical settlement between the heel and the toe of the wall and the rotation necessary to develop active earth pressure conditions (see Article C3.11.1).

Tolerable total and differential vertical deformations for a particular retaining wall are dependent on the ability of the wall to deflect without causing damage to the wall elements or adjacent structures, or without exhibiting unsightly deformations.

Surveys of the performance of bridges indicate that horizontal abutment movements less than 1.5 in. can usually be tolerated by bridge superstructures without significant damage, as reported in Bozozuk (1978); Walkinshaw (1978); Moulton et al. (1985); and Wahls (1990). Earth pressures used in design of abutments should be selected consistent with the requirement that the abutment should not move more than 1.5 in. laterally.

Regarding impact to the wall itself, differential settlement along the length of the wall and to some extent from front to back of wall is the best indicator of the potential for retaining wall structural damage or overstress. Wall facing stiffness and ability to adjust incrementally to movement affect the ability of a given wall system to tolerate differential movements. The total and differential vertical deformation of a retaining wall should be small for rigid gravity and semigravity retaining walls, and for soldier pile walls with a cast-in-place facing. For walls with anchors, any downward movement can cause significant stress relaxation of the anchors.

MSE walls can tolerate larger total and differential vertical deflections than rigid walls. The amount of total and differential vertical deflection that can be tolerated depends on the wall facing material, configuration and timing of facing construction. A cast-in-place facing has the same vertical deformation limitations as the more rigid retaining wall systems. However, an MSE wall with a cast-in-place facing can be specified with a waiting period before the cast-in-place facing is constructed so that vertical (as well as horizontal) deformations have time to occur. An MSE wall with welded wire or geosynthetic facing can tolerate the most deformation. An MSE wall with multiple precast concrete panels cannot tolerate as much vertical deformation as flexible welded wire or geosynthetic facings because of potential damage to the precast panels and unsightly panel separation.

### 11.5.3—Strength Limit State

Abutments and walls shall be investigated at the strength limit states using Eq. 1.3.2.1-1 for:

- Bearing resistance failure,
- Lateral sliding,
- Excessive loss of base contact,
- Pullout failure of anchors or soil reinforcements, and
- Structural failure.

### 11.5.4—Resistance Requirement

Abutments, piers and retaining structures and their foundations and other supporting elements shall be proportioned by the appropriate methods specified in Articles 11.6, 11.7, 11.8, 11.9, 11.10, or 11.11 so that their resistance satisfies Article 11.5.5.

The factored resistance,  $R_R$ , calculated for each applicable limit state shall be the nominal resistance,  $R_n$ , multiplied by an appropriate resistance factor,  $\phi$ , specified in Table 11.5.6-1.

### C11.5.4

Procedures for calculating nominal resistance are provided in Articles 11.6, 11.7, 11.8, 11.9, 11.10, and 11.11 for abutments and retaining walls, piers, nongravity cantilevered walls, anchored walls, mechanically stabilized earth walls, and prefabricated modular walls, respectively.

### 11.5.5—Load Combinations and Load Factors

Abutments, piers and retaining structures and their foundations and other supporting elements shall be proportioned for all applicable load combinations specified in Article 3.4.1.

### C11.5.5

Figures C11.5.5-1 and C11.5.5-2 show the typical application of load factors to produce the total extreme factored force effect for external stability of retaining walls. Where live load surcharge is applicable, the factored surcharge force is generally included over the backfill immediately above the wall only for evaluation of foundation bearing resistance and structure design, as shown in Figure C11.5.5-3. The live load surcharge is not included over the backfill for evaluation of eccentricity, sliding or other failure mechanisms for which such surcharge would represent added resistance to failure. Likewise, the live load on a bridge abutment is included only for evaluation of foundation bearing resistance and structure design. The load factor for live load surcharge is the same for both vertical and horizontal load effects.

The permanent and transient loads and forces shown in the figures include, but are not limited to:

- Permanent Loads

$DC$  = dead load of structural components  
and nonstructural attachments

$DW$  = dead load of wearing surfaces and  
utilities

$EH$  = horizontal earth pressure load

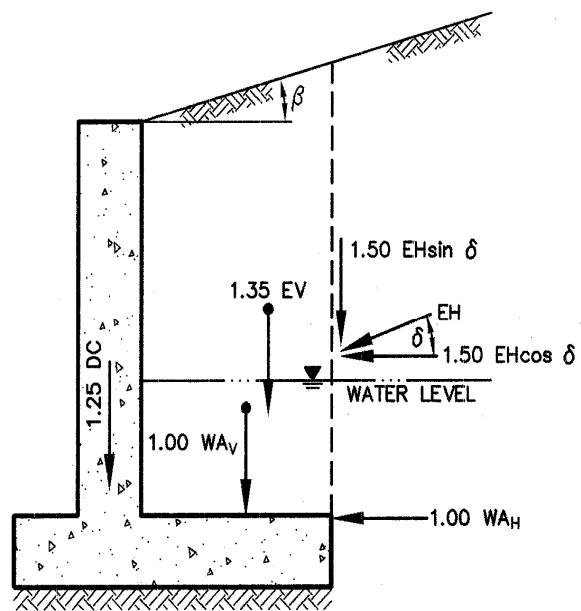

$ES$  = earth surcharge load

$EV$  = vertical pressure from dead load of  
earth fill

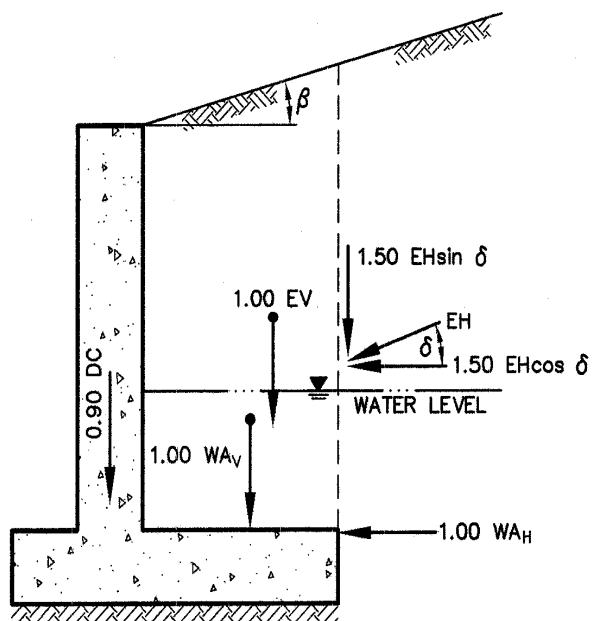

- Transient Loads

$LS$  = live load surcharge

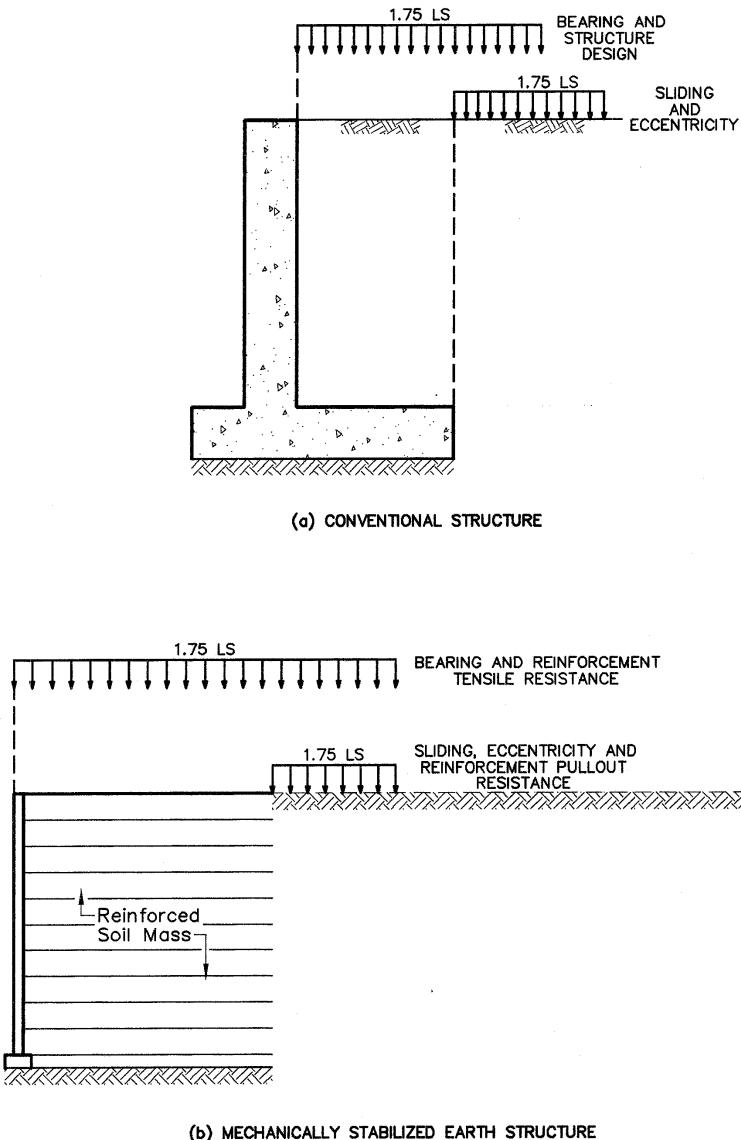

$WA$  = water load and stream pressure

**Figure C11.5.5-1—Typical Application of Load Factors for Bearing Resistance**

**Figure C11.5.5-2—Typical Application of Load Factors for Sliding and Eccentricity**

**Figure C11.5.3—Typical Application of Live Load Surcharge**

### 11.5.6—Resistance Factors

Resistance factors for geotechnical design of foundations are specified in Tables 10.5.5.2.2-1, 10.5.5.2.3-1, 10.5.5.2.4-1, and Table 11.5.6-1.

If methods other than those prescribed in these Specifications are used to estimate resistance, the resistance factors chosen shall provide the same reliability as those given in Tables 10.5.5.2.2-1, 10.5.5.2.3-1, 10.5.5.2.4-1, and Table 11.5.6-1.

Vertical elements, such as soldier piles, tangent-piles and slurry trench concrete walls shall be treated as either shallow or deep foundations, as appropriate, for purposes of estimating bearing resistance, using procedures described in Articles 10.6, 10.7, and 10.8.

### C11.5.6

The resistance factors given in Table 11.5.6-1, other than those referenced back to Section 10, were calculated by direct correlation to allowable stress design rather than reliability theory.

Since the resistance factors in Table 11.5.6-1 were based on direct correlation to allowable stress design, the differences between the resistance factors for tensile resistance of metallic versus geosynthetic reinforcement are based on historical differences in the level of safety applied to reinforcement designs for these two types of reinforcements. See Article C11.10.6.2.1 for additional comments regarding the differences between the resistance factors for metallic versus geosynthetic reinforcement.

Some increase in the prescribed resistance factors may be appropriate for design of temporary walls consistent with increased allowable stresses for temporary structures in allowable stress design.

The evaluation of overall stability of walls or earth slopes with or without a foundation unit should be investigated at the service limit state based on the Service I Load Combination and an appropriate resistance factor.

**Table 11.5.6-1—Resistance Factors for Permanent Retaining Walls**

Wall-Type and Condition		Resistance Factor
Nongravity Cantilevered and Anchored Walls		
Axial compressive resistance of vertical elements		Article 10.5 applies
Passive resistance of vertical elements		0.75
Pullout resistance of anchors <sup>(1)</sup>	<ul style="list-style-type: none"> <li>• Cohesionless (granular) soils</li> <li>• Cohesive soils</li> <li>• Rock</li> </ul>	0.65 <sup>(1)</sup> 0.70 <sup>(1)</sup> 0.50 <sup>(1)</sup>
Pullout resistance of anchors <sup>(2)</sup>	<ul style="list-style-type: none"> <li>• Where proof tests are conducted</li> </ul>	1.0 <sup>(2)</sup>
Tensile resistance of anchor tendon	<ul style="list-style-type: none"> <li>• Mild steel (e.g., <a href="#">ASTM A615</a> bars)</li> <li>• High strength steel (e.g., <a href="#">ASTM A722</a> bars)</li> </ul>	0.90 <sup>(3)</sup> 0.80 <sup>(3)</sup>
Flexural capacity of vertical elements		0.90
Mechanically Stabilized Earth Walls, Gravity Walls, and Semi-Gravity Walls		
Bearing resistance	<ul style="list-style-type: none"> <li>• Gravity and semi-gravity walls</li> <li>• MSE walls</li> </ul>	0.55 0.65
Sliding		1.0
Tensile resistance of metallic reinforcement and connectors	Strip reinforcements <sup>(4)</sup> <ul style="list-style-type: none"> <li>• Static loading</li> <li>• Combined static/earthquake loading</li> </ul> Grid reinforcements <sup>(4)(5)</sup> <ul style="list-style-type: none"> <li>• Static loading</li> <li>• Combined static/earthquake loading</li> </ul>	0.75 1.00 0.65 0.85
Tensile resistance of geosynthetic reinforcement and connectors	<ul style="list-style-type: none"> <li>• Static loading</li> <li>• Combined static/earthquake loading</li> </ul>	0.90 1.20
Pullout resistance of tensile reinforcement	<ul style="list-style-type: none"> <li>• Static loading</li> <li>• Combined static/earthquake loading</li> </ul>	0.90 1.20
Prefabricated Modular Walls		
Bearing		Article 10.5 applies
Sliding		Article 10.5 applies
Passive resistance		Article 10.5 applies

<sup>(1)</sup> Apply to presumptive ultimate unit bond stresses for preliminary design only in Article C11.9.4.2.

<sup>(2)</sup> Apply where proof test(s) are conducted on every production anchor to a load of 1.0 or greater times the factored load on the anchor.

<sup>(3)</sup> Apply to maximum proof test load for the anchor. For mild steel apply resistance factor to  $F_y$ . For high-strength steel apply the resistance factor to guaranteed ultimate tensile strength.

<sup>(4)</sup> Apply to gross cross-section less sacrificial area. For sections with holes, reduce gross area in accordance with Article 6.8.3 and apply to net section less sacrificial area.

<sup>(5)</sup> Applies to grid reinforcements connected to a rigid facing element, e.g., a concrete panel or block. For grid reinforcements connected to a flexible facing mat or which are continuous with the facing mat, use the resistance factor for strip reinforcements.

### 11.5.7—Extreme Event Limit State

The applicable load combinations and load factors specified in Table 3.4.1-1 shall be investigated. Unless otherwise specified, all resistance factors shall be taken as 1.0 when investigating the extreme event limit state.

## 11.6—ABUTMENTS AND CONVENTIONAL RETAINING WALLS

### 11.6.1—General Considerations

#### 11.6.1.1—General

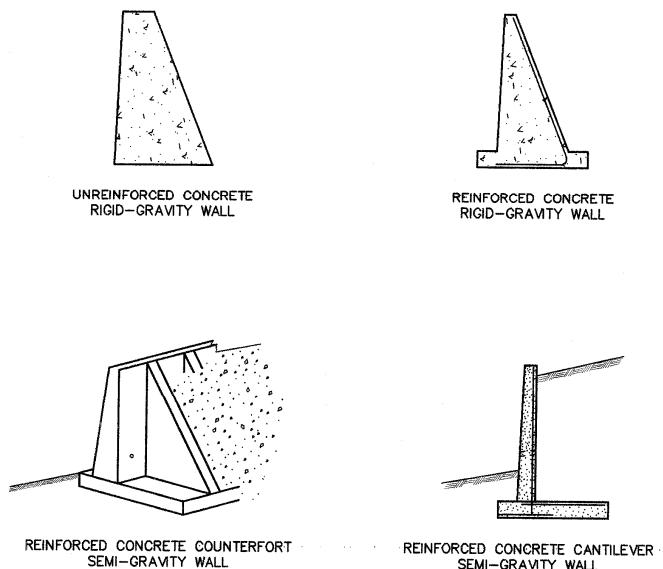

Rigid gravity and semigravity retaining walls may be used for bridge substructures or grade separation and are generally for permanent applications.

Rigid gravity and semigravity walls shall not be used without deep foundation support where the bearing soil/rock is prone to excessive total or differential settlement.

#### C11.6.1.1

Conventional retaining walls are generally classified as rigid gravity or semigravity walls, examples of which are shown in Figure C11.6.1.1-1. These types of walls can be effective for both cut and fill wall applications.

Excessive differential settlement, as defined in Article C11.6.2.2 can cause cracking, excessive bending or shear stresses in the wall, or rotation of the wall structure.

**Figure C11.6.1.1-1—Typical Rigid Gravity and Semigravity Walls**

#### 11.6.1.2—Loading

Abutments and retaining walls shall be investigated for:

- Lateral earth and water pressures, including any live and dead load surcharge;
- The self weight of the abutment/wall;
- Loads applied from the bridge superstructure;

#### C11.6.1.2

- Temperature and shrinkage deformation effects; and
- Earthquake loads, as specified herein, in Section 3 and elsewhere in these Specifications.

The provisions of Articles 3.11.5 and 11.5.5 shall apply. For stability computations, the earth loads shall be multiplied by the maximum and/or minimum load factors given in Table 3.4.1-2, as appropriate.

The design shall be investigated for any combination of forces which may produce the most severe condition of loading. The design of abutments on mechanically stabilized earth and prefabricated modular walls shall be in accordance with Articles 11.10.11 and 11.11.6.

For computing load effects in abutments, the weight of filling material directly over an inclined or stepped rear face, or over the base of a reinforced concrete spread footing may be considered as part of the effective weight of the abutment.

Where spread footings are used, the rear projection shall be designed as a cantilever supported at the abutment stem and loaded with the full weight of the superimposed material, unless a more exact method is used.

#### **11.6.1.3—Integral Abutments**

Integral abutments shall be designed to resist and/or absorb creep, shrinkage and thermal deformations of the superstructure.

Movement calculations shall consider temperature, creep, and long-term prestress shortening in determining potential movements of abutments.

Maximum span lengths, design considerations, details should comply with recommendations outlined in FHWA Technical Advisory T 5140.13 (1980), except where substantial local experience indicates otherwise.

To avoid water intrusion behind the abutment, the approach slab should be connected directly to the abutment (not to wingwalls), and appropriate provisions should be made to provide for drainage of any entrapped water.

#### **11.6.1.4 —Wingwalls**

Wingwalls may either be designed as monolithic with the abutments, or be separated from the abutment wall with an expansion joint and designed to be free standing.

The wingwall lengths shall be computed using the required roadway slopes. Wingwalls shall be of sufficient length to retain the roadway embankment and to furnish protection against erosion.

Cohesive backfills are difficult to compact. Because of the creep of cohesive soils, walls with cohesive backfills designed for active earth pressures will continue to move gradually throughout their lives, especially when the backfill is soaked by rain or rising groundwater levels. Therefore, even if wall movements are tolerable, walls backfilled with cohesive soils should be designed with extreme caution for pressures between the active and at-rest cases assuming the most unfavorable conditions. Consideration must be given for the development of pore water pressure within the soil mass in accordance with Article 3.11.3. Appropriate drainage provisions should be provided to prevent hydrostatic and seepage forces from developing behind the wall. In no case shall highly plastic clay be used for backfill.

#### **C11.6.1.3**

Deformations are discussed in Article 3.12.

Integral abutments should not be constructed on spread footings founded or keyed into rock unless one end of the span is free to displace longitudinally.

### 11.6.1.5—Reinforcement

#### 11.6.1.5.1—Conventional Walls and Abutments

Reinforcement to resist the formation of temperature and shrinkage cracks shall be designed as specified in Article 5.10.8.

#### 11.6.1.5.2—Wingwalls

Reinforcing bars or suitable rolled sections shall be spaced across the junction between wingwalls and abutments to tie them together. Such bars shall extend into the masonry on each side of the joint far enough to develop the strength of the bar as specified for bar reinforcement, and shall vary in length so as to avoid planes of weakness in the concrete at their ends. If bars are not used, an expansion joint shall be provided and the wingwall shall be keyed into the body of the abutment.

### 11.6.1.6—Expansion and Contraction Joints

Contraction joints shall be provided at intervals not exceeding 30.0 ft and expansion joints at intervals not exceeding 90.0 ft for conventional retaining walls and abutments. All joints shall be filled with approved filling material to ensure the function of the joint. Joints in abutments shall be located approximately midway between the longitudinal members bearing on the abutments.

### 11.6.2—Movement and Stability at the Service Limit State

#### 11.6.2.1—Abutments

The provisions of Articles 10.6.2.4, 10.6.2.5, 10.7.2.3 through 10.7.2.5, 10.8.2.2 through 10.8.2.4, and 11.5.2 shall apply as applicable.

#### 11.6.2.2—Conventional Retaining Walls

The provisions of Articles 10.6.2.4, 10.6.2.5, 10.7.2.3 through 10.7.2.5, 10.8.2.2 through 10.8.2.4, and 11.5.2 apply as applicable.

#### C11.6.2.2

For a conventional reinforced concrete retaining wall, experience suggests that differential wall settlements on the order of 1 in 500 to 1 in 1,000 may overstress the wall.

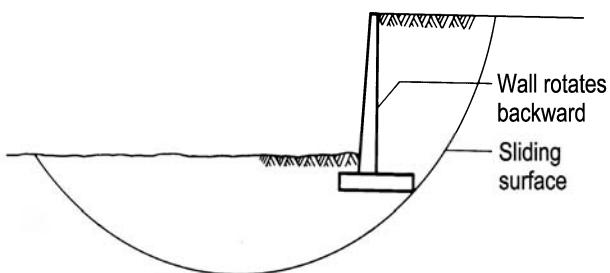

### 11.6.2.3—Overall Stability

The overall stability of the retaining wall, retained slope and foundation soil or rock shall be evaluated for all walls using limiting equilibrium methods of analysis. The overall stability of temporary cut slopes to facilitate construction shall also be evaluated. Special exploration, testing and analyses may be required for bridge abutments or retaining walls constructed over soft deposits.

The evaluation of overall stability of earth slopes with or without a foundation unit should be investigated at the Service I Load Combination and an appropriate resistance factor. In lieu of better information, the resistance factor,  $\phi$ , may be taken as:

- Where the geotechnical parameters are well defined, and the slope does not support or contain a structural element.....0.75
- Where the geotechnical parameters are based on limited information, or the slope contains or supports a structural element .....0.65

### C11.6.2.3

**Figure C11.6.2.3-1—Retaining Wall Overall Stability Failure**

Figure C11.6.2.3-1 shows a retaining wall overall stability failure. Overall stability is a slope stability issue, and, therefore, is considered a service limit state check.

The Modified Bishop, simplified Janbu or Spencer methods of analysis may be used.

Soft soil deposits may be subject to consolidation and/or lateral flow which could result in unacceptable long-term settlements or horizontal movements.

With regard to selection of a resistance factor for evaluation of overall stability of walls, examples of structural elements supported by a wall that may justify the use of the 0.65 resistance factor include a bridge or pipe arch foundation, a building foundation, a pipeline, a critical utility, or another retaining wall. If the structural element is located beyond the failure surface for external stability behind the wall illustrated conceptually in Figure 11.10.2-1, a resistance factor of 0.75 may be used.

Available slope stability programs produce a single factor of safety,  $FS$ . The specified resistance factors are essentially the inverse of the  $FS$  that should be targeted in the slope stability program.

### 11.6.3—Bearing Resistance and Stability at the Strength Limit State

#### 11.6.3.1—General

Abutments and retaining walls shall be proportioned to ensure stability against bearing capacity failure, overturning, and sliding. Safety against deep-seated foundation failure shall also be investigated, in accordance with the provisions of Article 10.6.2.5.

### 11.6.3.2—Bearing Resistance

Bearing resistance shall be investigated at the strength limit state using factored loads and resistances, assuming the following soil pressure distributions:

- Where the wall is supported by a soil foundation:

the vertical stress shall be calculated assuming a uniformly distributed pressure over an effective base area as shown in Figure 11.6.3.2-1.

The vertical stress shall be calculated as follows:

$$\sigma_v = \frac{\Sigma V}{B - 2e} \quad (11.6.3.2-1)$$

where:

$\Sigma V$  = the summation of vertical forces, and the other variables are as defined in Figure 11.6.3.2-1

- Where the wall is supported by a rock foundation:

the vertical stress shall be calculated assuming a linearly distributed pressure over an effective base area as shown in Figure 11.6.3.2-2. If the resultant is within the middle one-third of the base:

$$\sigma_{vmax} = \frac{\Sigma V}{B} \left( 1 + 6 \frac{e}{B} \right) \quad (11.6.3.2-2)$$

$$\sigma_{vmin} = \frac{\Sigma V}{B} \left( 1 - 6 \frac{e}{B} \right) \quad (11.6.3.2-3)$$

where the variables are as defined in Figure 11.6.3.2-2. If the resultant is outside the middle one-third of the base:

$$\sigma_{vmax} = \frac{2 \Sigma V}{3[(B/2) - e]} \quad (11.6.3.2-4)$$

$$\sigma_{vmin} = 0 \quad (11.6.3.2-5)$$

where the variables are as defined in Figure 11.6.3.2-2.

### C11.6.3.2

See Figure 11.10.10.1-1 for an example of how to calculate the vertical bearing stress where the loading is more complex. Though this figure shows the application of superposition principles to mechanically stabilized earth walls, these principles can also be directly applied to conventional walls.

See Article C11.5.5 for application of load factors for bearing resistance and eccentricity.

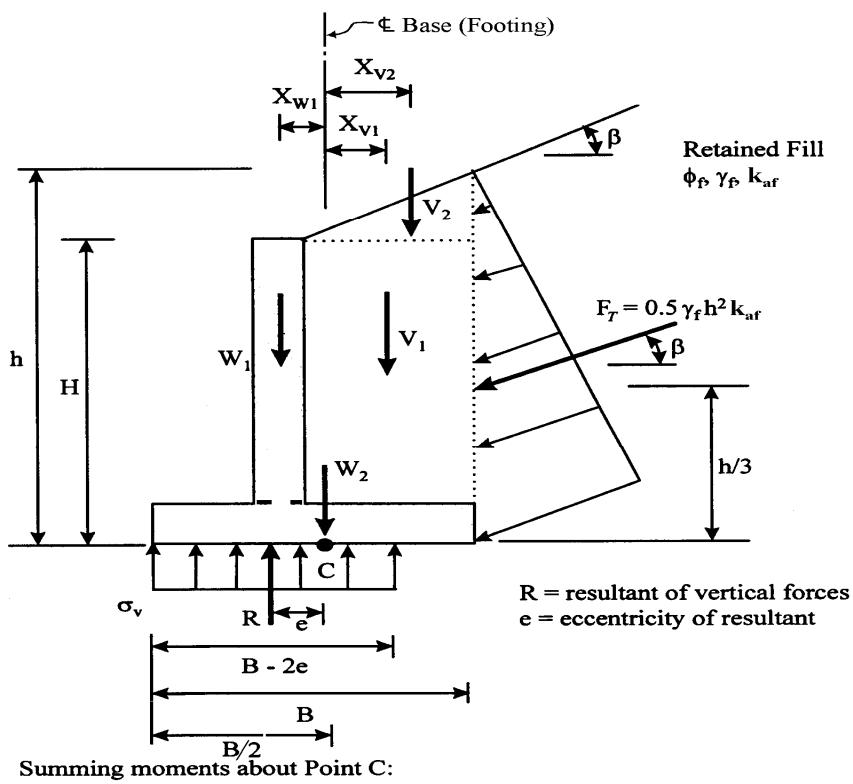

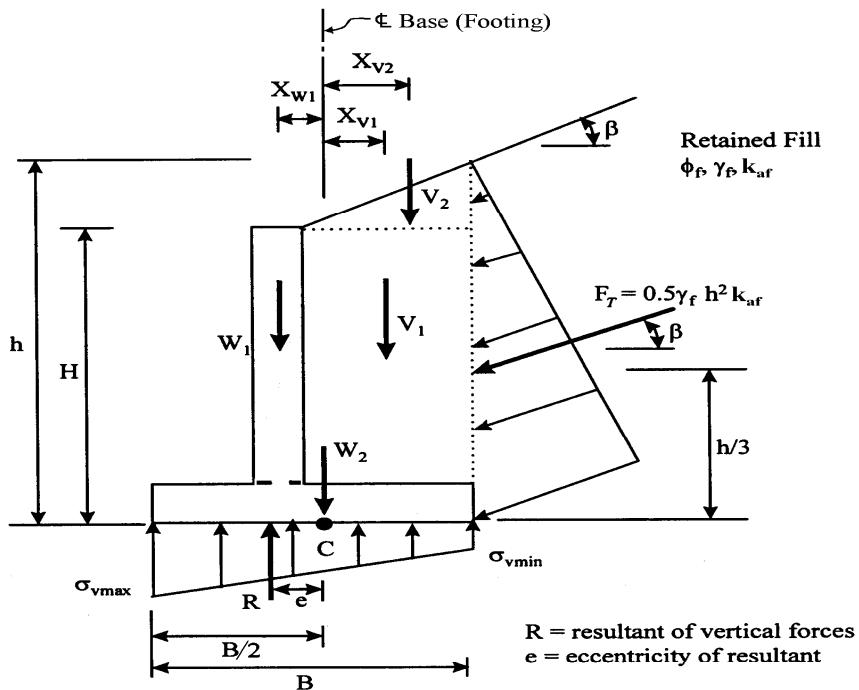

Figure 11.6.3.2-1—Bearing Stress Criteria for Conventional Wall Foundations on Soil

If  $e > B/6$ ,  $\sigma_{v\min}$  will drop to zero, and as "e" increases, the portion of the heel of the footing which has zero vertical stress increases.

Summing moments about Point C:

$$e = \frac{(F_T \cos \beta)h/3 - (F_T \sin \beta)B/2 - V_1 X_{v1} - V_2 X_{v2} + W_1 X_{w1}}{V_1 + V_2 + W_1 + W_2 + F_T \sin \beta}$$

Figure 11.6.3.2-2—Bearing Stress Criteria for Conventional Wall Foundations on Rock

### 11.6.3.3—Overturning

For foundations on soil, the location of the resultant of the reaction forces shall be within the middle one-half of the base width.

For foundations on rock, the location of the resultant of the reaction forces shall be within the middle three-fourths of the base width.

### C11.6.3.3

The specified criteria for the location of the resultant, coupled with investigation of the bearing pressure, replace the investigation of the ratio of stabilizing moment to overturning moment. Location of the resultant within the middle one-half of the base width for foundations on soil is based on the use of plastic bearing pressure distribution for the limit state.

### 11.6.3.4—Subsurface Erosion

For walls constructed along rivers and streams, scour of foundation materials shall be evaluated during design, as specified in Article 2.6.4.4.2. Where potential problem conditions are anticipated, adequate protective measures shall be incorporated in the design.

The provisions of Article 10.6.1.2 shall apply.

The hydraulic gradient shall not exceed:

- For silts and cohesive soils: 0.20
- For other cohesionless soils: 0.30

Where water seeps beneath a wall, the effects of uplift and seepage forces shall be considered.

### C11.6.3.4

The measures most commonly used to ensure that piping does not occur are:

- Seepage control,
- Reduction of hydraulic gradient, and
- Protective filters.

Seepage effects may be investigated by constructing a flow net, or in certain circumstances, by using generally accepted simplified methods.

**11.6.3.5—Passive Resistance****C11.6.3.5**

Passive resistance shall be neglected in stability computations, unless the base of the wall extends below the depth of maximum scour, freeze-thaw or other disturbances. In the latter case, only the embedment below the greater of these depths shall be considered effective.

Where passive resistance is utilized to ensure adequate wall stability, the calculated passive resistance of soil in front of abutments and conventional walls shall be sufficient to prevent unacceptable forward movement of the wall.

The passive resistance shall be neglected if the soil providing passive resistance is, or is likely to become soft, loose, or disturbed, or if the contact between the soil and wall is not tight.

Unacceptable deformations may occur before passive resistance is mobilized. Approximate deformations required to mobilize passive resistance are discussed in Article C3.11.1, where  $H$  in Table C3.11.1-1 is the effective depth of passive restraint.

**11.6.3.6—Sliding**

The provisions of Article 10.6.3.4 shall apply.

**11.6.4—Safety against Structural Failure**

The structural design of individual wall elements and wall foundations shall comply with the provisions of Sections 5, 6, 7, and 8.

The provisions of Article 10.6.1.3 shall be used to determine the distribution of contact pressure for structural design of footings.

**11.6.5—Seismic Design****C11.6.5**

The effect of earthquake loading on multi-span bridges shall be investigated using the extreme event limit state of Table 3.4.1-1 with resistance factors  $\phi = 1.0$ , an accepted methodology in Article 4.7.4.3, and the provisions of Article 3.10.9.2, 3.10.9.3, or 3.10.9.4, as appropriate.

Earthquake loading on single-span bridges shall be investigated in accordance with Articles 4.7.4.2 and 3.10.9.1.

For foundations on soil and rock, the location of the resultant of the reaction forces shall be within the middle two-thirds of the base for  $\gamma_{EQ} = 0.0$  and within the middle eight-tenths of the base for  $\gamma_{EQ} = 1.0$ .

In general, the pseudo-static approach developed by Mononobe and Okabe may be used to estimate the equivalent static forces for seismic loads for gravity and semigravity retaining walls. The estimation of seismic design forces should account for wall inertia forces in addition to the equivalent static forces. For flexible cantilevered walls, forces resulting from wall inertia effects may be ignored in estimating the seismic design forces. Where a wall supports a bridge structure, the seismic design forces should also include seismic forces transferred from the bridge through bearing supports which do not freely slide, e.g., elastomeric bearings. Refer to Appendix A11.

For values of  $\gamma_{EQ}$  between 0.0 and 1.0, the restrictions of the location of the resultant shall be obtained by linear interpolation of the values given in this Article.

Where all of the following conditions are met, seismic lateral loads may be reduced as provided in Article C11.6.5, as a result of lateral wall movement due to sliding, from values determined using the Mononobe-Okabe method specified in Article A11.1.1.1:

- the wall system and any structures supported by the wall can tolerate lateral movement resulting from sliding of the structure.
- the wall base is unrestrained against sliding, other than soil friction along its base and minimal soil passive resistance.
- If the wall functions as an abutment, the top of the wall must also be unrestrained, e.g., the superstructure is supported by sliding bearings.

For overall stability of the retaining wall when earthquake loading is included, a resistance factor,  $\phi$ , of 0.9 shall be used.

Procedures reducing seismic load due to lateral wall movement are provided in Article A11.1.1.2. In general, this reduction only applies to gravity and semigravity walls. Though the specifications in Article A11.1.1.2 relate to gravity and semigravity walls, these provisions may also apply to other types of walls provided the three conditions listed in Article A11.6.5 are met.

Kavazanjian et al., (1997) further simplified the relationship provided in Eq. A11.1.1.2-1 as follows, assuming that the velocity, in the absence of information on the time history of the ground motion, is equal to  $30A$ :

$$k_h = 0.74 A_s \left( \frac{A_s}{d} \right)^{0.25} \quad (\text{C11.6.5-1})$$

where:

$A_s$  = earthquake ground acceleration coefficient as specified in Eq. 3.10.4.2-2 (dim.)

$k_h$  = horizontal seismic acceleration coefficient (dim.)

$d$  = lateral wall displacement (in.)

This equation should not be used for displacements of less than 1.0 in. or greater than approximately 8.0 in., as this equation is an approximation of a more rigorous Newmark analysis. In general, typical practice among states located in seismically active areas is to design walls for reduced seismic pressures corresponding to 2.0 in. to 4.0 in. of displacement. However, the amount of deformation which is tolerable will depend on the nature of the wall and what it supports, as well as what is in front of the wall.

In addition to whether or not the wall can tolerate lateral deformation, it is recommended that this simplified approach not be used for walls which have a complex geometry, such as stacked walls, MSE walls with trapezoidal sections, or back-to-back walls supporting narrow ramps, for walls which are very tall (over 50.0 ft), nor for walls where the ground acceleration coefficient,  $A_s$ , is 0.3 or higher. In such cases, a specialist should be retained to evaluate the anticipated deformation response of the structure, as potentially unacceptable permanent lateral and vertical wall deformations could occur even if design criteria based on this pseudo static approach are met.

## 11.6.6—Drainage

Backfills behind abutments and retaining walls shall be drained or, if drainage cannot be provided, the abutment or wall shall be designed for loads due to earth pressure, plus full hydrostatic pressure due to water in the backfill.

## C11.6.6

Weep holes or geocomposite panel drains at the wall face do not assure fully drained conditions. Drainage systems should be designed to completely drain the entire retained soil volume behind the retaining wall face.

## 11.7—PIERS

### 11.7.1—Load Effects in Piers

Piers shall be designed to transmit the loads on the superstructure, and the loads acting on the pier itself, onto the foundation. The loads and load combinations shall be as specified in Section 3.

The structural design of piers shall be in accordance with the provisions of Sections 5, 6, 7, and 8, as appropriate.

### 11.7.2—Pier Protection

#### 11.7.2.1—Collision

Where the possibility of collision exists from highway or river traffic, an appropriate risk analysis should be made to determine the degree of impact resistance to be provided and/or the appropriate protection system. Collision loads shall be determined as specified in Articles 3.6.5 and 3.14.

#### 11.7.2.2—Collision Walls

Collision walls may be required by railroad owners if the pier is in close proximity to the railroad.

#### C11.7.2.2

Collision walls are usually required by the railroad owner if the column is within 25.0 ft of the rail. Some railroad owners require a collision wall 6.5 ft above the top of the rail between columns for railroad overpasses.

#### 11.7.2.3—Scour

The scour potential shall be determined and the design shall be developed to minimize failure from this condition as specified in Article 2.6.4.4.2.

#### 11.7.2.4—Facing

Where appropriate, the pier nose should be designed to effectively break up or deflect floating ice or drift.

#### C11.7.2.4

In these situations, pier life can be extended by facing the nosing with steel plates or angles, and by facing the pier with granite.

## 11.8—NONGRAVITY CANTILEVERED WALLS

### 11.8.1—General

Nongravity cantilevered walls may be considered for temporary and permanent support of stable and unstable soil and rock masses. The feasibility of using a nongravity cantilevered wall at a particular location shall be based on the suitability of soil and rock conditions within the depth of vertical element embedment to support the wall.

### 11.8.2—Loading

The provisions of Article 11.6.1.2 shall apply. The load factor for lateral earth pressure ( $EH$ ) shall be applied to the lateral earth pressures for the design of nongravity cantilevered walls.

#### C11.8.1

Depending on soil conditions, nongravity cantilevered walls less than about 10.0 to 15.0 ft in height are usually feasible, with the exception of cylinder or tangent pile walls, where greater heights can be used.

#### C11.8.2

Lateral earth pressure distributions for design of nongravity cantilevered walls are provided in Article 3.11.5.6.

### 11.8.3—Movement and Stability at the Service Limit State

#### 11.8.3.1—Movement

The provisions of Articles 10.7.2.2 and 10.8.2.1 shall apply. The effects of wall movements on adjacent facilities shall be considered in the selection of the design earth pressures in accordance with the provisions of Article 3.11.1.

#### 11.8.3.2—Overall Stability

The provisions of Article 11.6.2.3 shall apply.

#### C11.8.3.1

Table C3.11.1-1 provides approximate magnitudes of relative movements required to achieve active earth pressure conditions in the retained soil and passive earth pressure conditions in the resisting soil.

#### C11.8.3.2

Use of vertical wall elements to provide resistance against overall stability failure is described in Article C11.9.3.2. Discrete vertical elements penetrating across deep failure planes can provide resistance against overall stability failure. The magnitude of resistance will depend on the size, type, and spacing of the vertical elements.

### 11.8.4—Safety against Soil Failure at the Strength Limit State

#### 11.8.4.1—Overall Stability

The provisions of Article 11.6.2.3 shall apply.

The provisions of Article 11.6.3.5 shall apply.

Vertical elements shall be designed to support the full design earth, surcharge and water pressures between the elements. In determining the embedment depth to mobilize passive resistance, consideration shall be given to planes of weakness, e.g., slickensides, bedding planes, and joint sets that could reduce the strength of the soil or rock determined by field or laboratory tests. Embedment in intact rock, including massive to appreciably jointed rock which should not fail through a joint surface, shall be based on the shear strength of the rock mass.

#### C11.8.4.1

Discrete vertical elements penetrating across deep failure planes can provide resistance against failure. The magnitude of resistance will depend on the size, type, and spacing of vertical elements.

The maximum spacing between vertical supporting elements depends on the relative stiffness of the vertical elements. Spans of 6.0 to 10.0 ft are typical, depending on the type and size of facing.

In determining the embedment depth of vertical wall elements, consideration should be given to the presence of planes of weakness in the soil or rock that could result in a reduction of passive resistance. For laminated, jointed, or fractured soils and rocks, the residual strength along planes of weakness should be considered in the design and, where the planes are oriented at other than an angle of  $(45 \text{ degrees} - \phi'_f/2)$  from the horizontal in soil or  $45 \text{ degrees}$  from the horizontal in rock toward the excavation, the orientation of the planes should also be considered. Where the wall is located on a bench above a deeper excavation, consideration should be given to the potential for bearing failure of a supporting wedge of soil or rock through intact materials along planes of weakness.

In designing permanent nongravity cantilevered walls with continuous vertical elements, the simplified earth pressure distributions in Figure 3.11.5.6-3 may be used with the following procedure (Teng, 1962):

- Determine the magnitude of lateral pressure on the wall due to earth pressure, surcharge loads and differential water pressure over the design height of the wall using  $k_{a1}$ .

- Determine the magnitude of lateral pressure on the wall due to earth pressure, surcharge loads and differential water pressure over the design height of the wall using  $k_{a2}$ .
- Determine in the following equation the value  $x$  as defined in Figure 3.11.5.6-3 to determine the distribution of net passive pressure in front of the wall below the design height:

$$x = [\gamma k_{a2} \gamma'_{s1} H] / [(\phi k_{p2} - \gamma k_{a2}) \gamma'_{s2}] \quad (\text{C11.8.4.1-1})$$

where:

$\gamma$  = load factor for horizontal earth pressure,  $EH$  (dim.)

$k_{a2}$  = the active earth pressure coefficient for soil 2 (dim.)

$\gamma'_{s1}$  = the effective soil unit weight for soil 1 (kcf)

$H$  = the design height of the wall (ft)

$\phi$  = the resistance factor for passive resistance in front of the wall (dim.)

$k_{p2}$  = the passive earth pressure coefficient for soil 2 (dim.)

$\gamma'_{s2}$  = the effective soil unit weight for soil 2 (kcf)

- Sum moments about the point of action of  $F$  (the base of the wall) to determine the embedment ( $D_o$ ) for which the net passive pressure is sufficient to provide moment equilibrium.
- Determine the depth at which the shear in the wall is zero, i.e., the point at which the areas of the driving and resisting pressure diagrams are equivalent.
- Calculate the maximum bending moment at the point of zero shear.
- Calculate the design depth,  $D=1.2D_o$ , to account for errors inherent in the simplified passive pressure distribution.

## 11.8.5—Safety against Structural Failure

### 11.8.5.1—Vertical Wall Elements

Vertical wall elements shall be designed to resist all horizontal earth pressure, surcharge, water pressure, and earthquake loadings.

### C11.8.5.1

Discrete vertical wall elements include driven piles, drilled shafts, and auger-cast piles, i.e., piles and built-up sections installed in preaugered holes.

Continuous vertical wall elements are continuous throughout both their length and width, although vertical joints may prevent shear and/or moment transfer between adjacent sections. Continuous vertical wall elements include sheet piles, precast or cast-in-place concrete diaphragm wall panels, tangent-piles, and tangent drilled shafts.

The maximum bending moments and shears in vertical wall elements may be determined using the loading diagrams in Article 3.11.5.6, and appropriate load and resistance factors.

### 11.8.5.2—Facing

The maximum spacing between discrete vertical wall elements shall be determined based on the relative stiffness of the vertical elements and facing, the type and condition of soil to be supported, and the type and condition of the soil in which the vertical wall elements are embedded. Facing may be designed assuming simple support between elements, with or without soil arching, or assuming continuous support over several elements.

If timber facing is used, it shall be stress-grade pressure-treated lumber in conformance with Section 8. If timber is used where conditions are favorable for the growth of decay-producing organisms, wood should be pressure-treated with a wood preservative unless the heartwood of a naturally decay-resistant species is available and is considered adequate with respect to the decay hazard and expected service life of the structure.

### C11.8.5.2

In lieu of other suitable methods, for preliminary design the maximum bending moments in facing may be determined as follows:

- For simple spans without soil arching:

$$M_{max} = 0.125pL^2 \quad (\text{C11.8.5.2-1})$$

- For simple spans with soil arching:

$$M_{max} = 0.083pL^2 \quad (\text{C11.8.5.2-2})$$

- For continuous spans without soil arching:

$$M_{max} = 0.1pL^2 \quad (\text{C11.8.5.2-3})$$

- For continuous spans with soil arching:

$$M_{max} = 0.083pL^2 \quad (\text{C11.8.5.2-4})$$

where:

$M_{max}$  = factored flexural moment on a unit width or height of facing (kip-ft/ft)

$p$  = average factored lateral pressure, including earth, surcharge and water pressure acting on the section of facing being considered (ksf/ft)

$L$  = spacing between vertical elements or other facing supports (ft)

If the variations in lateral pressure with depth are large, moment diagrams should be constructed to provide more accuracy. The facing design may be varied with depth.

Eq. C11.8.5.2-1 is applicable for simply supported facing behind which the soil will not arch between vertical supports, e.g., in soft cohesive soils or for rigid concrete facing placed tightly against the in-place soil. Eq. C11.8.5.2-2 is applicable for simply supported facing behind which the soil will arch between vertical supports, e.g., in granular or stiff cohesive soils with flexible facing or rigid facing behind which there is sufficient space to permit the in-place soil to arch. Eqs. C11.8.5.2-3 and C11.8.5.2-14 are applicable for facing which is continuous over several vertical supports, e.g., reinforced shotcrete or concrete.

### 11.8.6—Seismic Design

The effect of earthquake loading shall be investigated using the Extreme Event I limit state of Table 3.4.1-1 with resistance factor  $\phi=1.0$  and load factor  $\gamma_p=1.0$  and an accepted methodology.

### 11.8.7—Corrosion Protection

The level and extent of corrosion protection shall be a function of the ground environment and the potential consequences of a wall failure.

### 11.8.8—Drainage

The provisions of Article 3.11.3 shall apply.

Seepage shall be controlled by installation of a drainage medium behind the facing with outlets at or near the base of the wall. Drainage panels shall maintain their drainage characteristics under the design earth pressures and surcharge loadings, and shall extend from the base of the wall to a level 1.0 ft below the top of the wall.

Where thin drainage panels are used behind walls, and saturated or moist soil behind the panels may be subjected to freezing and expansion, either insulation shall be provided on the walls to prevent freezing of the soil, or the wall shall be designed for the pressures exerted on the wall by frozen soil.

### C11.8.6

In general, the pseudo-static approach developed by Mononobe and Okabe may be used to estimate the equivalent static forces provided the maximum lateral earth pressure, active and passive are computed using a seismic coefficient,  $k_h = 0.5A_S$ . Forces resulting from wall inertia effects may be ignored in estimating the seismic lateral earth pressure. Refer to Appendix A11.

### C11.8.7

Corrosion protection for piles and miscellaneous hardware and material should be consistent with the design life of the structure.

### C11.8.8

In general, the potential for development of hydrostatic pressures behind walls with discrete vertical elements and lagging is limited due to the presence of openings in the lagging, and the disturbance of soil behind lagging as the wall is constructed. However, the potential for leakage through the wall should not be counted upon where the ground water level exceeds one-third the height of the wall because of the potential for plugging and clogging of openings in the wall with time by migration of soil fines. It is probable that, under such conditions, a wall with continuous vertical elements, i.e., a cutoff wall constructed with a drainage system designed to handle anticipated flows will be required.

Water pressures may be considered reduced in design only if positive drainage, e.g., drainage blanket, geocomposite drainage panels, gravel drains with outlet pipes is provided to prevent buildup of hydrostatic pressure behind the wall. Thin drains at the back of the wall face may not completely relieve hydrostatic pressure and may increase seepage forces on the back of the wall face due to rainwater infiltration, Terzaghi and Peck (1967), and Cedergren (1989). The effectiveness of drainage control measures should be evaluated by seepage analyses.

## 11.9—ANCHORED WALLS

### 11.9.1—General

Anchored walls, whose elements may be proprietary, employ grouted in anchor elements, vertical wall elements and facing.

Anchored walls, illustrated in Figure 11.9.1-1, may be considered for both temporary and permanent support of stable and unstable soil and rock masses.

The feasibility of using an anchored wall at a particular location should be based on the suitability of subsurface soil and rock conditions within the bonded anchor stressing zone.

Where fill is placed behind a wall, either around or above the unbonded length, special designs and construction specifications shall be provided to prevent anchor damage.

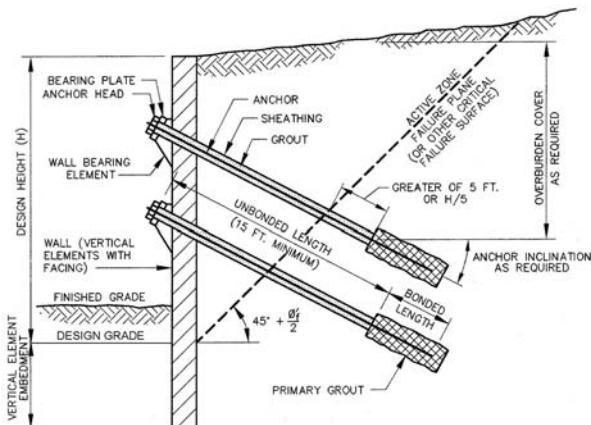

### C11.9.1

Depending on soil conditions, anchors are usually required for support of both temporary and permanent nongravity cantilevered walls higher than about 10.0 to 15.0 ft.

The availability or ability to obtain underground easements and proximity of buried facilities to anchor locations should also be considered in assessing feasibility.

Anchored walls in cuts are typically constructed from the top of the wall down to the base of the wall. Anchored walls in fill must include provisions to protect against anchor damage resulting from backfill and subsoil settlement or backfill and compaction activities above the anchors.

The minimum distance between the front of the bond zone and the active zone behind the wall of 5.0 ft or  $H/5$  is needed to insure that no load from the bonded zone is transferred into the no load zone due to load transfer through the grout column in the no load zone.

**Figure 11.9.1-1—Anchored Wall Nomenclature and Anchor Embedment Guidelines**

### 11.9.2—Loading

The provisions of Article 11.6.1.2 shall apply, except that shrinkage and temperature effects need not be considered.

### C11.9.2

Lateral earth pressures on anchored walls are a function of the rigidity of the wall-anchor system, soil conditions, method and sequence of construction, and level of prestress imposed by the anchors. Apparent earth pressure diagrams that are commonly used can be found in Article 3.11.5.7 and Sabatini et al. (1999).

### 11.9.3—Movement and Stability at the Service Limit State

#### 11.9.3.1—Movement

The provisions of Articles 10.6.2.2, 10.7.2.2, and 10.8.2.1 shall apply.

The effects of wall movements on adjacent facilities shall be considered in the development of the wall design.

#### C11.9.3.1

Settlement of vertical wall elements can cause reduction of anchor loads, and should be considered in design.

The settlement profiles in Figure C11.9.3.1-1 were recommended by Clough and O'Rourke (1990) to estimate ground surface settlements adjacent to braced or anchored excavations caused during the excavation and bracing stages of construction. Significant settlements may also be caused by other construction activities, e.g., dewatering or deep foundation construction within the excavation, or by poor construction techniques, e.g., soldier pile, lagging, or anchor installation. The field measurements used to develop Figure C11.9.3.1-1 were screened by the authors to not include movements caused by other construction activities or poor construction techniques. Therefore, such movements should be estimated separately.

Where noted in the definition of the various curves in Figure C11.9.3.1-1, the basal heave ratio,  $R_{BH}$ , shall be taken as:

$$R_{BH} = \frac{5.1S_u}{\gamma_s H + q_s} \quad (\text{C11.9.3.1-1})$$

where:

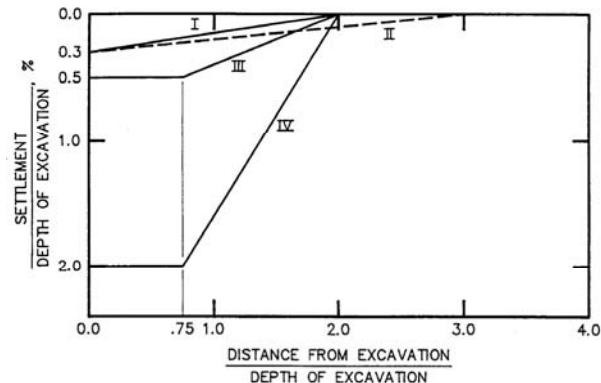

$S_u$  = undrained shear strength of cohesive soil (ksf)

$\gamma_s$  = unit weight of soil (kcf)

$H$  = height of wall (ft)

$q_s$  = surcharge pressure (ksf)

See Sabatini et al. (1999) for additional information on the effect of anchored wall construction and design on wall movement.

Curve I = Sand  
 Curve II = Stiff to very hard clay  
 Curve III = Soft to medium clay,  $R_{BH} = 2.0$   
 Curve IV = Soft to medium clay,  $R_{BH} = 1.2$

**Figure C11.9.3.1-1—Settlement Profiles behind Braced or Anchored Walls (adapted from Clough and O'Rourke, 1990)**

### 11.9.3.2—Overall Stability

The provisions of Article 11.6.2.3 shall apply.

### C11.9.3.2

Detailed guidance for evaluating the overall stability of anchored wall systems, including how to incorporate anchor forces in limit equilibrium slope stability analyses, is provided by Sabatini et al. (1999).

The effect of discrete vertical elements penetrating deep failure planes and acting as in-situ soil improvement may be negligible if the percentage of reinforcement provided by the vertical elements along the failure surface is small. However, it is possible to consider the effect of the discrete vertical elements by modeling the elements as a cohesion along the failure surface, or by evaluating the passive capacity of the elements.

### 11.9.4—Safety against Soil Failure

#### 11.9.4.1—Bearing Resistance

The provisions of Articles 10.6.3, 10.7.3, and 10.8.3 shall apply.

Bearing resistance shall be determined assuming that all vertical components of loads are transferred to the embedded section of the vertical wall elements.

#### C11.9.4.1

For drilled in place vertical wall elements, e.g., drilled-in soldier piles, in sands, if the  $\beta$ -method is used to calculate the skin friction capacity, the depth  $z$  should be referenced to the top of the wall. The vertical overburden stress,  $\sigma_v'$ , however, should be calculated with reference to the elevation of the midheight of the exposed wall, with  $\beta$  and  $\sigma_v'$  evaluated at the midpoint of each soil layer.

### 11.9.4.2—Anchor Pullout Capacity

Prestressed anchors shall be designed to resist pullout of the bonded length in soil or rock. The factored pullout resistance of a straight shaft anchor in soil or rock,  $Q_R$ , is determined as:

$$Q_R = \phi Q_n = \phi \pi d \tau_a L_b \quad (11.9.4.2-1)$$

where:

$\phi$  = resistance factor for anchor pullout (dim.)

$Q_n$  = nominal anchor pullout resistance (kips)

$d$  = diameter of anchor drill hole (ft)

$\tau_n$  = nominal anchor bond stress (ksf)

$L_b$  = anchor bond length (ft)

For preliminary design, the resistance of anchors may either be based on the results of anchor pullout load tests; estimated based on a review of geologic and boring data, soil and rock samples, laboratory testing and previous experience; or estimated using published soil/rock-grout bond guidelines. For final design, the contract documents may require preproduction tests such as pullout tests or extended creep tests on sacrificial anchors be conducted to establish anchor lengths and capacities that are consistent with the contractor's chosen method of anchor installation. Either performance or proof tests shall be conducted on every production anchor to 1.0 or greater times the factored load to verify capacity.

### C11.9.4.2

Anchor pullout capacity is influenced by soil and rock conditions, method of anchor hole advancement, hole diameter, bonded length, grout type and grouting pressure. Information on anchor pullout capacity may be found in Sabatini et al. (1999), PTI (1996), Cheney (1984) and Weatherby (1982). As a guide, the presumptive values provided in Tables C11.9.4.2-1, C11.9.4.2-2, and C11.9.4.2-3 may be used to estimate the nominal (ultimate) bond for small diameter anchors installed in cohesive soils, cohesionless soils and rock, respectively. It should be recognized that the values provided in the tables may be conservative.

**Table C11.9.4.2-1—Presumptive Ultimate Unit Bond Stress for Anchors in Cohesive Soils**

Anchor/Soil Type (Grout Pressure)	Soil Stiffness or Unconfined Compressive Strength (tsf)	Presumptive Ultimate Unit Bond Stress, $\tau_n$ (ksf)
Gravity Grouted Anchors (<50 psi)		
Silt-Clay Mixtures	Stiff to Very Stiff 1.0–4.0	0.6 to 1.5
Pressure Grouted Anchors (50 psi– 400 psi)		
High Plasticity Clay	Stiff 1.0–2.5 V. Stiff 2.5–4.0	0.6 to 2 1.5 to 3.6
Medium Plasticity Clay	Stiff 1.0–2.5 V. Stiff 2.5–4.0	2.0 to 5.2 2.9 to 7.3
Medium Plasticity Sandy Silt	V. Stiff 2.5–4.0	5.8 to 7.9

**Table C11.9.4.2-2—Presumptive Ultimate Unit Bond Stress for Anchors in Cohesionless Soils**

Anchor/Soil Type (Grout Pressure)	Soil Compactness or SPT Resistance <sup>(1)</sup>	Presumptive Ultimate Unit Bond Stress, $\tau_n$ (ksf)
Gravity Grouted Anchors (<50 psi)		
Sand or Sand- Gravel Mixtures	Medium Dense to Dense 11–50	1.5 to 2.9
Pressure Grouted Anchors (50 psi– 400 psi)		
Fine to Medium Sand	Medium Dense to Dense 11–50	1.7 to 7.9
Medium to Coarse Sand w/ Gravel	Medium Dense 11– 30 Dense to Very Dense 30–50	2.3 to 14 5.2 to 20
Silty Sands	—	3.5 to 8.5
Sandy Gravel	Medium Dense to Dense 11–40 Dense to Very Dense 40–50+	4.4 to 29 5.8 to 29
Glacial Till	Dense 31–50	6.3 to 11

<sup>(1)</sup> Corrected for overburden pressure.

**Table C11.9.4.2-3—Presumptive Ultimate Unit Bond Stress for Anchors in Rock**

Rock Type	Presumptive Ultimate Unit Bond Stress, $\tau_n$ (ksf)
Granite or Basalt	36 to 65
Dolomitic Limestone	29 to 44
Soft Limestone	21 to 29
Slates & Hard Shales	17 to 29
Sandstones	17 to 36
Weathered Sandstones	15 to 17
Soft Shales	4.2 to 17

The presumptive ultimate anchor bond stress values presented in Tables C11.9.4.2-1 through C11.9.4.2-3 are intended for preliminary design or evaluation of the feasibility of straight shaft anchors installed in small diameter holes. Pressure-grouted anchors may achieve much higher capacities. The total capacity of a pressure-grouted anchor may exceed 500 kips in soil or 2000 to 3000 kips in rock, although such high capacity anchors are seldom used for highway applications. Post-grouting can also increase the load carrying capacity of straight shaft anchors by 20–50 percent or more per phase of post-grouting.

The resistance factors in Table 11.5.6-1, in combination with the load factor for horizontal active earth pressure (Table 3.4.1-2), are consistent with what would be required based on allowable stress design, for preliminary design of anchors for pullout (Sabatini et al., 1999). These resistance factors are also consistent with the results of statistical calibration of full scale anchor pullout tests relative to the minimum values of presumptive ultimate unit bond stresses shown in Tables C11.9.4.2-1 through C11.9.4.2-3. Use of the resistance factors in Table 11.5.6-1 and the load factor for apparent earth pressure for anchor walls in Table 3.4.1-2, with values of presumptive ultimate unit bond stresses other than the minimum values in Tables C11.9.4.2-1 through C11.9.4.2-3 could result in unconservative designs unless the Engineer has previous experience with the particular soil or rock unit in which the bond zone will be established.

Presumptive bond stresses greater than the minimum values shown in Tables C11.9.4.2-1 through C11.9.4.2-3 should be used with caution, and be based on past successful local experience, such as a high percentage of passing proof tests in the specified or similar soil or rock unit at the design bond stress chosen, or anchor pullout test results in the specified or similar soil or rock unit. Furthermore, in some cases the specified range of presumptive bond stresses is representative of a range of soil conditions. Soil conditions at the upper end of the specified range, especially if coupled with previous experience with the particular soil unit, may be considered in the selection of anchor bond stresses above the minimum values shown. Selection of a presumptive bond stress for preliminary anchor sizing should consider the risk of failing proof tests if the selected bond stress was to be used for final design. The goal of preliminary anchor design is to reduce the risk of having a significant number of production anchors fail proof or performance tests as well as the risk of having to redesign the anchored wall to accommodate more anchors due to an inadequate easement behind the wall, should the anchor capacities predicted during preliminary design not be achievable.

See Article 11.9.8.1 for guidance on anchor testing.

The anchor load shall be developed by suitable embedment outside of the critical failure surface in the retained soil mass.

Determination of the unbonded anchor length, inclination, and overburden cover shall consider:

- The location of the critical failure surface furthest from the wall,
- The minimum length required to ensure minimal loss of anchor prestress due to long-term ground movements,
- The depth to adequate anchoring strata, as indicated in Figure 11.9.1-1, and
- The method of anchor installation and grouting.

The minimum horizontal spacing of anchors should be the larger of three times the diameter of the bonded zone, or 5.0 ft. If smaller spacings are required to develop the required load, consideration may be given to differing anchor inclinations between alternating anchors.

Significant increases in anchor capacity for anchor bond lengths greater than approximately 40.0 ft cannot be achieved unless specialized methods are used to transfer load from the top of the anchor bond zone towards the end of the anchor. This is especially critical for strain sensitive soils, in which residual soil strength is significantly lower than the peak soil strength.

Anchor inclination and spacing will be controlled by soil and rock conditions, the presence of geometric constraints and the required anchor capacity. For tremie-grouted anchors, a minimum angle of inclination of about 10 degrees and a minimum overburden cover of about 15.0 ft are typically required to assure grouting of the entire bonded length and to provide sufficient ground cover above the anchorage zone. For pressure-grouted anchors, the angle of inclination is generally not critical and is governed primarily by geometric constraints, and the minimum overburden cover is typically 6.0–15.0 ft. Steep inclinations may be required to avoid anchorage in unsuitable soil or rock. Special situations may require horizontal or near horizontal anchors, in which case proof of sufficient overburden and full grouting should be required.

The minimum horizontal spacing specified for anchors is intended to reduce stress overlap between adjacent anchors.

Anchors used for walls constructed in fill situations, i.e., bottom-up construction, should be enclosed in protective casing to prevent damage during backfill placement, compaction and settlement.

Selection of anchor type depends on anticipated service life, soil and rock conditions, ground water level, subsurface environmental conditions, and method of construction.

#### 11.9.4.3—Passive Resistance

The provisions of Articles 11.6.3.5, 11.6.3.6, and 11.8.4.1 shall apply.

#### C11.9.4.3

It is recommended in Sabatini et al. (1999) that methods such as the Broms Method or the Wang and Reese method be used to evaluate passive resistance and the wall vertical element embedment depth needed. However, these methods have not been calibrated for this application for LRFD as yet.

## 11.9.5—Safety against Structural Failure

### 11.9.5.1—Anchors

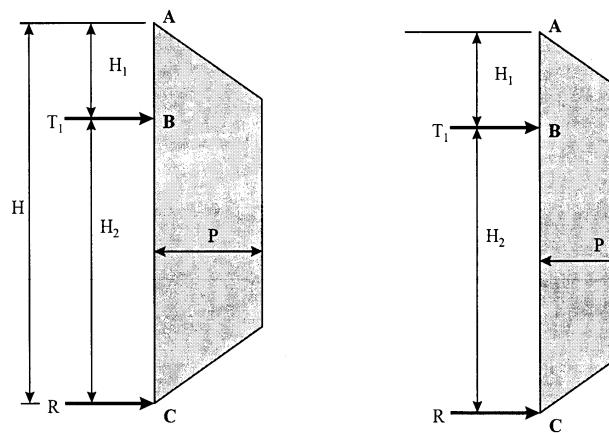

The horizontal component of anchor design force shall be computed using the provisions of Article 11.9.2 and any other horizontal pressure components acting on the wall in Article 3.11. The total anchor design force shall be determined based on the anchor inclination. The horizontal anchor spacing and anchor capacity shall be selected to provide the required total anchor design force.

### C11.9.5.1

Anchor tendons typically consist of steel bars, wires or strands. The selection of anchor type is generally the responsibility of the contractor.

A number of suitable methods for the determination of anchor loads are in common use. Sabatini et al. (1999) provides two methods which can be used: the Tributary Area Method, and the Hinge Method. These methods are illustrated in Figures C11.9.5.1-1 and C11.9.5.1-2. These figures assume that the soil below the base of the excavation has sufficient strength to resist the reaction force  $R$ . If the soil providing passive resistance below the base of the excavation is weak and is inadequate to carry the reaction force  $R$ , the lowest anchor should be designed to carry both the anchor load as shown in the figures as well as the reaction force. See Article 11.8.4.1 for evaluation of passive resistance. Alternatively, soil-structure interaction analyses, e.g., beam on elastic foundation, can be used to design continuous beams with small toe reactions, as it may be overly conservative to assume that all of the load is carried by the lowest anchor.

In no case should the maximum test load be less than the factored load for the anchor.

**Tributary area method**

$$T_1 = \text{Load over length } H_1 + H_2/2$$

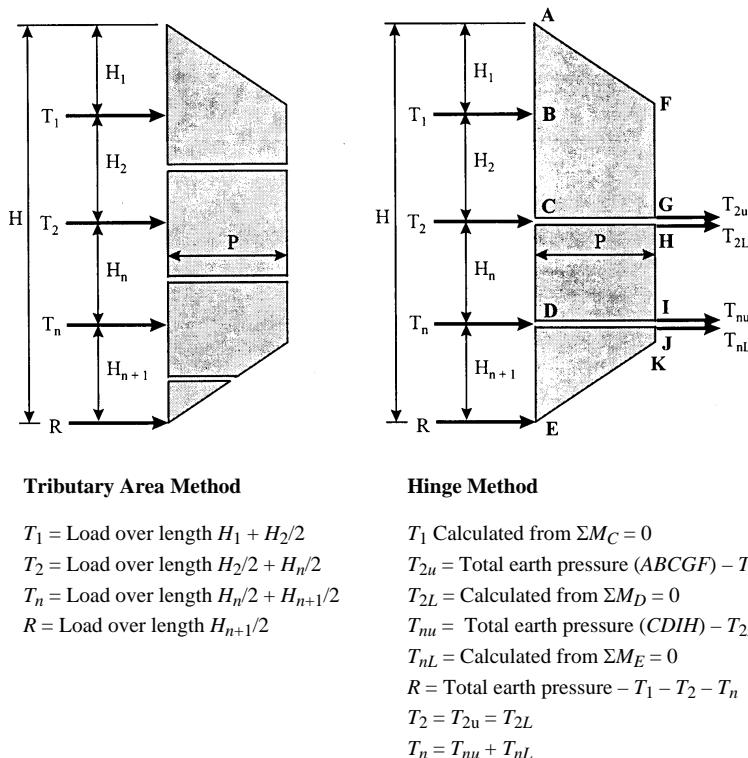

$$R = \text{Load over length } H_2/2$$

**Hinge method**

$$T_1 = \text{Calculated from } \Sigma M_C = 0$$

$$R = \text{Total earth pressure} - T_1$$

**Figure C11.9.5.1-1—Calculation of Anchor Loads for One-Level Wall after Sabatini et al. (1999)**

**Figure C11.9.5.1-2—Calculation of Anchor Loads for Multilevel Wall after Sabatini et al. (1999)**

### 11.9.5.2—Vertical Wall Elements

Vertical wall elements shall be designed to resist all horizontal earth pressure, surcharge, water pressure, anchor, and seismic loadings, as well as the vertical component of the anchor loads and any other vertical loads. Horizontal supports may be assumed at each anchor location and at the bottom of the excavation if the vertical element is sufficiently embedded below the bottom of the excavation.

### C11.9.5.2

Discrete vertical wall elements are continuous throughout their length and include driven piles, caissons, drilled shafts, and auger-cast piles, i.e., piles and built-up sections installed in preaugured holes and backfilled with structural concrete in the passive zone and lean concrete in the exposed section of the wall.

Continuous vertical wall elements are continuous throughout both their length and width, although vertical joints may prevent shear and/or moment transfer between adjacent sections. Continuous vertical wall elements include sheet piles, precast or cast-in-place concrete diaphragm wall panels, tangent-piles, and tangent caissons.

For structural analysis methods, see Section 4.

For walls supported in or through soft clays with  $S_u < 0.15\gamma_s' H$ , continuous vertical elements extending well below the exposed base of the wall may be required to prevent heave in front of the wall. Otherwise, the vertical elements are embedded approximately 3.0 ft or as required for stability or end bearing.

### 11.9.5.3—Facing

The provisions of Article 11.8.5.2 shall apply.

### 11.9.6—Seismic Design

The provisions of Article 11.8.6 shall apply.

### C11.9.6

See Article C11.8.6.

**11.9.7—Corrosion Protection**

Prestressed anchors and anchor heads shall be protected against corrosion consistent with the ground and groundwater conditions at the site. The level and extent of corrosion protection shall be a function of the ground environment and the potential consequences of an anchor failure. Corrosion protection shall be applied in accordance with the provisions of *AASHTO LRFD Bridge Construction Specifications*, Section 6, "Ground Anchors."

**11.9.8—Construction and Installation****11.9.8.1—Anchor Stressing and Testing**

All production anchors shall be subjected to load testing and stressing in accordance with the provisions of *AASHTO LRFD Bridge Construction Specifications*, Article 6.5.5, "Testing and Stressing." Preproduction load tests may be specified when unusual conditions are encountered to verify the safety with respect to the design load to establish the ultimate anchor load (pullout test), or to identify the load at which excessive creep occurs.

At the end of the testing of each production anchor, the anchor should be locked off to take up slack in the anchored wall system to reduce post-construction wall deformation. The lock-off load should be determined and applied as described in *AASHTO LRFD Bridge Construction Specifications*, Article 6.5.5.6.

**C11.9.7**

Corrosion protection for piles, wales, and miscellaneous hardware and material should be consistent with the level of protection for the anchors and the design life of the structure.

**C11.9.8.1**

Common anchor load tests include pullout tests performed on sacrificial preproduction anchors, and creep, performance, and proof tests performed on the production anchors. None of the production anchor tests determine the actual ultimate anchor load capacity. The production anchor test results only provide an indication of serviceability under a specified load. Performance tests consist of incremental loading and unloading of anchors to verify sufficient capacity to resist the test load, verify the free length and evaluate the permanent set of the anchor. Proof tests, usually performed on each production anchor, consist of a single loading and unloading cycle to verify sufficient capacity to resist the test load and to prestress the anchor. Creep tests, recommended for cohesive soils with a plasticity index greater than 20 percent or a liquid limit greater than 50 percent, and highly weathered, soft rocks, consist of incremental, maintained loading of anchors to assess the potential for loss of anchor bond capacity due to ground creep.

Pullout tests should be considered in the following circumstances:

- If the preliminary anchor design using unit bond stresses provided in the tables above indicate that anchored walls are marginally infeasible, requiring that a more accurate estimate of anchor capacity be obtained during wall design. This may occur due to lack of adequate room laterally to accommodate the estimated anchor length within the available right-of-way or easement;
- If the anticipated anchor installation method or soil/rock conditions are significantly different than those assumed to develop the presumptive values in Tables C11.9.4.2-1 through C11.9.4.2-3 and inadequate site specific experience is available to make a reasonably accurate estimate of the soil/rock-grout anchor bond stresses.

The FHWA recommends load testing anchors to 125 percent to 150 percent of the unfactored design load, Cheney (1984). Maximum load levels between 125 percent and 200 percent have been used to evaluate the potential for tendon overstress in service, to accommodate unusual or variable ground conditions or to assess the effect of ground creep on anchor capacity. Test load levels greater than 150 percent of the unfactored design load are normally applied only to anchors in soft cohesive soil or unstable soil masses where loss of anchor prestress due to creep warrants evaluation. The area of prestressing steel in the test anchor tendon may require being increased to perform these tests.

Note that the test details provided in the *AASHTO LRFD Bridge Construction Specifications*, Article 6.5.5, at least with regard to the magnitude of the incremental test loads, were developed for allowable stress design. These incremental test loads should be divided by the load factor for apparent earth pressure for anchored walls provided in Table 3.4.1-2 when testing to factored anchor loads.

Typically, the anchor lock-off load is equal to 80 to 100 percent of the nominal (unfactored) anchor load to ensure that the slack in the anchored wall system is adequately taken up so that post-construction wall deformation is minimized. However, a minimum lock-off load of 50 percent is necessary to properly engage strand anchor head wedges.

### 11.9.9—Drainage

The provisions of Article 11.8.8 shall apply.

### C11.9.9

Thin drains at the back of the wall face may not completely relieve hydrostatic pressure and may increase seepage forces on the back of the wall face due to rainwater infiltration, Terzaghi and Peck (1967), and Cedergren (1989). The effectiveness of drainage control measures should be evaluated by seepage analyses.

## 11.10—MECHANICALLY STABILIZED EARTH WALLS

### 11.10.1—General

MSE walls may be considered where conventional gravity, cantilever, or counterforted concrete retaining walls and prefabricated modular retaining walls are considered, and particularly where substantial total and differential settlements are anticipated.

When two intersecting walls form an enclosed angle of 70 degrees or less, the affected portion of the wall shall be designed as an internally tied bin structure with at-rest earth pressure coefficients.

MSE walls shall not be used under the following conditions:

### C11.10.1

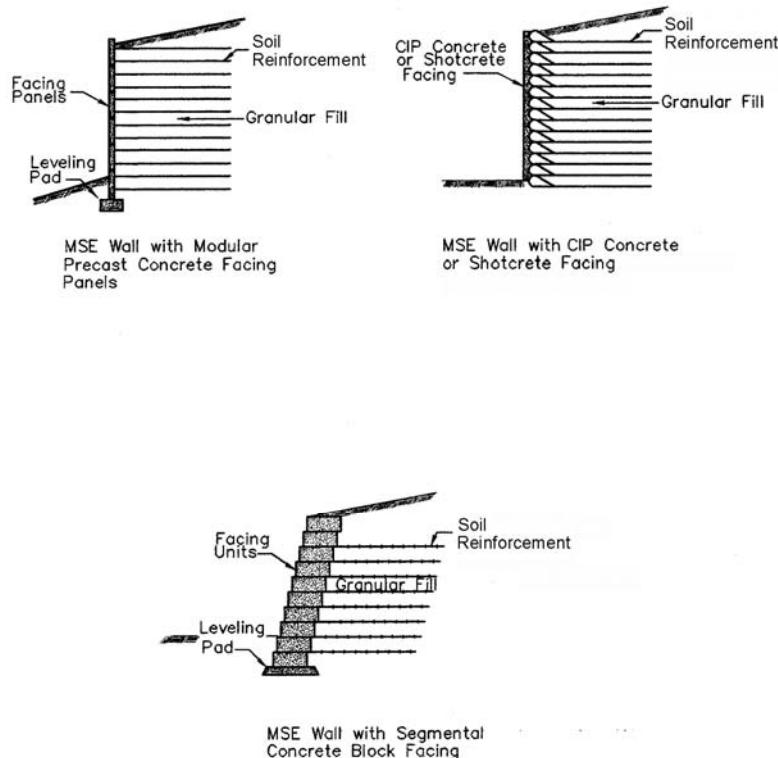

Mechanically stabilized earth (MSE) systems, whose elements may be proprietary, employ either metallic (strip or grid type) or geosynthetic (geotextile, strip, or geogrid) tensile reinforcements in the soil mass, and a facing element which is vertical or near vertical. MSE walls behave as a gravity wall, deriving their lateral resistance through the dead weight of the reinforced soil mass behind the facing. For relatively thick facings, the dead weight of the facing may also provide a significant contribution to the capacity of the wall system. Typical MSE walls are shown in Figure C11.10.1-1.

All available data indicates that corrosion in MSE walls is not accelerated by stray currents from electric rail lines due to the discontinuity of the earth reinforcements in a direction parallel to the source of the stray current. Where metallic reinforcements are used in areas of anticipated stray currents within 200 ft of the structure, and the metallic reinforcements are continuously connected in a direction parallel to the source of stray currents, a corrosion expert should evaluate the potential need for corrosion control requirements. More detailed information on stray current corrosion issues is provided by Sankey and Anderson (1999).

- Where utilities other than highway drainage are to be constructed within the reinforced zone unless access is provided to utilities without disrupting reinforcements and breakage or rupture of utility lines will not have a detrimental effect on the stability of the structure.
- Where floodplain erosion or scour may undermine the reinforced fill zone or facing, or any supporting footing.
- With reinforcements exposed to surface or ground water contaminated by acid mine drainage, other industrial pollutants, or other environmental conditions defined as aggressive in Article 7.3.6.3 of the *AASHTO LRFD Bridge Construction Specifications*, unless environmental-specific, long-term corrosion, or degradation studies are conducted.

Where future access to utilities may be gained without disrupting reinforcements and where leakage from utilities would not create detrimental hydraulic conditions or degrade reinforcements, utilities in the reinforced zone may be acceptable.

The potential for catastrophic failure due to scour is high for MSE walls if the reinforced fill is lost during a scour occurrence. Consideration may be given to lowering the base of the wall or to alternative methods of scour protection, such as sheetpile walls and/or riprap of sufficient size, placed to a sufficient depth to preclude scour.

**Figure C11.10.1-1—Typical Mechanically Stabilized Earth Walls**

MSE walls shall be designed for external stability of the wall system as well as internal stability of the reinforced soil mass behind the facing. Overall and compound stability failure shall be considered. Structural design of the wall facing shall also be considered.

The specifications provided herein for MSE walls do not apply to geometrically complex MSE wall systems such as tiered walls (walls stacked on top of one another), back-to-back walls, or walls which have trapezoidal sections. Design guidelines for these cases are provided in FHWA publication No. FHWA-NHI-00-043 (Elias et al., 2001). Compound stability should also be evaluated for these complex MSE wall systems (see Article 11.10.4.3).

## 11.10.2—Structure Dimensions

An illustration of the MSE wall element dimensions required for design is provided in Figure 11.10.2-1.

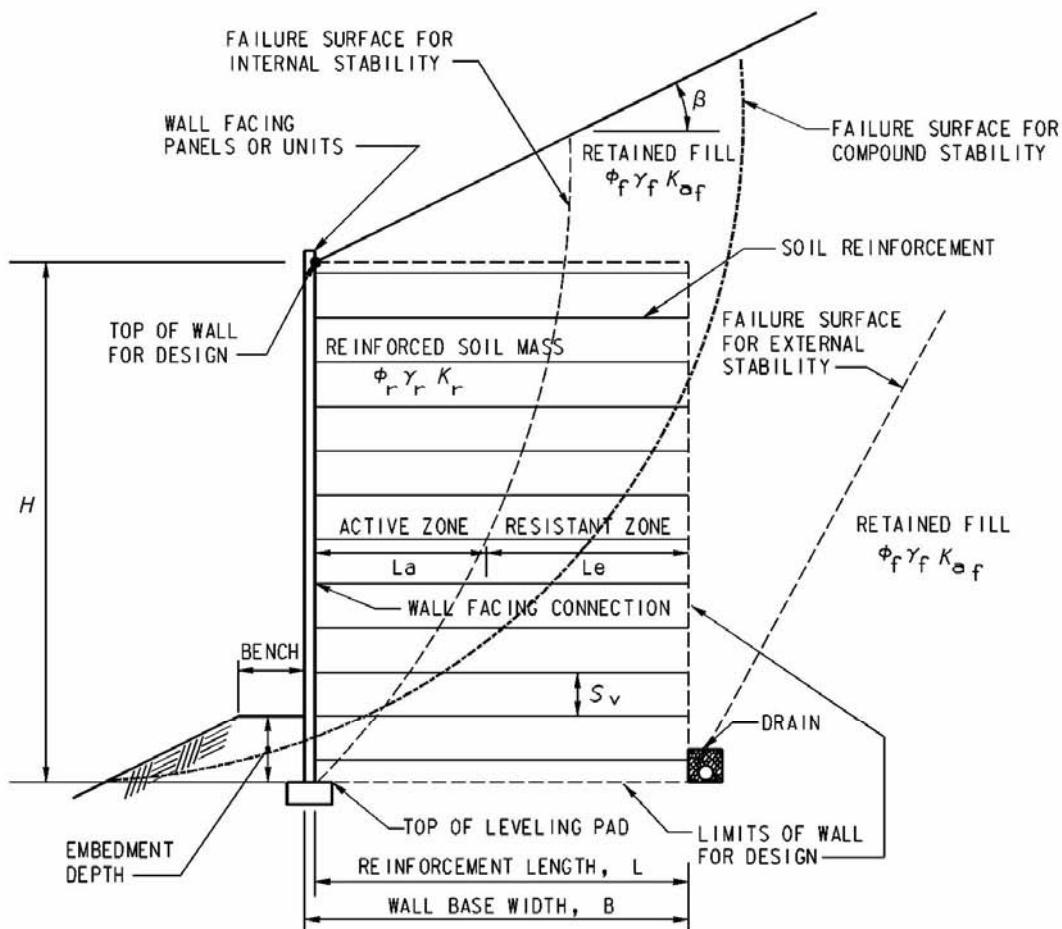

The size and embedment depth of the reinforced soil mass shall be determined based on:

- Requirements for stability and geotechnical strength, as specified in Article 11.10.5 consistent with requirements for gravity walls,

For simple structures with rectangular geometry, relatively uniform reinforcement spacing, and a near vertical face, compound failures passing both through the unreinforced and reinforced zones will not generally be critical. However, if complex conditions exist such as changes in reinforced soil types or reinforcement lengths, high surcharge loads, sloping faced structures, a slope at the toe of the wall, or stacked structures, compound failures must be considered.

Internal design of MSE wall systems requires knowledge of short- and long-term properties of the materials used as soil reinforcements as well as the soil mechanics which govern MSE wall behavior.

- Requirements for structural resistance within the reinforced soil mass itself, as specified in Article 11.10.6, for the panel units, and for the development of reinforcement beyond assumed failure zones, and
- Traditional requirements for reinforcement length not less than 70 percent of the wall height, except as noted in Article 11.10.2.1.

For external and internal stability calculations, the weight and dimensions of the facing elements are typically ignored. However, it is acceptable to include the facing dimensions and weight in sliding and bearing capacity calculations. For internal stability calculations, the wall dimensions are considered to begin at the back of the facing elements.

Figure 11.10.2-1—MSE Wall Element Dimensions Needed for Design

### 11.10.2.1—Minimum Length of Soil Reinforcement

For sheet-, strip-, and grid-type reinforcement, the minimum soil reinforcement length shall be 70 percent of the wall height as measured from the leveling pad. Reinforcement length shall be increased as required for surcharges and other external loads, or for soft foundation soils.

The reinforcement length shall be uniform throughout the entire height of the wall, unless substantiating evidence is presented to indicate that variation in length is satisfactory.

### C11.10.2.1

In general, a minimum reinforcement length of 8.0 ft, regardless of wall height, has been recommended based on historical practice, primarily due to size limitations of conventional spreading and compaction equipment. Shorter minimum reinforcement lengths, on the order of 6.0 ft, but no less than 70 percent of the wall height, can be considered if smaller compaction equipment is used, facing panel alignment can be maintained, and minimum requirements for wall external stability are met.

The requirement for uniform reinforcement length equal to 70 percent of the structure height has no theoretical justification, but has been the basis of many successful designs to-date. Parametric studies considering minimum acceptable soil strengths have shown that structure dimensions satisfying all of the requirements of Article 11.10.5 require length to height ratios varying from  $0.8H$  for low structures, i.e., 10.0 ft, to  $0.63H$  for high structures, i.e., 40.0 ft.

Significant shortening of the reinforcement elements below the minimum recommended ratio of  $0.7H$  may only be considered when accurate, site specific determinations of the strength of the unreinforced fill and the foundation soil have been made. Christopher et al. (1990) presents results which strongly suggest that shorter reinforcing length to height ratios, i.e.,  $0.5H$  to  $0.6H$ , substantially increase horizontal deformations.

A nonuniform reinforcement length may be considered under the following circumstances:

- Lengthening of the uppermost reinforcement layers to beyond  $0.7H$  to meet pullout requirements, or to address seismic or impact loads.
- Lengthening of the lowermost reinforcement layers beyond  $0.7H$  to meet overall (global) stability requirements based on the results of a detailed global stability analysis.
- Shortening of the bottom reinforcement layers to less than  $0.7H$  to minimize excavation requirements, provided the wall is bearing on rock or very competent foundation soil (see below).

For walls on rock or very competent foundation soil, e.g., SPT > 50, the bottom reinforcements may be shortened to a minimum of  $0.4H$  with the upper reinforcements lengthened to compensate for external stability issues in lieu of removing rock or competent soil for construction. Design guidelines for this case are provided in FHWA Publication No. FHWA-NHI-00-043 (Elias et al., 2001).

For conditions of marginal stability, consideration must be given to ground improvement techniques to improve foundation stability, or to lengthening of reinforcement.

### 11.10.2.2—Minimum Front Face Embedment

The minimum embedment depth of the bottom of the reinforced soil mass (top of the leveling pad) shall be based on bearing resistance, settlement, and stability requirements determined in accordance with Section 10.

Unless constructed on rock foundations, the embedment at the front face of the wall in ft shall not be less than:

- a depth based on the prevailing depth of frost penetration, if the soil below the wall is frost susceptible, and the external stability requirement, and
- 2.0 ft on sloping ground ( $4.0H:1V$  or steeper) or where there is potential for removal of the soil in front of the wall toe due to erosion or future excavation, or 1.0 ft on level ground where there is no potential for erosion or future excavation of the soil in front of the wall toe.

For walls constructed along rivers and streams, embedment depths shall be established at a minimum of 2.0 ft below potential scour depth as determined in accordance with Article 11.6.3.5.

As an alternative to locating the wall base below the depth of frost penetration where frost susceptible soils are present, the soil within the depth and lateral extent of frost penetration below the wall can be removed and replaced with nonfrost susceptible clean granular soil.

A minimum horizontal bench width of 4.0 ft shall be provided in front of walls founded on slopes. The bench may be formed or the slope continued above that level as shown in Figure 11.10.2-1.

The lowest backfill reinforcement layer shall not be located above the long-term ground surface in front of the wall.

### 11.10.2.3—Facing

Facing elements shall be designed to resist the horizontal force in the soil reinforcements at the reinforcement to facing connection, as specified in Articles 11.10.6.2.2 and 11.10.7.3.

In addition to these horizontal forces, the facing elements shall also be designed to resist potential compaction stresses occurring near the wall face during erection of the wall.

The tension in the reinforcement may be assumed to be resisted by a uniformly distributed earth pressure on the back of the facing.

The facing shall be stabilized such that it does not deflect laterally or bulge beyond the established tolerances.

### C11.10.2.2

The minimum embedment guidelines provided in Table C11.10.2.2-1 may be used to preclude local bearing resistance failure under the leveling pad or footing due to higher vertical stresses transmitted by the facing.

**Table C11.10.2.2-1—Guide for Minimum Front Face Embedment Depth**

Slope in Front of Structures	Minimum Embedment Depth	
	for walls	$H/20.0$
Horizontal	for abutments	$H/10.0$
$3.0H:1.0V$	walls	$H/10.0$
$2.0H:1.0V$	walls	$H/7.0$
$1.5H:1.0V$	walls	$H/5.0$

For structures constructed on slopes, minimum horizontal benches are intended to provide resistance to local bearing resistance failure consistent with resistance to general bearing resistance failure and to provide access for maintenance inspections.

### C11.10.2.3

See Article C3.11.2 for guidance. Additional information on compaction stresses can be found in Duncan and Seed (1986) and Duncan et al. (1991). Alternatively, compaction stresses can be addressed through the use of facing systems which have a proven history of being able to resist the compaction activities anticipated behind the wall and which have performed well in the long-term.

*11.10.2.3.1—Stiff or Rigid Concrete, Steel, and Timber Facings*

Facing elements shall be structurally designed in accordance with Sections 5, 6, and 8 for concrete, steel, and timber facings, respectively.

The minimum thickness for concrete panels at, and in the zone of stress influence of, embedded connections shall be 5.5 in. and 3.5 in. elsewhere. The minimum concrete cover shall be 1.5 in. Reinforcement shall be provided to resist the average loading conditions for each panel. Temperature and shrinkage steel shall be provided as specified in Article 5.10.8.

The structural integrity of concrete face panels shall be evaluated with respect to the shear and bending moment between reinforcements attached to the facing panel in accordance with Section 5.

For segmental concrete facing blocks, facing stability calculations shall include an evaluation of the maximum vertical spacing between reinforcement layers, the maximum allowable facing height above the uppermost reinforcement layer, inter-unit shear capacity, and resistance of the facing to bulging. The maximum spacing between reinforcement layers shall be limited to twice the width,  $W_u$  illustrated in Figure 11.10.6.4.4b-1, of the segmental concrete facing block unit or 2.7 ft, whichever is less. The maximum facing height up to the wall surface grade above the uppermost reinforcement layer shall be limited to  $1.5W_u$  illustrated in Figure 11.10.6.4.4b-1 or 24.0 in., whichever is less, provided that the facing above the uppermost reinforcement layer is demonstrated to be stable against a toppling failure through detailed calculations. The maximum depth of facing below the lowest reinforcement layer shall be limited to the width,  $W_u$ , of the proposed segmental concrete facing block unit.

*11.10.2.3.2—Flexible Wall Facings*

If welded wire, expanded metal, or similar facing is used, they shall be designed in a manner which prevents the occurrence of excessive bulging as backfill behind the facing compresses due to compaction stresses or self weight of the backfill. This may be accomplished by limiting the size of individual facing elements vertically and the vertical and horizontal spacing of the soil reinforcement layers, and by requiring the facing to have an adequate amount of vertical slip and overlap between adjacent elements.

The top of the flexible facing at the top of the wall shall be attached to a soil reinforcement layer to provide stability to the top facing.

*C11.10.2.3.1*

The specified minimum panel thicknesses and concrete cover recognize that MSE walls are often employed where panels may be exposed to salt spray and/or other corrosive environments. The minimum thicknesses also reflect the tolerances on panel thickness, and placement of reinforcement and connectors that can reasonably be conformed to in precast construction.

Based on research by Allen and Bathurst (2001), facings consisting of segmental concrete facing blocks behave as a very stiff facing, due to the ability of the facing blocks to transmit moment in a vertical direction throughout the facing column, and appear to have even greater stiffness than incremental precast concrete panels.

Experience has shown that for walls with segmental concrete block facings, the gap between soil reinforcement sections or strips at a horizontal level should be limited to a maximum of one block width to limit bulging of the facing between reinforcement levels or build up of unacceptable stresses that could result in performance problems. The ability of the facing to carry moment horizontally to bridge across the gaps in the reinforcement horizontally should be evaluated if horizontally discontinuous reinforcement is used, i.e., a reinforcement coverage ratio  $R_c < 1$ .

*C11.10.2.3.2*

Experience has shown that for welded wire, expanded metal, or similar facings, vertical reinforcement spacing should be limited to a maximum of 2.0 ft and the gap between soil reinforcement at a horizontal level limited to a maximum of 3.0 ft to limit bulging of the panels between reinforcement levels. The section modulus of the facing material should be evaluated and calculations provided to support reinforcement spacings, which will meet the bulging requirements stated in Article C11.10.4.2.

Geosynthetic facing elements shall not, in general, be left exposed to sunlight (specifically ultraviolet radiation) for permanent walls. If geosynthetic facing elements must be left exposed permanently to sunlight, the geosynthetic shall be stabilized to be resistant to ultraviolet radiation. Product specific test data shall be provided which can be extrapolated to the intended design life and which proves that the product will be capable of performing as intended in an exposed environment.

#### *11.10.2.3.3—Corrosion Issues for MSE Facing*

Steel-to-steel contact between the soil reinforcement connections and the concrete facing steel reinforcement shall be prevented so that contact between dissimilar metals, e.g., bare facing reinforcement steel and galvanized soil reinforcement steel, does not occur.

A corrosion protection system shall be provided where salt spray is anticipated.

#### *C11.10.2.3.3*

Steel-to-steel contact in this case can be prevented through the placement of a nonconductive material between the soil reinforcement face connection and the facing concrete reinforcing steel. Examples of measures which can be used to mitigate corrosion include, but are not limited to, coatings, sealants, or increased panel thickness.

### **11.10.3—Loading**

The provisions of Article 11.6.1.2 shall apply, except that shrinkage and temperature effects need not be considered to come in contact with steel wall elements.

### **11.10.4—Movement and Stability at the Service Limit State**

#### **11.10.4.1—Settlement**

The provisions of Article 11.6.2 shall apply as applicable.

The allowable settlement of MSE walls shall be established based on the longitudinal deformability of the facing and the ultimate purpose of the structure.

Where foundation conditions indicate large differential settlements over short horizontal distances, vertical full-height slip joints shall be provided.

Differential settlement from the front to the back of the wall shall also be evaluated, especially regarding the effect on facing deformation, alignment, and connection stresses.

#### **C11.10.4.1**

For systems with rigid concrete facing panels and with a maximum joint width of 0.75 in., the maximum tolerable slope resulting from calculated differential settlement may be taken as given in Table C11.10.4.1-1.

**Table C11.10.4.1-1—Guide for Limiting Distortion for Precast Concrete Facings of MSE Walls**

Joint Width (in.)	Limiting Differential Settlement	
	Area $\leq$ 30 ft $^2$	30 ft $^2$ $\leq$ Area $\leq$ 75 ft $^2$
0.75	1/100	1/200
0.50	1/200	1/300
0.25	1/300	1/600

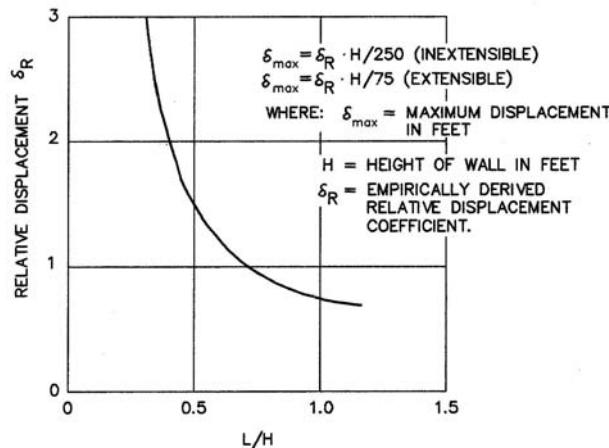

For MSE walls with full height precast concrete facing panels, total settlement should be limited to 2.0 in., and the limiting differential settlement should be 1/500. For walls with segmental concrete block facings, the limiting differential settlement should be 1/200. For walls with welded wire facings or walls in which cast-in-place concrete or shotcrete facing is placed after wall settlement is essentially complete, the limiting differential settlement should be 1/50. These limiting differential settlement criteria consider only structural needs of the facing. More stringent differential settlement criteria may be needed to meet aesthetic requirements.

#### 11.10.4.2—Lateral Displacement

Lateral wall displacements shall be estimated as a function of overall structure stiffness, compaction intensity, soil type, reinforcement length, slack in reinforcement-to-facing connections, and deformability of the facing system or based on monitored wall performance.

#### C11.10.4.2

A first order estimate of lateral wall displacements occurring during wall construction for simple MSE walls on firm foundations can be obtained from Figure C11.10.4.2-1. If significant vertical settlement is anticipated or heavy surcharges are present, lateral displacements could be considerably greater. Figure C11.10.4.2-1 is appropriate as a guide to establish an appropriate wall face batter to obtain a near vertical wall or to determine minimum clearances between the wall face and adjacent objects or structures.

Based on 20 ft. high walls, relative displacement increases approximately 25% for every 400 psf of surcharge. Experience indicates that for higher walls, the surcharge effect may be greater.

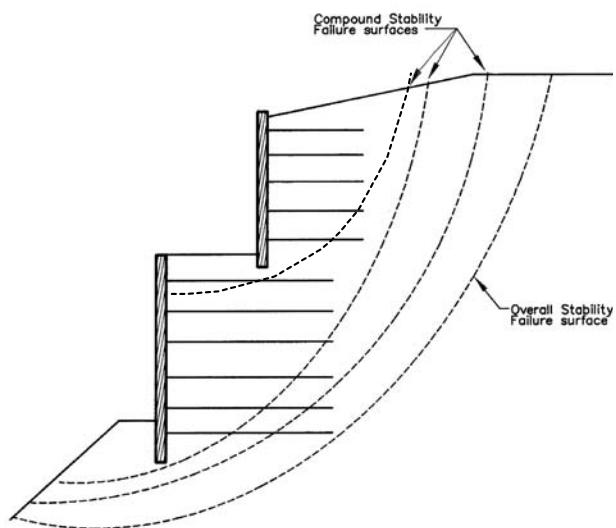

Note: This figure is only a guide. Actual displacement will depend, in addition to the parameters addressed in the figure, on soil characteristics, compaction effort, and contractor workmanship.

**Figure C11.10.4.2-1—Empirical Curve for Estimating Anticipated Lateral Displacement during Construction for MSE Walls**

For welded wire or similarly faced walls such as gabion faced walls, the maximum tolerable facing bulge between connections, both horizontally and vertically, with soil reinforcement is approximately 2.0 in. For geosynthetic facings, the maximum facing bulge between reinforcement layers should be approximately 2.75 in. for 1.0 ft vertical reinforcement spacing to 5.0 in. for 2.0 ft vertical reinforcement spacing.

### 11.10.4.3—Overall Stability

The provisions of Article 11.6.2.3 shall apply. Additionally for MSE walls with complex geometrics, compound failure surfaces which pass through a portion of the reinforced soil mass as illustrated in Figure 11.10.4.3-1 shall be investigated, especially where the wall is located on sloping or soft ground where overall stability may be inadequate. The long-term strength of each backfill reinforcement layer intersected by the failure surface should be considered as restoring forces in the limit equilibrium slope stability analysis.

**Figure 11.10.4.3-1—Overall and Compound Stability of Complex MSE Wall Systems**

### 11.10.5—Safety against Soil Failure (External Stability)

#### 11.10.5.1—General

MSE structures shall be proportioned to satisfy eccentricity and sliding criteria normally associated with gravity structures.

Safety against soil failure shall be evaluated by assuming the reinforced soil mass to be a rigid body. The coefficient of active earth pressure,  $k_a$ , used to compute the earth pressure of the retained soil behind the reinforced soil mass shall be determined using the friction angle of the retained soil. In the absence of specific data, a maximum friction angle of 30 degrees may be used for granular soils. Tests should be performed to determine the friction angle of cohesive soils considering both drained and undrained conditions.

#### C11.10.5.1

Eccentricity requirements seldom govern design. Sliding and overall stability usually govern design of structures greater than 30.0 ft in height, structures constructed on weak foundation soils, or structures loaded with sloping surcharges.

### 11.10.5.2—Loading

Lateral earth pressure distributions for design of MSE walls shall be taken as specified in Article 3.11.5.8. Application of loads for external and internal stability shall be taken as specified in Articles 11.10.5 and 11.10.6, respectively. Application of surcharge loads shall be taken as specified in Article 11.10.11. Application of load factors for these loads shall be taken as specified in Article 11.5.5.

For external stability calculations only, the active earth pressure coefficients for retained backfill, i.e., fill behind the reinforced soil mass, shall be taken as specified in Article 3.11.5.3 with  $\delta = \beta$ .

Dead load surcharges, if present, shall be taken into account in accordance with Article 11.10.10.

For investigation of sliding stability and eccentricity, the continuous traffic surcharge loads shall be considered to act beyond the end of the reinforced zone as shown in Figure 11.10.5.2-1. Application of load factors for these loads shall be taken as specified in Article 11.5.5.

### C11.10.5.2

Figures 3.11.5.8.1-1, 3.11.5.8.1-2, and 3.11.5.8.1-3 illustrate lateral earth pressure distributions for external stability of MSE walls with horizontal backslope, inclined backslope, and broken backslope, respectively.

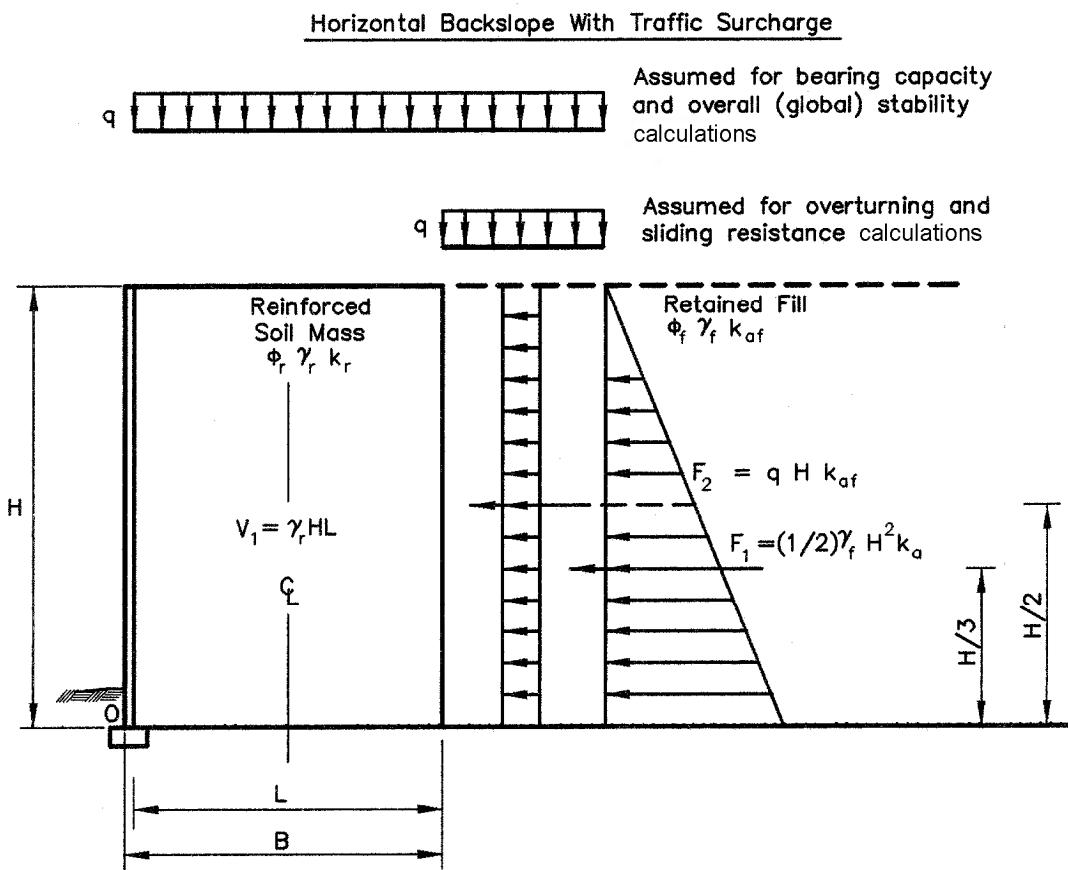

Figure 11.10.5.2-1—External Stability for Wall with Horizontal Backslope and Traffic Surcharge

### 11.10.5.3—Sliding

The provisions of Article 10.6.3.4 shall apply.

The coefficient of sliding friction at the base of the reinforced soil mass shall be determined using the friction angle of the foundation soil. For discontinuous reinforcements, e.g., strips, the angle of sliding friction shall be taken as the lesser of  $\phi_r$  of the reinforced fill and  $\phi_f$  of the foundation soil. For continuous reinforcements, e.g., grids and sheets, the angle of sliding friction shall be taken as the lesser of  $\phi_r$ ,  $\phi_f$  and  $\rho$ , where  $\rho$  is the soil-reinforcement interface friction angle. In the absence of specific data, a maximum friction angle,  $\phi_f$ , of 30 degrees and a maximum soil-reinforcement interface angle,  $\rho$ , of  $2/3 \phi_f$  may be used.

### 11.10.5.4—Bearing Resistance

For the purpose of computing bearing resistance, an equivalent footing shall be assumed whose length is the length of the wall, and whose width is the length of the reinforcement strip at the foundation level. Bearing pressures shall be computed using a uniform base pressure distribution over an effective width of footing determined in accordance with the provisions of Articles 10.6.3.1 and 10.6.3.2.

Where soft soils or sloping ground in front of the wall are present, the difference in bearing stress calculated for the wall reinforced soil zone relative to the local bearing stress beneath the facing elements shall be considered when evaluating bearing capacity. In both cases, the leveling pad shall be embedded adequately to meet bearing capacity requirements.

### 11.10.5.5—Overturning

The provisions of Article 11.6.3.3 shall apply.

### C11.10.5.3

For relatively thick facing elements, it may be desirable to include the facing dimensions and weight in sliding and overturning calculations, i.e., use  $B$  in lieu of  $L$  as shown in Figure 11.10.5.2-1.

### C11.10.5.4

The effect of eccentricity and load inclination is accommodated by the introduction of an effective width,  $B' = L - 2e$ , instead of the actual width.

For relatively thick facing elements, it may be reasonable to include the facing dimensions and weight in bearing calculations, i.e., use  $B$  in lieu of  $L$  as shown in Figure 11.10.2-1.

Note, when the value of eccentricity  $e$  is negative:  $B' = L$ .

Due to the flexibility of MSE walls, a triangular pressure distribution at the wall base cannot develop, even if the wall base is founded on rock, as the reinforced soil mass has limited ability to transmit moment. Therefore, an equivalent uniform base pressure distribution is appropriate for MSE walls founded on either soil or rock.

Concentrated bearing stresses from the facing weight on soft soil could create concentrated stresses at the connection between the facing elements and the wall backfill reinforcement.

## 11.10.6—Safety against Structural Failure (Internal Stability)

### 11.10.6.1—General

Safety against structural failure shall be evaluated with respect to pullout and rupture of reinforcement.

A preliminary estimate of the structural size of the stabilized soil mass may be determined on the basis of reinforcement pullout beyond the failure zone, for which resistance is specified in Article 11.10.6.3.

### C11.10.6.1

The resistance factors, specified in Article 11.5.6, are consistent with the use of select backfill in the reinforced zone, homogeneously placed and carefully controlled in the field for conformance with Section 7 of *AASHTO LRFD Bridge Construction Specifications*. The basis for the factors is the successful construction of thousands of structures in accordance with these criteria, and the use of conservative pullout resistance factors representing high confidence limits.

### 11.10.6.2—Loading

The load in the reinforcement shall be determined at two critical locations: the zone of maximum stress and the connection with the wall face. Potential for reinforcement rupture and pullout are evaluated at the zone of maximum stress, which is assumed to be located at the boundary between the active zone and the resistant zone in Figure 11.10.2-1. Potential for reinforcement rupture and pullout are also evaluated at the connection of the reinforcement to the wall facing.

The maximum friction angle used for the computation of horizontal force within the reinforced soil mass shall be assumed to be 34 degrees, unless the specific project select backfill is tested for frictional strength by triaxial or direct shear testing methods, AASHTO T 296 and T 297 or T 236, respectively. A design friction angle of greater than 40 degrees shall not be used with the Simplified Method even if the measured friction angle is greater than 40 degrees.

### C11.10.6.2

Loads carried by the soil reinforcement in mechanically stabilized earth walls are the result of vertical and lateral earth pressures, which exist within the reinforced soil mass, reinforcement extensibility, facing stiffness, wall toe restraint, and the stiffness and strength of the soil backfill within the reinforced soil mass. The soil reinforcement extensibility and material type are major factors in determining reinforcement load. In general, inextensible reinforcements consist of metallic strips, bar mats, or welded wire mats, whereas extensible reinforcements consist of geotextiles or geogrids. Inextensible reinforcements reach their peak strength at strains lower than the strain required for the soil to reach its peak strength. Extensible reinforcements reach their peak strength at strains greater than the strain required for soil to reach its peak strength. Internal stability failure modes include soil reinforcement rupture (strength limit state), and excessive reinforcement elongation under the design load (service limit state). The service limit state is not evaluated in current practice for internal stability design. Internal stability is determined by equating the factored tensile load applied to the reinforcement to the factored tensile resistance of the reinforcement, the tensile resistance being governed by reinforcement rupture and pullout.

Analysis of full scale wall data in comparison to the Simplified Method or other widely accepted design methods (see Article 11.10.6.2.1) indicates that these methods will significantly underestimate reinforcement loads if design soil friction angles greater than 40 degrees are used. This recommendation applies to soil friction angles as determined using triaxial or direct shear tests, as the Simplified Method was calibrated using triaxial or direct shear soil strengths (see Allen et al., 2001).

#### 11.10.6.2.1—Maximum Reinforcement Loads

Maximum reinforcement loads shall be calculated using the Simplified Method or the Coherent Gravity Method. The Simplified Method shall be considered to apply to both steel and geosynthetic reinforced wall systems. The Coherent Gravity Method shall be applied primarily to steel soil reinforcement systems. For the Simplified Method, the load in the reinforcements shall be obtained by multiplying the vertical earth pressure at the reinforcement by a lateral earth pressure coefficient, and applying the resulting lateral pressure to the tributary area for the reinforcement. For the Coherent Gravity Method, the load in the reinforcements shall be obtained in the same way as the Simplified Method, except as follows:

- The vertical earth pressure at each reinforcement level shall be computed using an equivalent uniform base pressure distribution over an effective width of reinforced wall mass determined in accordance with the provisions of Articles 11.6.3.1 and 11.6.3.2, and
- For steel reinforced wall systems, the lateral earth pressure coefficient used shall be equal to  $k_0$  at the point of intersection of the theoretical failure surface with the ground surface at or above the wall top, transitioning to  $k_a$  at a depth of 20.0 ft below that intersection point, and constant at  $k_a$  at depths greater than 20.0 ft. If used for geosynthetic reinforced systems,  $k_a$  shall be used throughout the wall height.

All other provisions in this article are applicable to both methods.

Other widely accepted and published design methods for calculation of reinforcement loads may be used at the discretion of the wall owner or approving agency, provided the designer develops method-specific resistance factors for the method employed.

For the Simplified Method, factored horizontal stress,  $\sigma_H$ , at each reinforcement level shall be determined as:

$$\sigma_H = \gamma_P (\sigma_v k_r + \Delta\sigma_H) \quad (11.10.6.2.1-1)$$

where:

$\gamma_P$  = the load factor for vertical earth pressure  $EV$  from Table 3.4.1-2

$k_r$  = horizontal pressure coefficient (dim.)

$\sigma_v$  = pressure due to resultant of gravity forces from soil self weight within and immediately above the reinforced wall backfill, and any surcharge loads present (ksf)

#### C11.10.6.2.1

The development of the Simplified Method for estimating reinforcement loads is provided in Allen, et al. (2001). The Coherent Gravity Method has been used in MSE wall design practice for many years for steel reinforced wall systems. Detailed procedures for the Coherent Gravity Method are provided in Allen, et al. (2001) and in Mitchell and Villet (1987). Its application to geosynthetic soil reinforcement systems results in conservative designs.

The design specifications provided herein assume that the wall facing combined with the reinforced backfill acts as a coherent unit to form a gravity retaining structure. Research by Allen and Bathurst (2003) and Allen et al. (2003) indicates that reinforcement load is linear with reinforcement spacing to a reinforcement vertical spacing of 2.7 ft or more, though a vertical spacing of this magnitude should not be attempted unless the facing is considered to be adequately stiff to prevent excessive bulging between layers (see Article C11.10.2.3.2).

These MSE wall specifications also assume that inextensible reinforcements are not mixed with extensible reinforcements within the same wall. MSE walls which contain a mixture of inextensible and extensible reinforcements are not recommended.

The calculation method for  $T_{max}$  is empirically derived, based on reinforcement strain measurements, converted to load based on the reinforcement modulus, from full scale walls at working stress conditions. The load factor  $EV$ , on the other hand, was determined in consideration of vertical earth pressure exerted by a soil mass without inclusions, and was calibrated to address uncertainties implied by allowable stress design for external stability for walls.  $EV$  is not directly applicable to internal reinforcement loads in MSE walls, since the calibration of  $EV$  was not performed with internal stability of a reinforced system in mind.

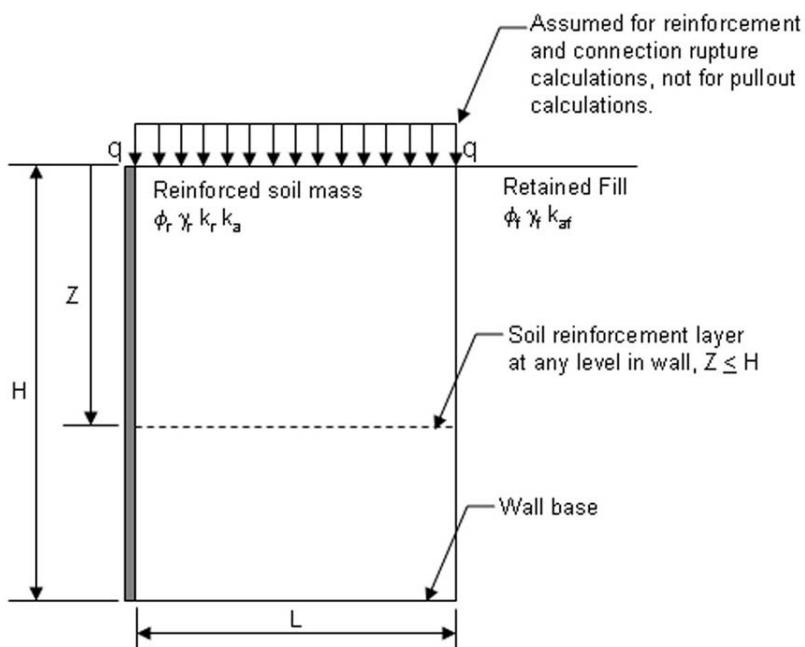

The use of  $EV$  for the load factor in this case for both methods (i.e., the Simplified and Coherent Gravity Methods) should be considered an interim measure until research is completed to quantify load prediction bias and uncertainty.

$\Delta\sigma_H$  = horizontal stress at reinforcement level resulting from any applicable concentrated horizontal surcharge load as specified in Article 11.10.10.1 (ksf)

For the Simplified Method, vertical stress for maximum reinforcement load calculations shall be determined as shown in Figures 11.10.6.2.1-1 and 11.10.6.2.1-2. For the Coherent Gravity Method, vertical stress shall be calculated at each reinforcement level using an equivalent uniform base pressure that accounts for load eccentricity caused by the lateral earth pressure acting at the back of the reinforced soil mass above the reinforcement level being considered. This base pressure shall be applied over an effective width of reinforced wall mass determined in accordance with the provisions of Articles 11.6.3.1 and 11.6.3.2. As is true for the Simplified Method, live load is not included in the vertical stress calculation to determine  $T_{max}$  for assessing pullout loads when using the Coherent Gravity Method.

Sloping soil surcharges are taken into account through an equivalent uniform surcharge and assuming a level backslope condition. For these calculations, the depth  $Z$  is referenced from the top of the wall at the wall face, excluding any copings and appurtenances.

Note that  $T_{max}$ , the factored tensile load in the soil reinforcement, must be calculated twice for internal stability design as follows: (1) for checking reinforcement and connection rupture, determine  $T_{max}$  with live load surcharge included in the calculation of  $\sigma_v$ ; (2) for checking pullout, determine  $T_{max}$  with live load surcharge excluded from the calculation of  $\sigma_v$ .

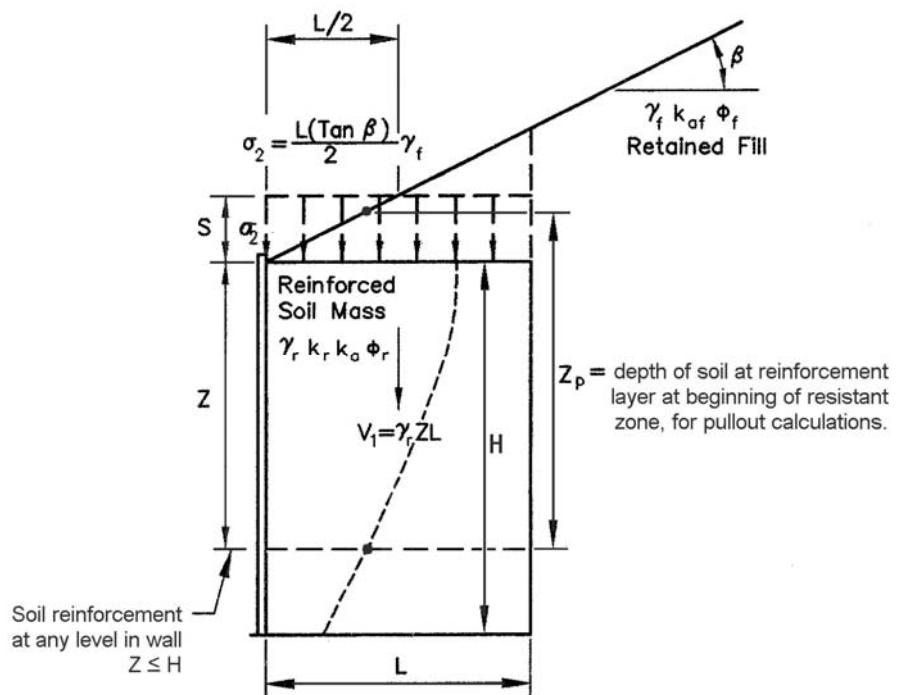

$$\text{Max Stress: } \sigma_v = \gamma_r Z + q + \Delta\sigma_v$$

$$\text{Pullout: } \sigma_v = \gamma_r Z + \Delta\sigma_v$$

Note:  $\Delta\sigma_v$  is determined from Figure 11.10.10.1-1.

$H$  is the total wall height at the face.

**Figure 11.10.6.2.1-1—Calculation of Vertical Stress for Horizontal Backslope Condition, Including Live Load and Dead Load Surcharges for Internal Stability Analysis**

$$\text{Max Stress: } S = (1/2)L \tan\beta$$

$$\sigma_v = \gamma_r Z + (1/2)L(\tan\beta)\gamma_f$$

Determine  $k_{af}$  using a slope angle of  $\beta$

Determine  $k_r$  from Figure 11.10.6.2.1-3

Pullout:  $\sigma_v = \gamma_r Z_p$  and  $Z_p \geq Z + S$

Note:  $H$  is the total height of the wall at the face.

**Figure 11.10.6.2.1-2—Calculation of Vertical Stress for Sloping Backslope Condition for Internal Stability Analysis**

For the Simplified Method, the lateral earth pressure coefficient  $k_r$  is determined by applying a multiplier to the active earth pressure coefficient,  $k_a$ . The  $k_a$  multiplier for the Simplified Method shall be determined as shown in Figure 11.10.6.2.1-3. For assessment of reinforcement pullout, the Simplified Method multiplier for steel strip walls shall be used for all steel reinforced walls. For reinforcement rupture, the multiplier applicable to the specific type of steel reinforcement shall be used. For the Coherent Gravity Method, the lateral earth pressure coefficient used for internal stability design of steel reinforced MSE wall systems shall be determined as shown in Figure 11.10.6.2.1-4. For geosynthetic reinforced wall systems,  $k_a$  is used throughout the wall height. For both methods,  $k_a$  shall be determined using Eq. 3.11.5.3-1, assuming no wall friction, i.e.,  $\delta = \beta$ . For the Coherent Gravity Method,  $k_0$  shall be determined using Eq. 3.11.5.2-1.

Since it is assumed that  $\delta = \beta$ , and  $\beta$  is assumed to always be zero for internal stability, for a vertical wall, the Coulomb equation simplifies mathematically to the simplest form of the Rankine equation.

The applied factored load to the reinforcements,  $T_{max}$ , shall be determined using a load per unit of wall width basis as follows:

$$T_{max} = \sigma_H S_v \quad (11.10.6.2.1-2)$$

where:

$\sigma_H$  = factored horizontal soil stress at the reinforcement (ksf)

$S_v$  = vertical spacing of the reinforcement (ft)

A vertical spacing,  $S_v$ , greater than 2.7 ft should not be used without full scale wall data (e.g., reinforcement loads and strains, and overall deflections) that support the acceptability of larger vertical spacing.

Live loads shall be positioned for extreme force effect. The provisions of Article 3.11.6 shall apply.

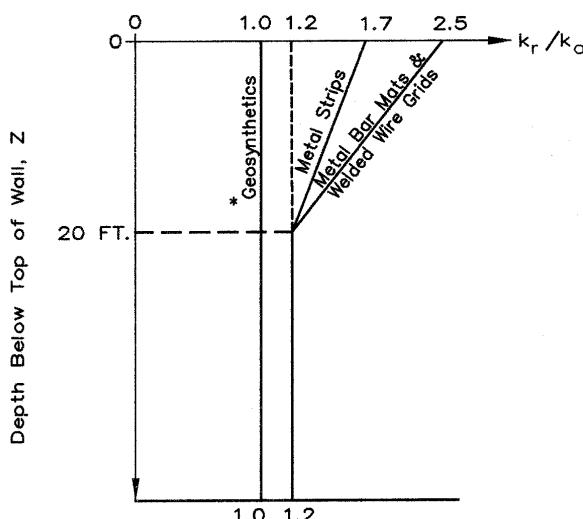

$$k_a = \tan^2 \left( 45 - \frac{\phi'_f}{2} \right) \quad (C11.10.6.2.1-1)$$

If the wall face is battered, the following simplified form of the Coulomb equation can be used:

$$k_a = \frac{\sin^2 (\theta + \phi'_f)}{\sin^3 \theta \left( 1 + \frac{\sin \phi'_f}{\sin \theta} \right)^2} \quad (C11.10.6.2.1-2)$$

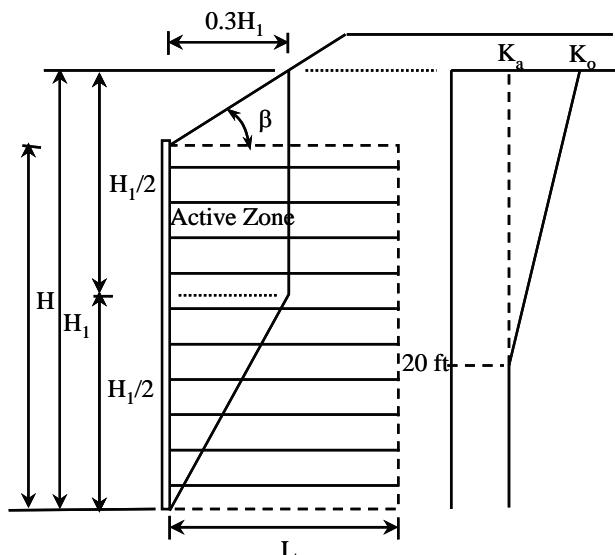

with variables as defined in Figure 3.11.5.3-1.

Based on Figure 11.10.6.2.1-3, the  $k_a$  multiplier is a function of the reinforcement type and the depth of the reinforcement below the wall top. Multipliers for other reinforcement types can be developed as needed through analysis of measurements of reinforcement load and strain in full scale structures.

\* Does not apply to polymer strip reinforcement

Figure 11.10.6.2.1-3—Variation of the Coefficient of Lateral Stress Ratio  $k_r/k_a$  with Depth in a Mechanically Stabilized Earth Wall

**Figure 11.10.6.2.1-4—Determination of Lateral Earth Pressure Coefficients for Internal Stability Design of Steel Reinforced MSE Walls Using the Coherent Gravity Method**

#### 11.10.6.2.2—Reinforcement Loads at Connection to Wall Face

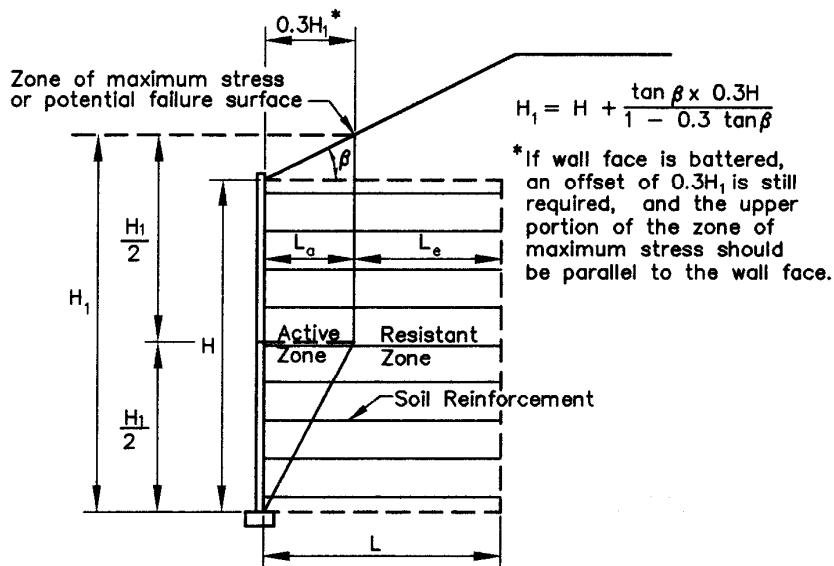

The factored tensile load applied to the soil reinforcement connection at the wall face,  $T_o$ , shall be equal to the maximum factored reinforcement tension,  $T_{max}$ , for all wall systems regardless of facing and reinforcement type.

#### 11.10.6.3—Reinforcement Pullout

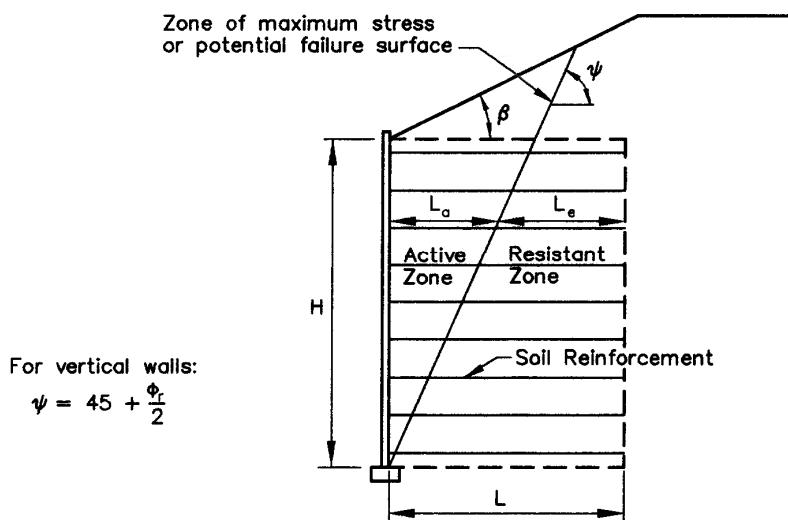

##### 11.10.6.3.1—Boundary between Active and Resistant Zones

The location of the zone of maximum stress for inextensible and extensible wall systems, i.e., the boundary between the active and resistant zones, is determined as shown in Figure 11.10.6.3-1. For all wall systems, the zone of maximum stress shall be assumed to begin at the back of the facing elements at the toe of the wall.

For extensible wall systems with a face batter of less than ten degrees from the vertical, the zone of maximum stress should be determined using the Rankine method. Since the Rankine method cannot account for wall face batter or the effect of concentrated surcharge loads above the reinforced backfill zone, the Coulomb method shall be used for walls with extensible reinforcement in cases of significant batter, defined as ten degrees from vertical or more, and concentrated surcharge loads to determine the location of the zone of maximum stress.

(a) Inextensible Reinforcements

For walls with a face batter 10 degrees or more from the vertical,

$$\tan(\Psi - \phi_r) = \frac{-\tan(\phi_r - \beta) + \sqrt{\tan(\phi_r - \beta)[\tan(\phi_r - \beta) + \cot(\phi_r + \theta - 90)][1 + \tan(\delta + 90 - \theta)\cot(\phi_r + \theta - 90)]}}{1 + \tan(\delta + 90 - \theta)[\tan(\phi_r - \beta) + \cot(\phi_r + \theta - 90)]}$$

with  $\delta = \beta$  and all other variables defined in Figure 3.11.5.3-1.

(b) Extensible Reinforcements

**Figure 11.10.6.3.1-1—Location of Potential Failure Surface for Internal Stability Design of MSE Walls**

11.10.6.3.2—*Reinforcement Pullout Design*

## C11.10.6.3.2

The reinforcement pullout resistance shall be checked at each level against pullout failure. Only the effective pullout length which extends beyond the theoretical failure surfaces in Figure 11.10.6.3.1-1 shall be used in this calculation. A minimum length,  $L_e$ , in the resistant zone of 3.0 ft shall be used. The total length of reinforcement required for pullout is equal to  $L_a + L_e$  as shown in Figure 11.10.6.3.1-1.

Note that traffic loads are neglected in pullout calculations (see Figure 11.10.6.2.1-1).

The effective pullout length shall be determined using the following equation:

$$L_e \geq \frac{T_{max}}{\phi F^* \alpha \sigma_v C R_c} \quad (11.10.6.3.2-1)$$

$F^* \alpha \sigma_v C L_e$  is the ultimate pullout resistance  $P_r$  per unit of reinforcement width.

where:

$L_e$  = length of reinforcement in resisting zone (ft)

$T_{max}$  = applied factored load in the reinforcement from Eq. 11.10.6.2.1-2 (kips/ft)

$\phi$  = resistance factor for reinforcement pullout from Table 11.5.6-1 (dim.)

$F^*$  = pullout friction factor (dim.)

$\alpha$  = scale effect correction factor (dim.)

$\sigma_v$  = unfactored vertical stress at the reinforcement level in the resistant zone (ksf)

$C$  = overall reinforcement surface area geometry factor based on the gross perimeter of the reinforcement and is equal to 2 for strip, grid and sheet-type reinforcements, i.e., two sides (dim.)

$R_c$  = reinforcement coverage ratio from Article 11.10.6.4.1 (dim.)

$F^*$  and  $\alpha$  shall be determined from product-specific pullout tests in the project backfill material or equivalent soil, or they can be estimated empirically/theoretically.

For standard backfill materials (see *AASHTO LRFD Bridge Construction Specifications*, Article 7.3.6.3), with the exception of uniform sands, i.e., coefficient of uniformity  $C_u=D_{60}/D_{10} < 4$ , in the absence of test data it is acceptable to use conservative default values for  $F^*$  and  $\alpha$  as shown in Figure 11.10.6.3.2-1 and Table 11.10.6.3.2-1. For ribbed steel strips, if the specific  $C_u$  for the wall backfill is unknown at the time of design, a  $C_u$  of 4.0 should be assumed for design to determine  $F^*$ .

Pullout testing and interpretation procedures (and direct shear testing for some parameters), as well as typical empirical data, are provided in Appendix A of FHWA Publication No. FHWA-NHI-00-043 (Elias et al., 2001).

Recent experience with pullout test results on new geogrids coming into the market has indicated that some materials have pullout values that are lower than the previous  $F^*$  default value of  $0.8 \tan \phi$ . Data obtained by D'Appolonia (1999) also indicates that  $0.8 \tan \phi$  is closer to a mean value rather than a default lower bound value for geogrids. The default values for other reinforcement types shown in Figure 11.10.6.3.2-1 are

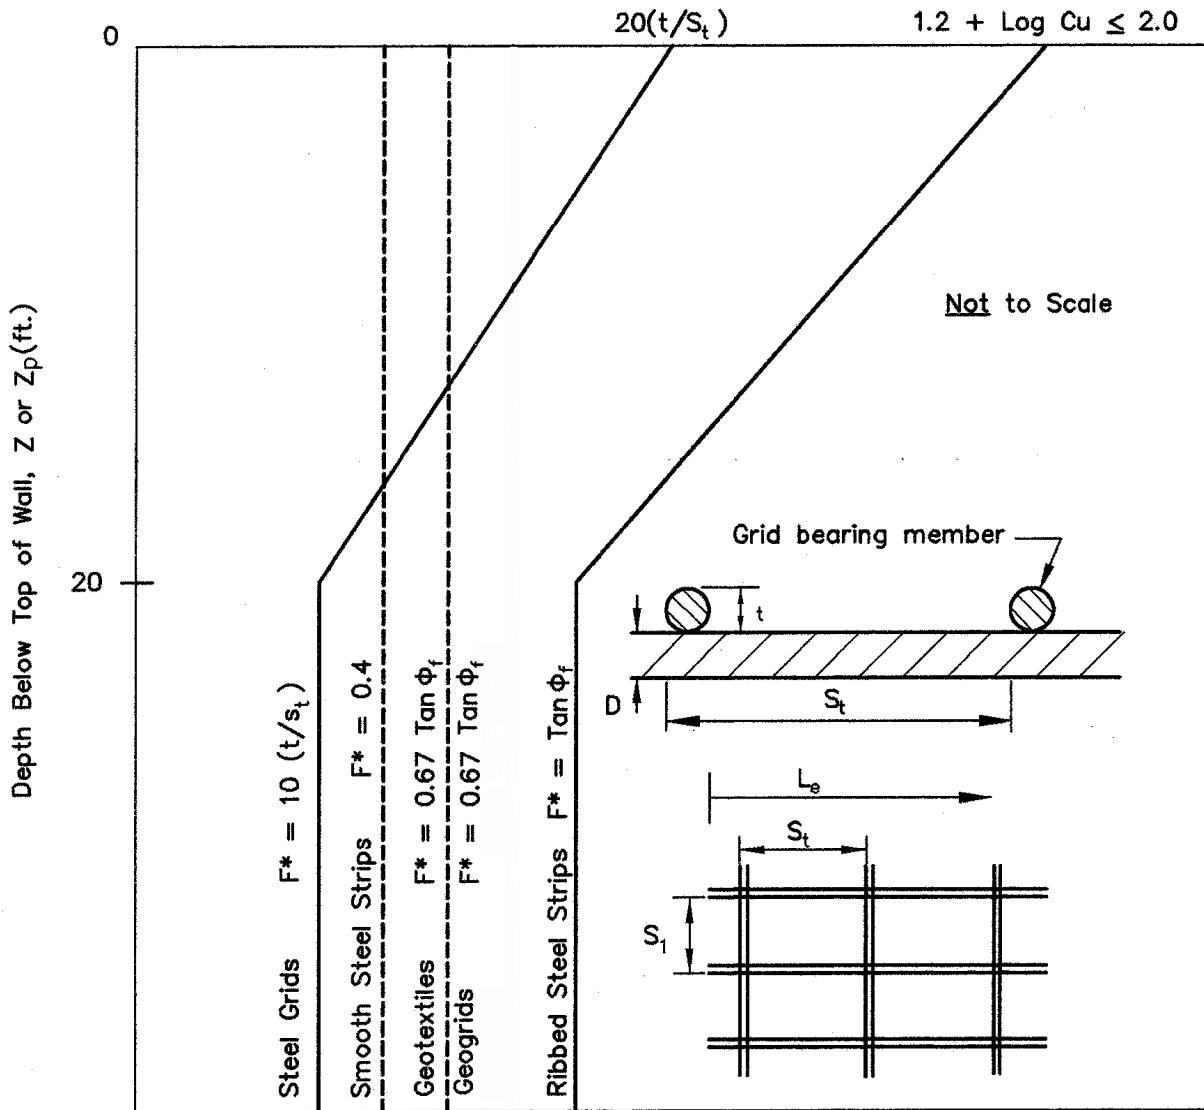

**Table 11.10.6.3.2-1—Default Values for the Scale Effect Correction Factor,  $\alpha$**

Reinforcement Type	Default Value for $\alpha$
All Steel Reinforcements	1.0
Geogrids	0.8
Geotextiles	0.6

For grids, the spacing between transverse grid elements,  $S_t$ , shall be uniform throughout the length of the reinforcement rather than having transverse grid members concentrated only in the resistant zone.

more representative of lower bound values. The  $F^*$  default value has thus been lowered to a more conservative value of  $0.67 \tan \phi$  in consideration of these results.

**Default Values for Pullout Friction Factor,  $F^*$**

**Figure 11.10.6.3.2-1—Default Values for the Pullout Friction Factor,  $F^*$**

These pullout calculations assume that the factored long-term strength of the reinforcement (see Article 11.10.6.4.1) in the resistant zone is greater than  $T_{max}$ .

#### 11.10.6.4—Reinforcement Strength

##### 11.10.6.4.1—General

The reinforcement strength shall be checked at every level within the wall, both at the boundary between the active and resistant zones (i.e., zone of maximum stress), and at the connection of the reinforcement to the wall face, for applicable strength limit states as follows:

At the zone of maximum stress:

$$T_{max} \leq \phi T_{al} R_c \quad (11.10.6.4.1-1)$$

where:

$T_{max}$  = applied factored load to the reinforcement determined from Eq. 11.10.6.2.1-2 (kips/ft)

$\phi$  = resistance factor for reinforcement tension, specified in Table 11.5.6-1 (dim.)

$T_{al}$  = nominal long-term reinforcement design strength (kips/ft)

$R_c$  = reinforcement coverage ratio specified in Article 11.10.6.4.1 (dim.)

$T_{al}$  shall be determined as specified in Article 11.10.6.4.3a for steel reinforcement and Article 11.10.6.4.3b for geosynthetic reinforcement.

At the connection with the wall face:

$$T_o \leq \phi T_{ac} R_c \quad (11.10.6.4.1-2)$$

where:

$T_o$  = applied factored load at reinforcement/facing connection specified in Article 11.10.6.2.2 (kips/ft)

$\phi$  = resistance factor for reinforcement tension in connectors specified in Table 11.5.6-1 (dim.)

$T_{ac}$  = nominal long-term reinforcement/facing connection design strength (kips/ft)

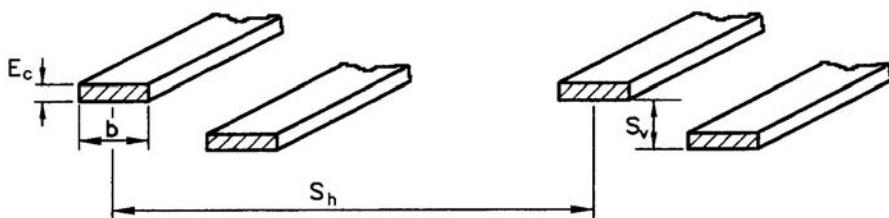

$R_c$  = reinforcement coverage ratio specified in Article 11.10.6.4.1 (dim.)

##### C11.10.6.4.1

The serviceability limit state is not specifically evaluated in current practice to design backfill reinforcement for internal stability. A first order estimate of lateral deformation of the entire wall structure, however, can be obtained as shown in Article 11.10.4.2.

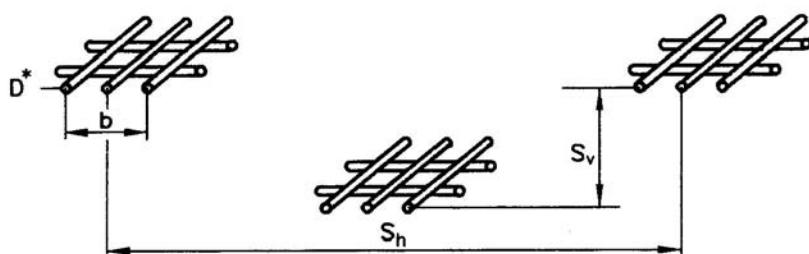

$T_{ac}$  shall be determined at the wall face connection as specified in Article 11.10.6.4.4a for steel reinforcement and Article 11.10.6.4.4b for geosynthetic reinforcement. The difference in the environment occurring immediately behind the wall face relative to the environment within the reinforcement backfill zone and its effect on the long-term durability of the reinforcement/connection shall be considered when determining  $T_{ac}$ .

$T_{al}$  shall be determined on a long-term strength per unit of reinforcement width basis and multiplied by the reinforcement coverage ratio  $R_c$  so that it can be directly compared to  $T_{max}$  which is determined on a load per unit of wall width basis (this also applies to  $T_{ac}$  and  $T_o$ ). For discrete, i.e., not continuous, reinforcements, such as steel strips or bar mats, the strength of the reinforcement is converted to a strength per unit of wall width basis as shown in Figures 11.10.6.4.1-1 and 11.10.6.4.1-2. For continuous reinforcement layers,  $b = 1$  and  $R_c = 1$ .

$$A_c = bE_c$$

$E_c$  = strip thickness corrected for corrosion loss.

$$A_c = (\text{No. of longitudinal bars}) \left( \pi \frac{D^*^2}{4} \right)$$

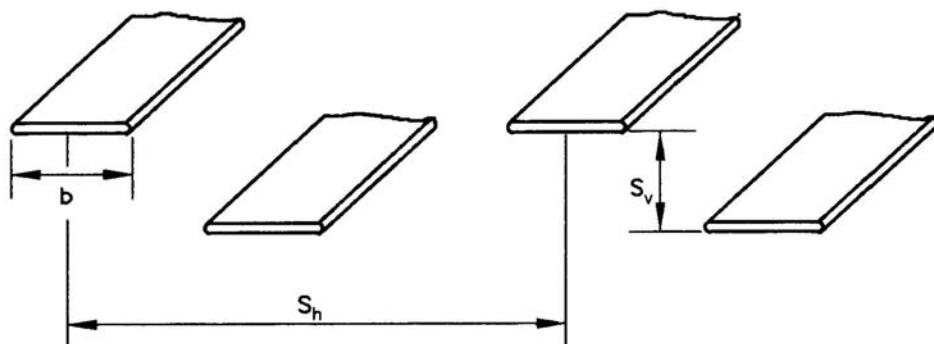

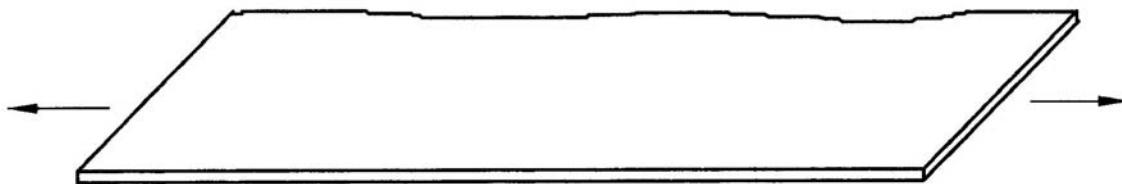

$D^*$  = diameter of bar or wire corrected for corrosion loss.

$b$  = unit width of reinforcement (if reinforcement is continuous count number of bars for reinforcement width of 1 unit).

$$R_c = \text{reinforcement coverage ratio} = \frac{b}{S_h}$$

Use  $R_c = 1$  for continuous reinforcement (i.e.,  $S_h = b = 1$  unit width).

Figure 11.10.6.4.1-1—Reinforcement Coverage Ratio for Metal Reinforcement

**Discontinuous Geosynthetic Sheets:****Continuous Geosynthetic reinforcement sheets:**

$$R_c = \text{reinforcement coverage ratio} = \frac{b}{S_h}$$

Use  $R_c = 1$  for continuous geosynthetic sheets (i.e.,  $S_h = b = 1$  unit width)

**Figure 11.10.6.4.1-2—Reinforcement Coverage Ratio for Geosynthetic Reinforcement**

#### 11.10.6.4.2—Design Life Considerations

The provisions of Article 11.5.1 shall apply.

##### 11.10.6.4.2a—Steel Reinforcements

Steel soil reinforcements shall comply with the provisions of *AASHTO LRFD Bridge Construction Specifications*, Article 7.6.4.2, "Steel Reinforcements."

The structural design of steel soil reinforcements and connections shall be made on the basis of a thickness,  $E_c$ , as follows:

$$E_c = E_n - E_s \quad (11.10.6.4.2a-1)$$

where:

$E_c$  = thickness of metal reinforcement at end of service life as shown in Figure 11.10.6.4.1-1 (mil.)

##### C11.10.6.4.2a

Corrosion loss rates summarized in Yannas (1985) and supplemented by field data developed under other FHWA research studies have been used to establish the sacrificial thicknesses herein.

The backfill specifications contained in *AASHTO LRFD Bridge Construction Specifications*, Section 7, for MSE structures using steel reinforcements present minimum electrochemical requirements, which will generally ensure a mild to moderate potential for corrosion. Where deicing salts are used, adequate drainage provisions for salt laden runoff is required. In some cases, an impervious membrane may be required between the pavement structure and the select backfill. Criteria for evaluating potential corrosion losses are given in Elias (1990).

$E_n$  = nominal thickness of steel reinforcement at construction (mil.)

$E_s$  = sacrificial thickness of metal expected to be lost by uniform corrosion during service life of structure (mil.)

For structural design, sacrificial thicknesses shall be computed for each exposed surface as follows, assuming that the soil backfill used is nonaggressive:

- Loss of galvanizing      = 0.58 mil./yr. for first 2 years  
                                  = 0.16 mil./yr. for subsequent years
- Loss of carbon steel      = 0.47 mil./yr. after zinc depletion

Soils shall typically be considered nonaggressive if they meet the following criteria:

- pH = 5 to 10
- Resistivity  $\geq$  3000 ohm-cm
- Chlorides  $\leq$  100 ppm
- Sulfates  $\leq$  200 ppm
- Organic Content  $\leq$  1 percent

If the resistivity is greater than or equal to 5000 ohm-cm, the chlorides and sulfates requirements may be waived. For bar mat or grid-type reinforcements, the sacrificial thickness listed above shall be applied to the radius of the wire or bar when computing the cross-sectional area of the steel remaining after corrosion losses.

Transverse and longitudinal grid members shall be sized in accordance with [ASTM A185](#). The transverse wire diameter shall be less than or equal to the longitudinal wire diameter.

Galvanized coatings shall be a minimum of 2 oz./ft<sup>2</sup> or 3.4 mils. in thickness, applied in conformance to AASHTO M 111M/M 111 ([ASTM A123/A 123M](#)) for strip-type reinforcements or [ASTM A641](#) for bar mat or grid-type steel reinforcement.

These sacrificial thicknesses account for potential pitting mechanisms and much of the uncertainty due to data scatter, and are considered to be maximum anticipated losses for soils which are defined as nonaggressive.

Recommended test methods for soil chemical property determination include AASHTO T 289 I for pH, AASHTO T 288 I for resistivity, AASHTO T 291 I for chlorides and AASHTO T 290 I for sulfates.

These sacrificial thickness requirements are not applicable for soils which do not meet one or more of the nonaggressive soil criteria. Additionally, these sacrificial thickness requirements are not applicable in applications where:

- The MSE wall will be exposed to a marine or other chloride rich environment,
- The MSE wall will be exposed to stray currents such as from nearby underground power lines or adjacent electric railways,
- The backfill material is aggressive, or
- The galvanizing thickness is less than specified in these guidelines.

Each of these situations creates a special set of conditions which should be specifically analyzed by a corrosion specialist. Alternatively, noncorrosive reinforcing elements can be considered. Furthermore, these corrosion rates do not apply to other metals. The use of alloys such as aluminum and stainless steel is not recommended.

Requiring the transverse wire diameter to be less than or equal to the longitudinal wire diameter will preclude local overstressing of the longitudinal wires.

Corrosion-resistant coatings should generally be limited to galvanization.

There is insufficient evidence at this time regarding the long-term performance of epoxy coatings for these coatings to be considered equivalent to galvanizing. If epoxy-type coatings are used, they should meet the requirements of [ASTM A884](#) for bar mat and grid reinforcements, or AASHTO M 284M/M 284 for strip reinforcements, and have a minimum thickness of 16 mils.

*11.10.6.4.2b—Geosynthetic Reinforcements*

Within specific limits of wall application, soil conditions, and polymer type, strength degradation due to environmental factors can be anticipated to be minimal and relatively consistent from product-to-product, and the impact of any degradation which does occur will be minimal. This allows application of a single default reduction factor,  $RF$ , to the ultimate tensile strength to account for long-term strength losses, as described in Article 11.10.6.4.3b.

Where wall application limits, soil aggressiveness and polymer requirements are consistent with the conditions below, a single default reduction factor specified herein may be used:

- Poor performance of failure will not have severe consequences
  - The soil is considered nonaggressive
  - The polymer material meets the requirements provided in Table 11.10.6.4.2b-1
- 1) *Structure Application Issues:* Identification of applications for which the consequences of poor performance or failure are severe shall be as described in Article 11.5.1. In such applications, a single default reduction factor shall not be used for final design.
  - 2) *Determination of Soil Aggressiveness:* Soil aggressiveness for geosynthetics shall be assessed based on the soil pH, gradation, plasticity, organic content, and in-ground temperature. Soil shall be defined as nonaggressive if the following criteria are met:
    - pH, as determined by AASHTO T 289,  $I = 4.5$  to 9 for permanent applications and 3 to 10 for temporary applications,
    - Maximum soil particle size is less than 0.75 in., unless full scale installation damage tests are conducted in accordance with [ASTM D5818](#),
    - Soil organic content, as determined by AASHTO T 267 for material finer than the 0.0787 in. (No. 10) sieve  $\leq 1$  percent, and
    - Design temperature at wall site:
      - $\leq 86^{\circ}\text{F}$  for permanent applications
      - $\leq 95^{\circ}\text{F}$  for temporary applications

Soil backfill not meeting these requirements as provided herein shall be considered to be aggressive. The environment at the face, in addition to that within the wall backfill, shall be evaluated, especially if the stability of the facing is dependent on the strength of the geosynthetic at the face, i.e., the geosynthetic reinforcement forms the primary connection between the body of the wall and the facing.

*C11.10.6.4.2b*

The durability of geosynthetic reinforcement is influenced by environmental factors such as time, temperature, mechanical damage, stress levels and chemical exposure, e.g., oxygen, water, and pH, which are the most common chemical factors. Microbiological attack may also affect certain polymers, although not most polymers used for carrying load in soil reinforcement applications. The effects of these factors on product durability are dependent on the polymer type used, i.e., resin type, grade, additives, and manufacturing process, and the macrostructure of the reinforcement. Not all of these factors will have a significant effect on all geosynthetic products. Therefore, the response of geosynthetic reinforcements to these long-term environmental factors is product specific.

The effective design temperature is defined as the temperature which is halfway between the average yearly air temperature and the normal daily air temperature for the warmest month at the wall site. Note that for walls which face the sun, it is possible that the temperature immediately behind the facing could be higher than the air temperature. This condition should be considered when assessing the design temperature, especially for wall sites located in warm, sunny climates.

The chemical properties of the native soil surrounding the mechanically stabilized soil backfill shall also be considered if there is potential for seepage of groundwater from the native surrounding soils to the mechanically stabilized backfill. If this is the case, the surrounding soils shall also meet the chemical criteria required for the backfill material if the environment is to be considered nonaggressive, or adequate long-term drainage around the geosynthetic reinforced mass shall be provided to ensure that chemically aggressive liquid does not enter into the reinforced backfill.

- 3) *Polymer Requirements:* Polymers which are likely to have good resistance to long-term chemical degradation shall be used if a single default reduction factor is to be used, to minimize the risk of the occurrence of significant long-term degradation. The polymer material requirements provided in Table 11.10.6.4.2b-1 shall, therefore, be met if detailed product specific data as described in Elias et al. (2001) and Elias (2000) is not obtained. Polymer materials not meeting the requirements in Table 11.10.6.4.2b-1 may be used if this detailed product specific data extrapolated to the design life intended for the structure are obtained.

For applications involving:

- Severe consequences of poor performance or failure,
- Aggressive soil conditions,
- Polymers not meeting the specific requirements set in Table 11.10.6.4.2b-1, or
- A desire to use an overall reduction factor less than the default reduction factor recommended herein,

then product-specific durability studies shall be carried out prior to product use to determine the product-specific long-term strength reduction factor, *RF*. These product-specific studies shall be used to estimate the short-term and long-term effects of these environmental factors on the strength and deformational characteristics of the geosynthetic reinforcement throughout the reinforcement design life.

Guidelines for product-specific studies to determine *RF* are provided in Elias et al. (2001) and Elias (2000).

**Table 11.10.6.4.2b-1—Minimum Requirements for Geosynthetic Products to Allow Use of Default Reduction Factor for Long-Term Degradation**

Polymer Type	Property	Test Method	Criteria to Allow Use of Default RF
Polypropylene	UV Oxidation Resistance	<a href="#">ASTM D4355</a>	Minimum 70% strength retained after 500 hrs. in weatherometer
Polyethylene	UV Oxidation Resistance	<a href="#">ASTM D4355</a>	Minimum 70% strength retained after 500 hrs. in weatherometer
Polyester	Hydrolysis Resistance	Intrinsic Viscosity Method ( <a href="#">ASTM D4603</a> ) and GRI Test Method GG8, or Determine Directly Using Gel Permeation Chromatography	Minimum Number Average Molecular Weight of 25000
Polyester	Hydrolysis Resistance	GRI Test Method GG7	Maximum of Carboxyl End Group Content of 30
All Polymers	Survivability	Weight per Unit Area ( <a href="#">ASTM D5261</a> )	Minimum 270 g/m <sup>2</sup>
All Polymers	% Post-Consumer Recycled Material by Weight	Certification of Materials Used	Maximum of 0%

**11.10.6.4.3—Design Tensile Resistance****11.10.6.4.3a—Steel Reinforcements**

The nominal reinforcement tensile resistance is determined by multiplying the yield stress by the cross-sectional area of the steel reinforcement after corrosion losses (see Figure 11.10.6.4.1-1). The loss in steel cross-sectional area due to corrosion shall be determined in accordance with Article 11.10.6.4.2a. The reinforcement tensile resistance shall be determined as:

$$T_{al} = \frac{A_c F_y}{b} \quad (11.10.6.4.3a-1)$$

where:

$T_{al}$  = nominal long-term reinforcement design strength (kips/ft)

$F_y$  = minimum yield strength of steel (ksi)

$A_c$  = area of reinforcement corrected for corrosion loss (Figure 11.10.6.4.1-1) (in.<sup>2</sup>)

$b$  = unit width of reinforcement (Figure 11.10.6.4.1-1) (ft)

#### 11.10.6.4.3b—Geosynthetic Reinforcements

The nominal long-term reinforcement tensile strength shall be determined as:

$$T_{al} = \frac{T_{ul}}{RF} \quad (11.10.6.4.3b-1)$$

where:

$$RF = RF_{ID} \times RF_{CR} \times RF_D \quad (11.10.6.4.3b-2)$$

and:

$T_{al}$  = nominal long-term reinforcement design strength (kips/ft)

$T_{ul}$  = minimum average roll value (MARV) ultimate tensile strength (kips/ft)

$RF$  = combined strength reduction factor to account for potential long-term degradation due to installation damage, creep and chemical aging (dim.)

$RF_{ID}$  = strength reduction factor to account for installation damage to reinforcement (dim.)

$RF_{CR}$  = strength reduction factor to prevent long-term creep rupture of reinforcement (dim.)

$RF_D$  = strength reduction factor to prevent rupture of reinforcement due to chemical and biological degradation (dim.)

Values for  $RF_{ID}$ ,  $RF_{CR}$ , and  $RF_D$  shall be determined from product specific test results as specified in Article 11.10.6.4.2b. Even with product specific test results, neither  $RF_{ID}$  nor  $RF_D$  shall be less than 1.1.

For wall applications which are defined as not having severe consequences should poor performance or failure occur, having nonaggressive soil conditions, and if the geosynthetic product meets the minimum requirements listed in Table 11.10.6.4.3b-1, the long-term tensile strength of the reinforcement may be determined using a default reduction factor for  $RF$  as provided in Table 11.10.6.4.3b-1 in lieu of product-specific test results.

#### C11.10.6.4.3b

$T_{al}$  is the long-term tensile strength required to prevent rupture calculated on a load per unit of reinforcement width basis.  $T_{ul}$  is the ultimate tensile strength of the reinforcement determined from wide width tensile tests specified in [ASTM D 4595](#) for geotextiles and [ASTM D6637](#) for geogrids. The value selected for  $T_{ul}$  is the minimum average roll value (MARV) for the product to account for statistical variance in the material strength.

Guidelines for determination of  $RF_{ID}$ ,  $RF_{CR}$ , and  $RF_D$  from product-specific data are provided in Elias et al. (2001) and Elias (2001).

**Table 11.10.6.4.3b-1—Default and Minimum Values for the Total Geosynthetic Ultimate Limit State Strength Reduction Factor,  $RF$** 

Application	Total Reduction Factor, $RF$
All applications, but with product-specific data obtained and analyzed in accordance with Elias (2001) and Elias et al. (2001)	All reduction factors shall be based on product specific data. Neither $RF_{ID}$ nor $RF_D$ shall be less than 1.1.
Permanent applications not having severe consequences should poor performance or failure occur, nonaggressive soils, and polymers meeting the requirements listed in Table 11.10.6.4.2b-1	7.0
Temporary applications not having severe consequences should poor performance or failure occur, nonaggressive soils, and polymers meeting the requirements listed in Table 11.10.6.4.2b-1 provided product specific data are not available	3.5

*11.10.6.4.4—Reinforcement/Facing Connection Design Strength*

*11.10.6.4.4a—Steel Reinforcements*

Connections shall be designed to resist stresses resulting from active forces,  $T_o$ , in Article 11.10.6.2.2, as well as from differential movements between the reinforced backfill and the wall facing elements.

Elements of the connection which are embedded in the facing element shall be designed with adequate bond length and bearing area in the concrete to resist the connection forces. The capacity of the embedded connector shall be checked by tests as required in Article 5.11.3. Connections between steel reinforcement and the wall facing units, e.g., welds, bolts, pins, etc., shall be designed in accordance with Article 6.13.3.

Connection materials shall be designed to accommodate losses due to corrosion in accordance with Article 11.10.6.4.2a. Potential differences between the environment at the face relative to the environment within the reinforced soil mass shall be considered when assessing potential corrosion losses.

*11.10.6.4.4b—Geosynthetic Reinforcements*

The portion of the connection embedded in the concrete facing shall be designed in accordance with Article 5.11.3.

The nominal long-term geosynthetic connection strength  $T_{ac}$  on a load per unit reinforcement width basis shall be determined as follows:

$$T_{ac} = \frac{T_{ult} \times CR_{cr}}{RF_D} \quad (11.10.6.4.4b-1)$$

where:

$T_{ac}$  = nominal long-term reinforcement/facing connection design strength per unit of reinforcement width at a specified confining pressure (kips/ft)

*C11.10.6.4.4b*

The long-term creep reduced geosynthetic strength at the connection with the wall facing is obtained by reducing  $T_{ult}$  by  $CR_{cr}$  using the connection/seam strength determined in accordance with long-term connection strength test protocol as described in Appendix A of Elias et al. (2001). The connection test is similar in nature to a wide width tensile test ([ASTM D4595](#) or [ASTM D6637](#)), except that one end of the reinforcement material is sandwiched between two courses of concrete blocks to form one of the grips. This protocol consists of a series of connection creep tests carried out over an extended period of time to evaluate the potential for creep rupture at the connection.  $CR_{cr}$  is taken as the creep reduced connection strength,  $T_{crc}$ , extrapolated to the specified design life, divided by the ultimate wide width tensile strength ([ASTM D4595](#) or [D6637](#)) for the reinforcement material lot used for the connection strength testing,  $T_{lot}$ .

$T_{ult}$	= minimum average roll value (MARV) ultimate tensile strength of soil reinforcement (kips/ft)
$CR_{cr}$	= long-term connection strength reduction factor to account for reduced ultimate strength resulting from connection (dim.)
$RF_D$	= reduction factor to prevent rupture of reinforcement due to chemical and biological degradation (Article 11.10.6.4.3b) (dim.)

$CR_{cr}$  may also be obtained from short-term connection test ([ASTM D4884](#) for seam connections, or NCMA Test Method SRWU-1 in Simac et al. (1993) for segmental concrete block connections) results, which are to obtain a short-term ultimate connection strength reduction factor  $CR_u$ .  $C_{nu}$  is taken as the ultimate connection strength  $T_{ultconn}$  from SRWU-1 or [ASTM D4884](#), divided by  $T_{lot}$  as described above. In this case,  $CR_u$  must be further reduced by the creep reduction factor  $RF_{CR}$  (Article 11.10.6.4.3b) in order to account for the potential of creep rupture as follows:

$$CR_{cr} = \frac{CR_u}{RF_{CR}} \quad (\text{C11.10.6.4.4b-1})$$

For reinforcements connected to the facing through embedment between facing elements, e.g., segmental concrete block faced walls, the capacity of the connection is conceptually governed by one of two failure modes: rupture, or pullout of the reinforcement. This is consistent with the evaluation of internal wall stability in the reinforced backfill zone, where both the rupture and pullout mode of failure must be considered.

The objective of the connection design is to assess the long-term capacity of the connection. If rupture is the mode of failure, the long-term effects of creep and durability on the geosynthetic reinforcement at the connection, as well as on the connector materials, must be taken into account, as the capacity of the connection is controlled by the reinforcement or connector long-term strength. If pullout is the mode of failure, the capacity of the connection is controlled by the frictional interface between the facing blocks and the geosynthetic reinforcement. It is assumed for design that this interface is not significantly affected by time dependent mechanisms such as creep or chemical degradation. This again is consistent with the design of the soil reinforcement within the wall backfill. The load bearing fibers or ribs of the geosynthetic do not necessarily have to experience rupture in the connection test for the mode of failure to be rupture. If the connector is a material that is susceptible to creep, failure of the connectors between blocks due to creep rupture of the connector could result in long-term connection strength losses. In these cases, the value of  $CR_{cr}$  and  $RF_D$  to be used in Eq. C11.10.6.4.4b-1 should be based on the durability of the connector, not the geosynthetic.

Regardless of the failure mode, the long-term connection test referenced in Elias et al. (2001) addresses the long-term capacity of the connection. Eq. C11.10.6.4.4b-1 above should also be considered to conservatively apply to both failure modes, if the long-term connection test is not performed.

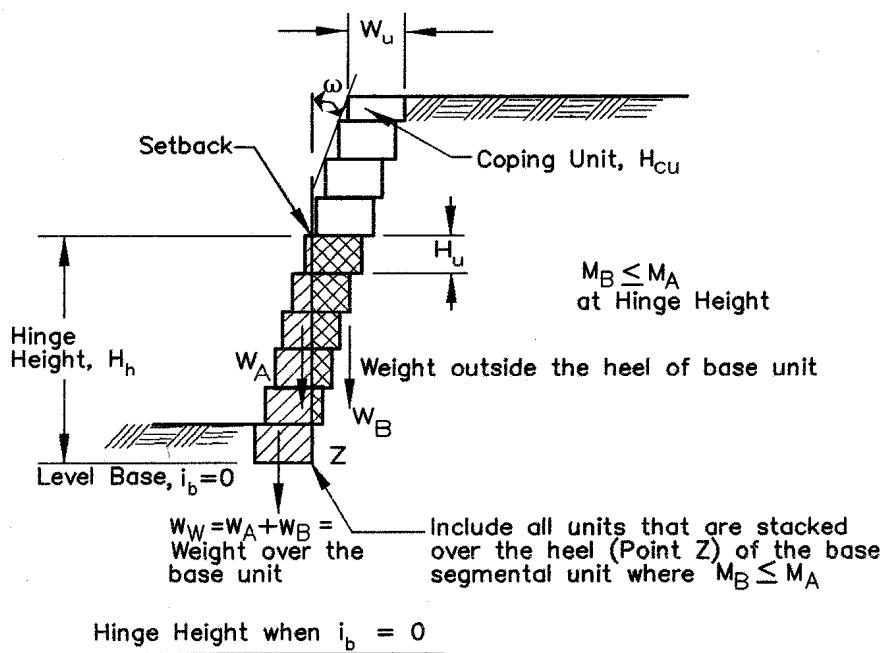

Values for  $RF_{CR}$  and  $RF_D$  shall be determined from product-specific test results, except as otherwise specified herein. The environment at the wall face connection may be different than the environment away from the wall face in the wall backfill. This shall be considered when determining  $RF_{CR}$  and  $RF_D$ .

$CR_{cr}$  shall be determined at the anticipated vertical confining pressure at the wall face between the facing blocks. The vertical confining pressure shall be calculated using the Hinge Height Method as shown in Figure 11.10.6.4.4b-1 for a face batter,  $\omega$ , of greater than 8 degrees.  $T_{ac}$  should not be greater than  $T_{al}$ .

Geosynthetic walls may be designed using a flexible reinforcement sheet as the facing using only an overlap with the main soil reinforcement. The overlaps shall be designed using a pullout methodology. By replacing  $T_{max}$  with  $T_o$ , Eq. 11.10.6.3.2-1 may be used to determine the minimum overlap length required, but in no case shall the overlap length be less than 3.0 ft. If  $\tan \rho$  is determined experimentally based on soil to reinforcement contact,  $\tan \rho$  shall be reduced by 30 percent where reinforcement to reinforcement contact is anticipated.

If the connectors between blocks are intended to be used for maintaining block alignment during wall construction and are not intended for long-term connection shear capacity, the alignment connectors should be removed before assessing the connection capacity for the selected block-geosynthetic combination. If the pins or other connection devices are to be relied upon for long-term capacity, the durability of the connector material must be established.

Guidelines for determining  $RF_{CR}$  and  $RF_D$  from product-specific data are provided in Elias et al. (2001) and Elias (2001). The use of default reduction factors may be acceptable where the reinforcement load is maximum, i.e., in the middle of the wall backfill, and still not be acceptable at the facing connection if the facing environment is defined as aggressive.

**Hinge Height,  $H_h$ .** The full weight of all segmental facing block units within  $H_h$  will be considered to act at the base of the lowermost segmental facing block.

Figure 11.10.6.4.4b-1—Determination of Hinge Height for Segmental Concrete Block Faced MSE Walls

The hinge height,  $H_h$ , shown in Figure 11.10.6.4.4b-1, shall be determined as:

$$H_h = 2[(W_u - G_u - 0.5H_u \tan i_b) \cos i_b] / \tan(\omega + i_b) \quad (11.10.6.4.4b-2)$$

where:

$H_u$  = segmental facing block unit height (ft)

$W_u$  = segmental facing block unit width, front to back (ft)

$G_u$  = distance to the center of gravity of a horizontal segmental facing block unit, including aggregate fill, measured from the front of the unit (ft)

$\omega$  = wall batter due to setback per course (degrees)

$H$  = total height of wall (ft)

$H_h$  = hinge height (ft)

### 11.10.7—Seismic Design

#### 11.10.7.1—External Stability

Stability determinations shall be made by applying the sum of static forces, the horizontal inertial force,  $P_{IR}$ , and 50 percent of the dynamic horizontal thrust,  $P_{AE}$  to the wall. The locations of  $P_{AE}$  and  $P_{IR}$  shall be taken as illustrated in Figure 11.10.7.1-1. These forces are combined with the static forces, factored in accordance with Article 3.4.1. The dynamic horizontal thrust,  $P_{AE}$ , shall be evaluated using the pseudo-static Mononobe-Okabe method and shall be applied to the back surface of the reinforced fill at the height of  $0.6H$  from the base and the horizontal inertial force shall be applied at the center of dynamic mass of the structure.  $A_m$ , the maximum acceleration coefficient at the wall centroid, except as noted in Article C11.10.7.1, shall be determined as:

$$A_m = (1.45 - A_s) A_s \quad (11.10.7.1-1)$$

where:

$A_s$  = peak seismic ground acceleration coefficient modified by short-period site factor specified in Article 3.10.4 (dim.)

Values of  $P_{AE}$  and  $P_{IR}$  for structures with horizontal backfill may be determined using the following simplified equations:

$$P_{AE} = 0.375 \gamma_{EQ} A_m \gamma_s H^2 \quad (11.10.7.1-2)$$

$$P_{IR} = 0.5 \gamma_{EQ} A_m \gamma_s H^2 \quad (11.10.7.1-3)$$

where:

$\gamma_{EQ}$  = load factor for  $EQ$  loads from Table 3.4.1-1 (dim.)

$A_m$  = maximum wall acceleration coefficient at the centroid of the wall mass (dim.)

$\gamma_s$  = soil unit weight (kcf)

$H$  = height of wall (ft)

For structures with sloping backfills, the inertial force,  $P_{IR}$ , shall be based on an effective mass having a height  $H_2$  and a base width equal to  $0.5 H_2$  determined as follows:

$$H_2 = H + \frac{0.5H \tan(\beta)}{\left[1 - 0.5 \tan(\beta)\right]} \quad (11.10.7.1-4)$$

#### C11.10.7.1

The equation for  $P_{AE}$  was developed assuming a friction angle of 30 degrees.  $P_{AE}$  may be calculated using the Mononobe-Okabe method, with the horizontal acceleration  $k_h$  equal to  $A_m$  and  $k_v$  equal to zero, multiplied by the load factor  $\gamma_{EQ}$ .

The seismic earth pressure calculated using the Mononobe-Okabe method may be reduced in accordance with Article 11.6.5 for walls which can displace laterally. If it is desired to apply the procedures provided in Article C11.6.5 to account for the effect of lateral displacement in reducing seismic lateral earth pressures, calculate  $A_m$  as follows:

$$A_m = (1.45 - k_h) k_h \quad (C11.10.7.1-1)$$

where  $k_h$  is obtained from Eq. C11.6.5-1.

It is recommended that this reduced acceleration value only be used for external stability calculations, including wall inertial forces as well as seismic earth pressures behind the wall, to be consistent with the concept of the MSE wall behaving as a rigid block. Internally, the lateral deformation response of the MSE wall is much more complex, and it is not clear at this time how much the acceleration coefficient could decrease due to the allowance of some lateral deformation during seismic loading internally in the MSE wall.

If either  $A_s$  or  $k_h$  is greater than 0.45, set  $A_m = A_s$  or  $A_m = k_h$ , respectively, as this equation has not been specifically validated for higher accelerations, and a value of  $A_m$  less than  $A_s$  or  $k_h$  would result.

The seismic design procedures provided herein do not directly account for the lateral deformation that may occur during large earthquake seismic loading. It is, therefore, recommended that if the anticipated ground acceleration is greater than  $0.29g$ , a detailed lateral deformation analysis of the structure during seismic loading should be performed, such as a Newmark sliding analysis or numerical modeling.

where:

$\beta$  = slope of backfill (degrees)

$P_{IR}$  for sloping backfills shall be determined as:

$$P_{IR} = P_{ir} + P_{is} \quad (11.10.7.1-5)$$

where:

$$P_{ir} = 0.5\gamma_{EQ}A_m\gamma_sH_2H \quad (11.10.7.1-6)$$

$$P_{is} = 0.125\gamma_{EQ}A_m\gamma_s(H_2)^2\tan(\beta) \quad (11.10.7.1-7)$$

where:

$P_{ir}$  = the inertial force caused by acceleration of the reinforced backfill (kips/ft)

$P_{is}$  = the inertial force caused by acceleration of the sloping soil surcharge above the reinforced backfill (kips/ft)

The width of mass contributing to  $P_{IR}$  shall be equal to  $0.5H_2$ .  $P_{IR}$  shall act at the combined centroid of  $P_{ir}$  and  $P_{is}$ .

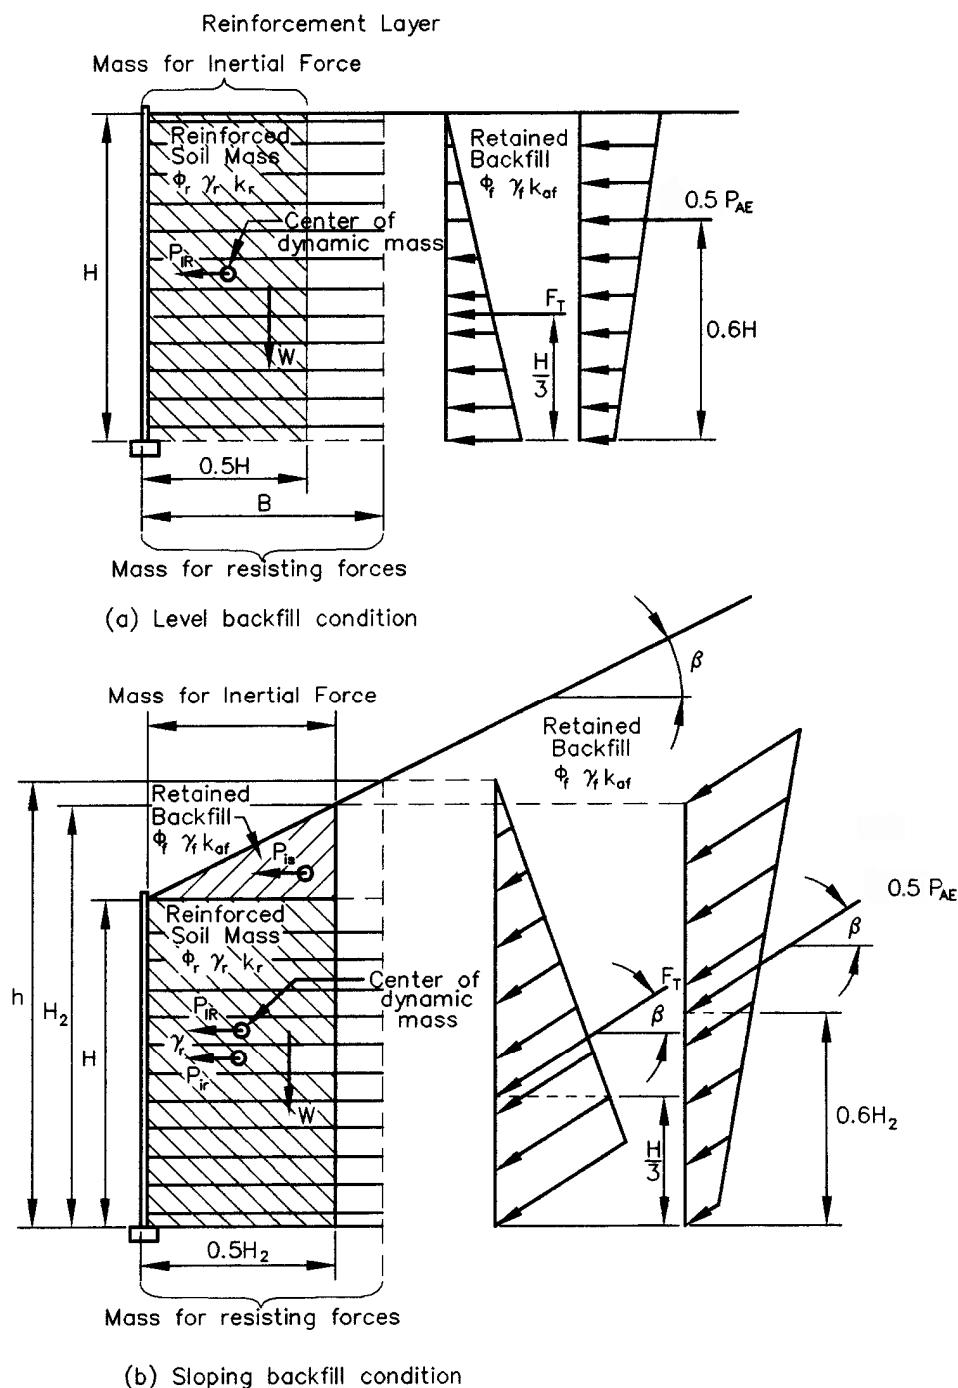

Figure 11.10.7.1-1—Seismic External Stability of a MSE Wall

**11.10.7.2—Internal Stability****C11.10.7.2**

Reinforcements shall be designed to withstand horizontal forces generated by the internal inertia force,  $P_i$ , and the static forces. The total inertia force,  $P_i$ , per unit length of structure shall be considered equal to the mass of the active zone times the maximum wall acceleration coefficient  $A_m$ . This inertial force shall be distributed to the reinforcements proportionally to their resistant areas on a load per unit width of wall basis as follows:

$$T_{md} = \gamma P_i \frac{L_{ei}}{\sum_{i=1}^m (L_{ei})} \quad (11.10.7.2-1)$$

where:

$T_{md}$  = factored incremental dynamic inertia force at Layer  $i$  (kips/ft)

$\gamma$  = load factor for  $EQ$  loads from Table 3.4.1-1 (dim.)

$P_i$  = internal inertia force due to the weight of backfill within the active zone, i.e., the shaded area on Figure 11.10.7.2-1 (kips/ft)

$$P_i = A_m W_a$$

where  $W_a$  is the weight of the active zone and  $A_m$  given by Eq. 11.10.7.1-1

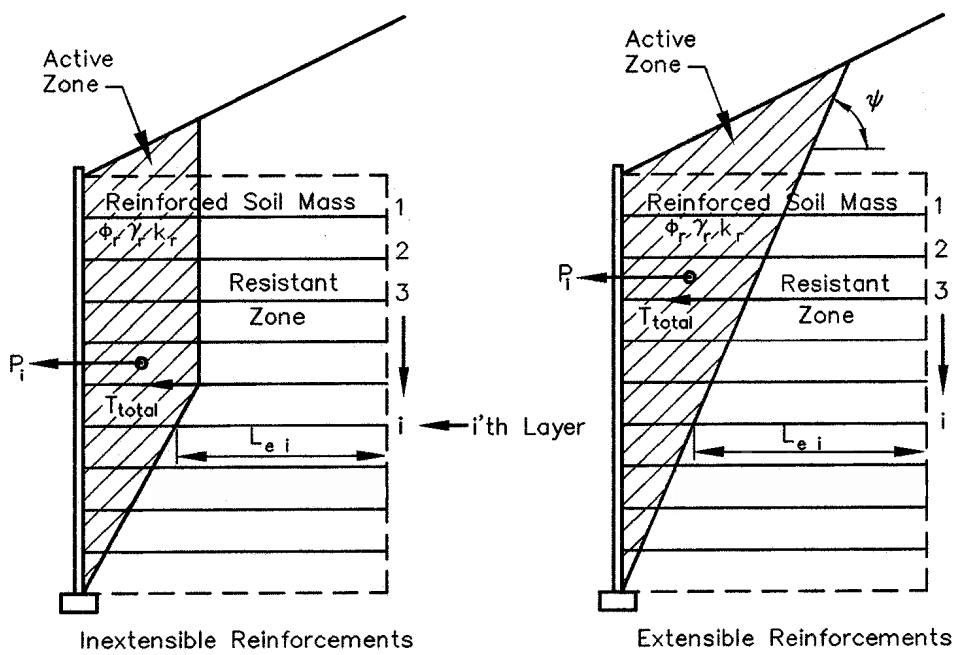

$L_{ei}$  = effective reinforcement length for layer  $i$  (ft)

The total factored load applied to the reinforcement on a load per unit of wall width basis as shown in Figure 11.10.7.2-1 is determined as follows:

$$T_{total} = T_{max} + T_{md} \quad (11.10.7.2-2)$$

where:

$T_{max}$  = the factored static load applied to the reinforcements determined using Eq. 11.10.6.2.1-2.

$P_i$  = Internal inertial force due to the weight of the backfill within the active zone.

$L_{ei}$  = The length of reinforcement in the resistant zone of the  $i^{\text{th}}$  layer.

$T_{\max}$  = The factored load per unit wall width applied to each reinforcement layer due to static forces.

$T_{md}$  = The factored load per unit wall width applied to each reinforcement layer due to dynamic forces.

The total factored load per unit wall width applied to each reinforcement layer,

$$T_{\text{total}} = T_{\max} + T_{md}$$

Figure 11.10.7.2-1—Seismic Internal Stability of an MSE Wall

For geosynthetic reinforcement rupture, the reinforcement shall be designed to resist the static and dynamic components of the load determined as:

For the static component:

$$S_{rs} \geq \frac{T_{max} RF}{\phi R_c} \quad (11.10.7.2-3)$$

For the dynamic component:

$$S_{rt} \geq \frac{T_{md} RF_{ID} RF_D}{\phi R_c} \quad (11.10.7.2-4)$$

where:

$\phi$  = resistance factor for combined static/earthquake loading from Table 11.5.6-1 (dim.)

$S_{rs}$  = ultimate reinforcement tensile resistance required to resist static load component (kips/ft)

$S_{rt}$  = ultimate reinforcement tensile resistance required to resist dynamic load component (kips/ft)

$R_c$  = reinforcement coverage ratio specified in Article 11.10.6.4.1 (dim.)

$RF$  = combined strength reduction factor to account for potential long-term degradation due to installation damage, creep, and chemical aging specified in Article 11.10.6.4.3b (dim.)

$RF_{ID}$  = strength reduction factor to account for installation damage to reinforcement specified in Article 11.10.6.4.3b (dim.)

$RF_D$  = strength reduction factor to prevent rupture of reinforcement due to chemical and biological degradation specified in Article 11.10.6.4.3b (dim.)

The required ultimate tensile resistance of the geosynthetic reinforcement shall be determined as:

$$T_{ult} = S_{rs} + S_{rt} \quad (11.10.7.2-5)$$

For pullout of steel or geosynthetic reinforcement:

$$L_e \geq \frac{T_{total}}{\phi (0.8F^* \alpha \sigma_v C R_c)} \quad (11.10.7.2-6)$$

The reinforcement must be designed to resist the dynamic component of the load at any time during its design life. Design for static loads requires the strength of the reinforcement at the end of the design life to be reduced to account for creep and other degradation mechanisms. Strength loss in polymeric materials due to creep requires long term, sustained loading. The dynamic component of load for seismic design is a transient load and does not cause strength loss due to creep. The resistance of the reinforcement to the static component of load,  $T_{max}$ , must, therefore, be handled separately from the dynamic component of load,  $T_{md}$ . The strength required to resist  $T_{max}$  must include the effects of creep, but the strength required to resist  $T_{md}$  should not include the effects of creep.

where:

- $L_e$  = length of reinforcement in resisting zone (ft)
- $T_{total}$  = maximum factored reinforcement tension from Eq. 11.10.7.2-2 (kips/ft)
- $\phi$  = resistance factor for reinforcement pullout from Table 11.5.6-1 (dim.)
- $F^*$  = pullout friction factor (dim.)
- $\alpha$  = scale effect correction factor (dim.)
- $\sigma_v$  = unfactored vertical stress at the reinforcement level in the resistant zone (ksf)
- $C$  = overall reinforcement surface area geometry factor (dim.)
- $R_c$  = reinforcement coverage ratio specified in Article 11.10.6.4.1 (dim.)

For seismic loading conditions, the value of  $F^*$ , the pullout resistance factor, shall be reduced to 80 percent of the value used for static design, unless dynamic pullout tests are performed to directly determine the  $F^*$  value.

### 11.10.7.3—Facing Reinforcement Connections

### C11.10.7.3

Facing elements shall be designed to resist the seismic loads determined as specified in Article 11.10.7.2, i.e.,  $T_{total}$ . Facing elements shall be designed in accordance with applicable provisions of Sections 5, 6, and 8 for reinforced concrete, steel, and timber, respectively.

For segmental concrete block faced walls, the blocks located above the uppermost backfill reinforcement layer shall be designed to resist toppling failure during seismic loading.

For geosynthetic connections subjected to seismic loading, the factored long-term connection strength,  $\phi T_{ac}$ , must be greater than  $T_{max} + T_{md}$ . If the connection strength is partially or fully dependent on friction between the facing blocks and the reinforcement, the connection strength to resist seismic loads shall be reduced to 80 percent of its static value as follows:

For the static component of the load:

$$S_{rs} \geq \frac{T_{max} RF_D}{0.8\phi CR_{cr} R_c} \quad (11.10.7.3-1)$$

For the dynamic component of the load:

$$S_{rs} \geq \frac{T_{md}RF_D}{0.8\phi CR_u R_c} \quad (11.10.7.3-2)$$

where:

$S_{rs}$  = ultimate reinforcement tensile resistance required to resist static load component (kip/ft)

$T_{max}$  = applied load to reinforcement (kip/ft)

$RF_D$  = reduction factor to prevent rupture of reinforcement due to chemical and biological degradation specified in Article 11.10.6.4.4b (dim.)

$\phi$  = resistance factor from Table 11.5.6-1 (dim.)

$CR_{cr}$  = long-term connection strength reduction factor to account for reduced ultimate strength resulting from connection (dim.)

$R_c$  = reinforcement coverage ratio from Article 11.10.6.4.1 (dim.)

$S_{rt}$  = ultimate reinforcement tensile resistance required to resist dynamic load component (kip/ft)

$T_{md}$  = factored incremental dynamic inertia force (kip/ft)

$CR_u$  = short-term reduction factor to account for reduced ultimate strength resulting from connection as specified in Article C11.10.6.4.4b (dim.)

For mechanical connections that do not rely on a frictional component, the 0.8 multiplier may be removed from Eqs. 11.10.7.3-1 and 11.10.7.3-2.

The required ultimate tensile resistance of the geosynthetic reinforcement at the connection is:

$$T_{ult} = S_{rs} + S_{rt} \quad (11.10.7.3-3)$$

For structures in seismic performance Zones 3 or 4, facing connections in segmental block faced walls shall use shear resisting devices between the facing blocks and soil reinforcement such as shear keys, pins, etc., and shall not be fully dependent on frictional resistance between the soil reinforcement and facing blocks.

For steel reinforcement connections, resistance factors for combined static and seismic loads may be increased by 33 percent of factors used for static loading. Based on these resistance factors, the available factored connection strength must be greater than  $T_{total}$ .

The connection capacity of a facing/reinforcement connection system that is fully dependent on the shear resisting devices for the connection capacity will not be significantly influenced by the normal stress between facing blocks. The percentage of connection load carried by the shear resisting devices relative to the frictional resistance to meet the specification requirements should be determined based on past successful performance of the connection system.

### 11.10.8—Drainage

Internal drainage measures shall be considered for all structures to prevent saturation of the reinforced backfill and to intercept any surface flows containing aggressive elements.

MSE walls in cut areas and side-hill fills with established groundwater levels shall be constructed with drainage blankets in back of, and beneath, the reinforced zone.

For MSE walls supporting roadways which are chemically deiced in the winter, an impervious membrane may be required below the pavement and just above the first layer of soil reinforcement to intercept any flows containing deicing chemicals. The membrane shall be sloped to drain away from the facing to an intercepting longitudinal drain outletted beyond the reinforced zone. Typically, a roughened surface PVC, HDPE or LLDPE geomembrane with a minimum thickness of 30 mils. should be used. All seams in the membrane shall be welded to prevent leakage.

### 11.10.9—Subsurface Erosion

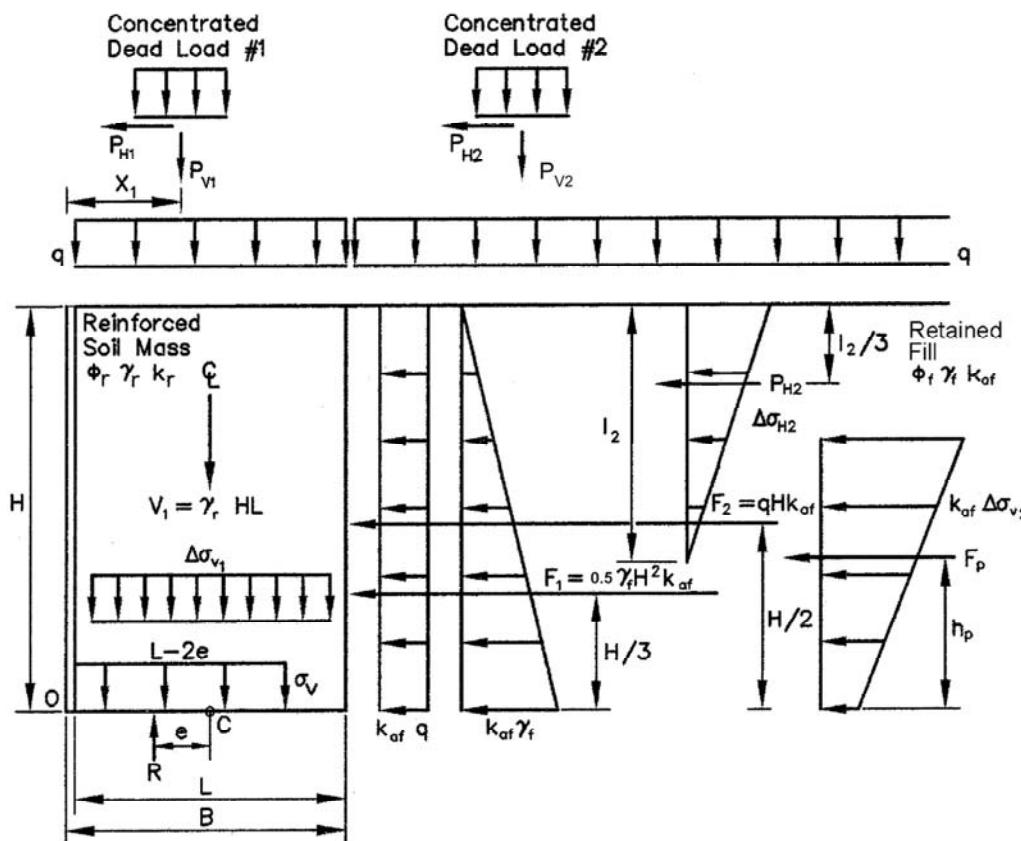

The provisions of Article 11.6.3.5 shall apply.

### 11.10.10—Special Loading Conditions

#### 11.10.10.1—Concentrated Dead Loads

The distribution of stresses within and behind the wall resulting from concentrated loads applied to the wall top or behind the wall shall be determined in accordance with Article 3.11.6.3.

Figure 11.10.10.1-1 illustrates the combination of loads using superposition principles to evaluate external and internal wall stability. Depending on the size and location of the concentrated dead load, the location of the boundary between the active and resistant zones may have to be adjusted as shown in Figure 11.10.10.1-2.

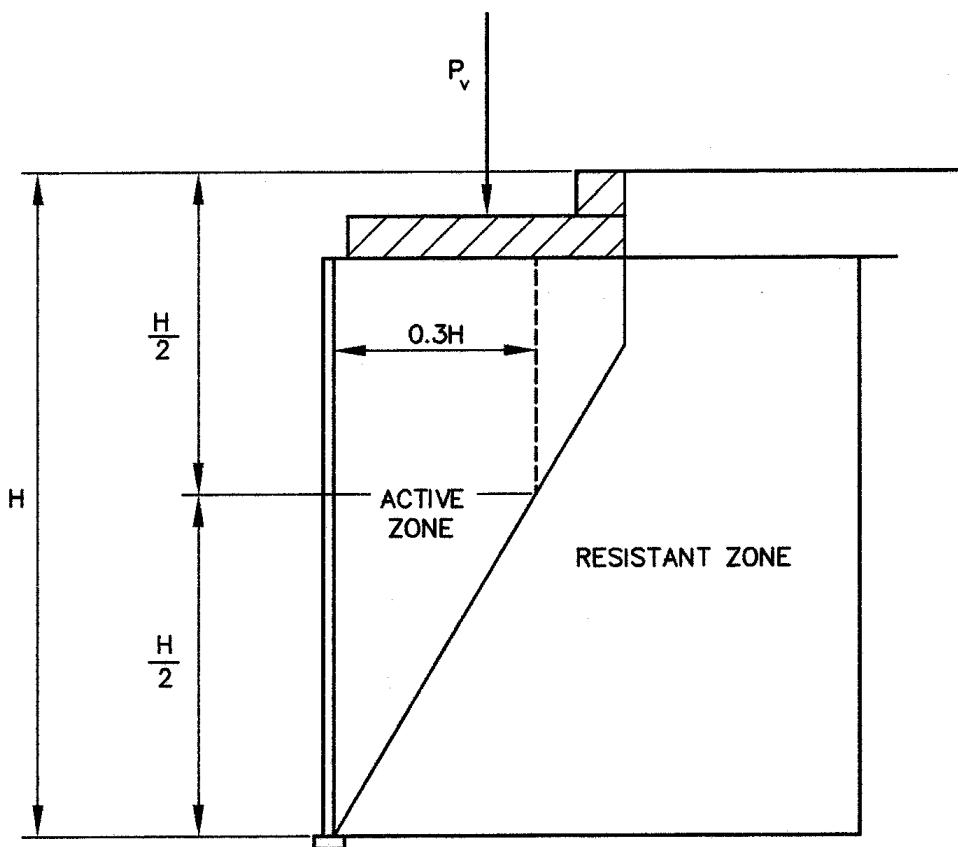

Note: These equations assume that concentrated dead load #2 is located within the active zone behind the reinforced soil mass.

Note: For relatively thick facing elements, (e.g., segmental concrete facing blocks), it is acceptable to include the facing dimensions and weight in sliding, overturning, and bearing capacity calculations (i.e., use  $B$  in lieu of  $L$ ).

Note:  $P_{V1}$ ,  $P_{H1}$ ,  $\Delta\sigma_{v1}$ ,  $\Delta\sigma_{v2}$ ,  $\Delta\sigma_{H2}$ , and  $I_2$  are as determined from Figures 3.11.6.3-1 and 3.11.6.3-2, and  $F_p$  results from  $P_{V2}$  (i.e.,  $K\Delta\sigma_{v2}$  from Figure 3.11.6.3-1).  $H$  is the total wall height at the face.

**Figure 11.10.10.1-1—Superposition of Concentrated Dead Loads for External and Internal Stability Evaluation**

**Figure 11.10.10.1-2—Location of Maximum Tensile Force Line in Case of Large Surcharge Slabs (Inextensible Reinforcements)**

### 11.10.10.2—Traffic Loads and Barriers

Traffic loads shall be treated as uniform surcharge loads in accordance with the criteria outlined in Article 3.11.6.2. The live load surcharge pressure shall not be less than 2.0 ft of earth. Parapets and traffic barriers, constructed over or in line with the front face of the wall, shall be designed to resist overturning moments by their own mass. Base slabs shall not have any transverse joints, except construction joints, and adjacent slabs shall be joined by shear dowels. The upper layer(s) of soil reinforcements shall have sufficient tensile capacity to resist a concentrated horizontal load of  $\gamma P_H$  where  $P_H = 10$  kips distributed over a barrier length of 5.0 ft. This force distribution accounts for the local peak force in the soil reinforcements in the vicinity of the concentrated load. This distributed force would be equal to  $\gamma P_{H1}$  where  $P_{H1} = 2.0$  kips/ft and is applied as shown in Figure 3.11.6.3-2a.  $\gamma P_{H1}$  would be distributed to the reinforcements assuming  $b_f$  equal to the width of the base slab. Adequate space shall be provided laterally between the back of the facing panels and the traffic barrier/slab to allow the traffic barrier and slab to resist the impact load in sliding and overturning without directly transmitting load to the top facing units.

### C11.10.10.2

The force distribution for pullout calculations is different than that used for tensile calculations because the entire base slab must move laterally to initiate a pullout failure due to the relatively large deformation required.

For checking pullout safety of the reinforcements, the lateral traffic impact load shall be distributed to the upper soil reinforcement using Figure 3.11.6.3-2a, assuming  $b_f$  equal to the width of the base slab. The full-length of reinforcements shall be considered effective in resisting pullout due to the impact load. The upper layer(s) of soil reinforcement shall have sufficient pullout capacity to resist a horizontal load of  $\gamma P_{HI}$  where  $P_{HI} = 10.0$  kips distributed over a 20.0 ft base slab length.

Due to the transient nature of traffic barrier impact loads, when designing for reinforcement rupture, the geosynthetic reinforcement must be designed to resist the static and transient (impact) components of the load as follows:

For the static component, see Eq. 11.10.7.2-3.

For the transient components:

$$\Delta\sigma_H S_v \leq \frac{\phi S_{ri} R_c}{RF_{ID} RF_D} \quad (11.10.10.2-1)$$

where:

$\Delta\sigma_H$  = traffic barrier impact stress applied over reinforcement tributary area per Article 11.10.10.1 (ksf)

$S_v$  = vertical spacing of reinforcement (ft)

$S_{rt}$  = ultimate reinforcement tensile resistance required to resist dynamic load component (kips/ft)

$R_c$  = reinforcement coverage ratio from Article 11.10.6.4.1 (dim.)

$RF_{ID}$  = strength reduction factor to account for installation damage to reinforcement from Article 11.10.6.4.3b (dim.)

$RF_D$  = strength reduction factor to prevent rupture of reinforcement due to chemical and biological degradation from Article 11.10.6.4.3b (dim.)

The reinforcement strength required for the static load component must be added to the reinforcement strength required for the transient load component to determine the required total ultimate strength using Eq. 11.10.7.3-3.

Parapets and traffic barriers shall satisfy crash testing requirements as specified in Section 13. The anchoring slab shall be strong enough to resist the ultimate strength of the standard parapet.

Refer to C11.10.7.2 which applies to transient loads, such as impact loads on traffic barriers, as well as earthquake loads.

Flexible post and beam barriers, when used, shall be placed at a minimum distance of 3.0 ft from the wall face, driven 5.0 ft below grade, and spaced to miss the reinforcements where possible. If the reinforcements cannot be missed, the wall shall be designed accounting for the presence of an obstruction as described in Article 11.10.10.4. The upper two rows of reinforcement shall be designed for an additional horizontal load  $\gamma P_{H1}$ , where  $P_{H1} = 300$  lbs. per linear ft of wall, 50 percent of which is distributed to each layer of reinforcement.

#### **11.10.10.3—Hydrostatic Pressures**

For structures along rivers and streams, a minimum differential hydrostatic pressure equal to 3.0 ft of water shall be considered for design. This load shall be applied at the high-water level. Effective unit weights shall be used in the calculations for internal and external stability beginning at levels just below the application of the differential hydrostatic pressure.

#### **11.10.10.4—Obstructions in the Reinforced Soil Zone**

If the placement of an obstruction in the wall soil reinforcement zone such as a catch basin, grate inlet, signal or sign foundation, guardrail post, or culvert cannot be avoided, the design of the wall near the obstruction shall be modified using one of the following alternatives:

- 1) Assuming reinforcement layers must be partially or fully severed in the location of the obstruction, design the surrounding reinforcement layers to carry the additional load which would have been carried by the severed reinforcements.
- 2) Place a structural frame around the obstruction capable of carrying the load from the reinforcements in front of the obstruction to reinforcements connected to the structural frame behind the obstruction as illustrated in Figure 11.10.10.4-1.
- 3) If the soil reinforcements consist of discrete strips and depending on the size and location of the obstruction, it may be possible to splay the reinforcements around the obstruction.

For Alternative 1, the portion of the wall facing in front of the obstruction shall be made stable against a toppling (overturning) or sliding failure. If this cannot be accomplished, the soil reinforcements between the obstruction and the wall face can be structurally connected to the obstruction such that the wall face does not topple, or the facing elements can be structurally connected to adjacent facing elements to prevent this type of failure.

#### **C11.10.10.3**

Situations where the wall is influenced by tide or river fluctuations may require that the wall be designed for rapid drawdown conditions, which could result in differential hydrostatic pressure considerably greater than 3.0 ft, or alternatively rapidly draining backfill material such as shot rock or open graded coarse gravel can be used as backfill. Backfill material meeting the gradation requirements in the *AASHTO LRFD Bridge Construction Specifications* for MSE structure backfill is not considered to be rapid draining.

#### **C11.10.10.4**

Field cutting of longitudinal or transverse wires of metal grids, e.g., bar mats, should not be allowed unless one of the alternatives in Article 11.10.10.4 is followed and compensating adjustment is made in the wall design.

Typically, the splay of reinforcements is limited to a maximum of 15 degrees.

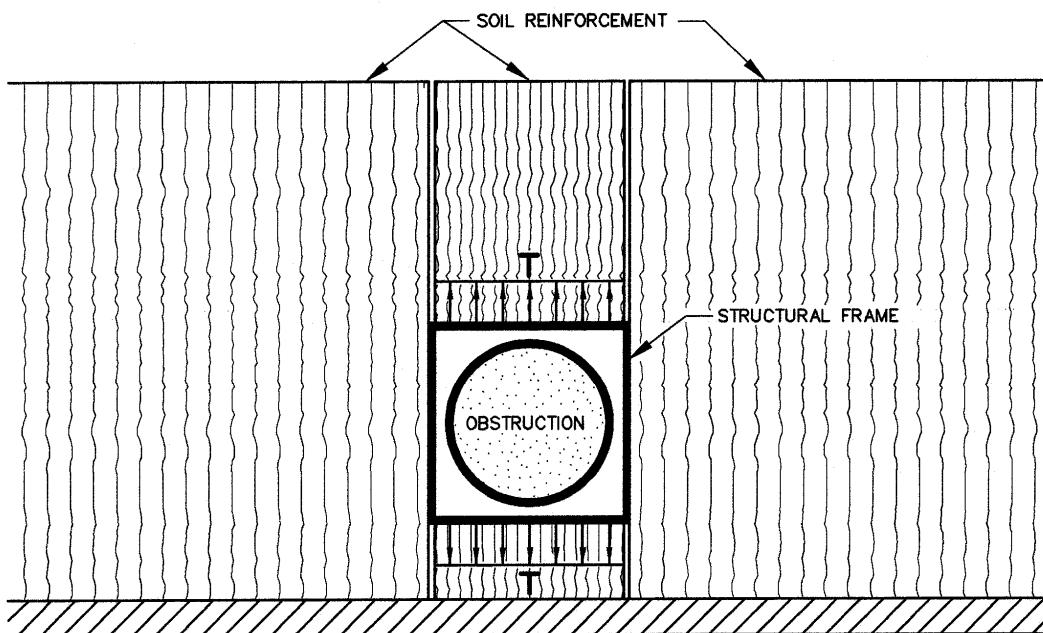

For the second alternative, the frame and connections shall be designed in accordance with Section 6 for steel frames.

For the third alternative, the splay angle, measured from a line perpendicular to the wall face, shall be small enough that the splaying does not generate moment in the reinforcement or the connection of the reinforcement to the wall face. The tensile resistance of the splayed reinforcement shall be reduced by the cosine of the splay angle.

If the obstruction must penetrate through the face of the wall, the wall facing elements shall be designed to fit around the obstruction such that the facing elements are stable, i.e., point loads should be avoided, and such that wall backfill soil cannot spill through the wall face where it joins the obstruction. To this end, a collar next to the wall face around the obstruction may be needed.

If driven piles or drilled shafts must be placed through the reinforced zone, the recommendations provided in Article 11.10.11 shall be followed.

Note that it may be feasible to connect the soil reinforcement directly to the obstruction depending on the reinforcement type and the nature of the obstruction.

**Figure 11.10.10.4-1—Structural Connection of Soil Reinforcement around Backfill Obstructions**

#### 11.10.11—MSE Abutments

#### C11.10.11

Abutments on MSE walls shall be proportioned to meet the criteria specified in Article 11.6.2 through 11.6.6.

The MSE wall below the abutment footing shall be designed for the additional loads imposed by the footing pressure and supplemental earth pressures resulting from horizontal loads applied at the bridge seat and from the backwall. The footing load may be distributed as described in Article 11.10.10.1.

The factored horizontal force acting on the reinforcement at any reinforcement level,  $T_{max}$ , shall be taken as:

$$T_{max} = \sigma_{Hmax} S_v \quad (11.10.11-1)$$

where:

$\sigma_{Hmax}$  = factored horizontal stress at layer  $i$ , as defined by Eq.11.10.11-2 (ksf)

$S_v$  = vertical spacing of reinforcement (ft)

Horizontal stresses in abutment reinforced zones shall be determined by superposition as follows, and as specified in Article 11.10.10.1:

$$\sigma_{Hmax} = \gamma_p (\sigma_v k_r + \Delta\sigma_v k_r + \Delta\sigma_H) \quad (11.10.11-2)$$

where:

$\gamma_p$  = load factor for vertical earth pressure in Table 3.4.1-2

$\Delta\sigma_H$  = magnitude of lateral pressure due to surcharge (ksf)

$\sigma_v$  = vertical soil stress over effective base width ( $B - 2e$ ) (ksf)

$\Delta\sigma_v$  = vertical soil stress due to footing load (ksf)

$k_r$  = earth pressure coefficient varying as a function of  $k_a$  as specified in Article 11.10.6.2.1

$k_a$  = active earth pressure coefficient specified in Article 3.11.5.8

The effective length used for calculations of internal stability under the abutment footing shall be as described in Article 11.10.10.1 and Figure 11.10.10.1-2.

The minimum distance from the centerline of the bearing on the abutment to the outer edge of the facing shall be 3.5 ft. The minimum distance between the back face of the panel and the footing shall be 6.0 in.

Where significant frost penetration is anticipated, the abutment footing shall be placed on a bed of compacted coarse aggregate 3.0 ft thick as described in Article 11.10.2.2.

The density, length, and cross-section of the soil reinforcements designed for support of the abutment shall be carried on the wingwalls for a minimum horizontal distance equal to 50 percent of the height of the abutment.

The minimum length of reinforcement, based on experience, has been the greater of 22.0 ft or  $0.6(H + d) + 6.5$  ft. The length of reinforcement should be constant throughout the height to limit differential settlements across the reinforced zone. Differential settlements could overstress the reinforcements.

The permissible level of differential settlement at abutment structures should preclude damage to superstructure units. This subject is discussed in Article 10.6.2.2. In general, abutments should not be constructed on mechanically stabilized embankments if anticipated differential settlements between abutments or between piers and abutments are greater than one-half the limiting differential settlements described in Article C10.5.2.2.

In pile or drilled shaft supported abutments, the horizontal forces transmitted to the deep foundation elements shall be resisted by the lateral capacity of the deep foundation elements by provision of additional reinforcements to tie the drilled shaft or pile cap into the soil mass, or by batter piles. Lateral loads transmitted from the deep foundation elements to the reinforced backfill may be determined using a P-Y lateral load analysis technique. The facing shall be isolated from horizontal loads associated with lateral pile or drilled shaft deflections. A minimum clear distance of 1.5 ft shall be provided between the facing and deep foundation elements. Piles or drilled shafts shall be specified to be placed prior to wall construction and cased through the fill if necessary.

The equilibrium of the system should be checked at each level of reinforcement below the bridge seat.

Due to the relatively high bearing pressures near the panel connections, the adequacy and ultimate capacity of panel connections should be determined by conducting pullout and flexural tests on full-sized panels.

Moments should be taken at each level under consideration about the centerline of the reinforced mass to determine the eccentricity of load at each level. A uniform vertical stress is then calculated using a fictitious width taken as  $(B - 2e)$ , and the corresponding horizontal stress should be computed by multiplying by the appropriate coefficient of lateral earth pressure.

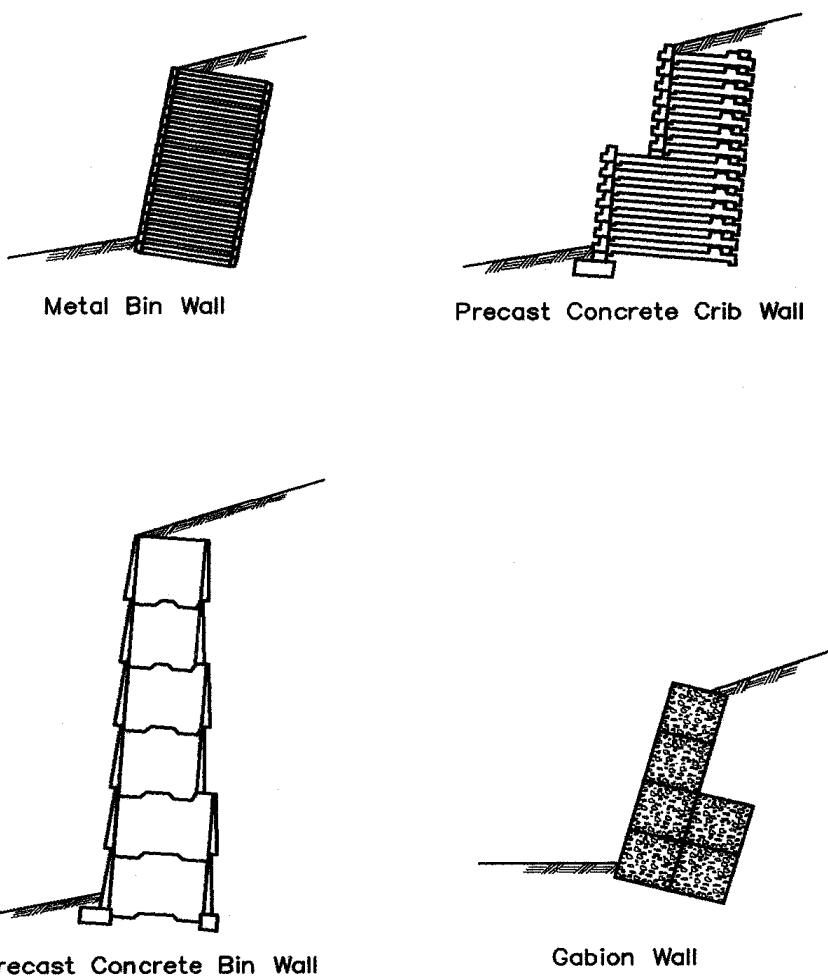

## 11.11—PREFABRICATED MODULAR WALLS

### 11.11.1—General

Prefabricated modular systems may be considered where conventional gravity, cantilever or counterfort concrete retaining walls are considered.

### C11.11.1

Prefabricated modular wall systems, whose elements may be proprietary, generally employ interlocking soil-filled reinforced concrete or steel modules or bins, rock filled gabion baskets, precast concrete units, or dry cast segmental masonry concrete units (without soil reinforcement) which resist earth pressures by acting as gravity retaining walls. Prefabricated modular walls may also use their structural elements to mobilize the dead weight of a portion of the wall backfill through soil arching to provide resistance to lateral loads. Typical prefabricated modular walls are shown in Figure C11.11.1-1.

**Figure C11.11.1-1—Typical Prefabricated Modular Gravity Walls**

Prefabricated modular wall systems shall not be used under the following conditions:

- On curves with a radius of less than 800 ft, unless the curve can be substituted by a series of chords.
- Steel modular systems shall not be used where the groundwater or surface runoff is acid contaminated or where deicing spray is anticipated.

### 11.11.2—Loading

The provisions of Articles 11.6.1.2 and 3.11.5.9 shall apply, except that shrinkage and temperature effects need not be considered.

### 11.11.3—Movement at the Service Limit State

The provisions of Article 11.6.2 shall apply as applicable.

### C11.11.3

Calculated longitudinal differential settlements along the face of the wall should result in a slope less than 1/200.

## 11.11.4—Safety Against Soil Failure

### 11.11.4.1—General

For sliding and overturning stability, the system shall be assumed to act as a rigid body. Determination of stability shall be made at every module level.

Passive pressures shall be neglected in stability computations, unless the base of the wall extends below the depth of maximum scour, freeze-thaw, or other disturbance. For these cases only, the embedment below the greater of these depths may be considered effective in providing passive resistance.

### 11.11.4.2—Sliding

The provisions of Article 10.6.3.4 shall apply.

Computations for sliding stability may consider that the friction between the soil-fill and the foundation soil, and the friction between the bottom modules or footing and the foundation soil are effective in resisting sliding. The coefficient of sliding friction between the soil-fill and foundation soil at the wall base shall be the lesser of  $\phi_f$  of the soil fill and  $\phi_f$  of the foundation soil. The coefficient of sliding friction between the bottom modules or footing and the foundation soil at the wall base shall be reduced, as necessary, to account for any smooth contact areas.

In the absence of specific data, a maximum friction angle of 30 degrees shall be used for  $\phi_f$  for granular soils. Tests should be performed to determine the friction angle of cohesive soils considering both drained and undrained conditions.

### 11.11.4.3—Bearing Resistance

The provisions of Article 10.6.3 shall apply.

Bearing resistance shall be computed by assuming that dead loads and earth pressure loads are resisted by point supports per unit length at the rear and front of the modules or at the location of the bottom legs. A minimum of 80 percent of the soil weight inside the modules shall be considered to be transferred to the front and rear support points. If foundation conditions require a footing under the total area of the module, all of the soil weight inside the modules shall be considered.

### 11.11.4.4—Overturning

The provisions of Article 11.6.3.3 shall apply.

A maximum of 80 percent of the soil-fill inside the modules is effective in resisting overturning moments.

### C11.11.4.3

Concrete modular systems are relatively rigid and are subject to structural damage due to differential settlements, especially in the longitudinal direction. Therefore, bearing resistance for footing design should be determined as specified in Article 10.6.

### C11.11.4.4

The entire volume of soil within the module cannot be counted on to resist overturning, as some soil will not arch within the module. If a structural bottom is provided to retain the soil within the module, no reduction of the soil weight to compute overturning resistance is warranted.

#### **11.11.4.5 —Subsurface Erosion**

Bin walls may be used in scour-sensitive areas only where their suitability has been established. The provisions of Article 11.6.3.5 shall apply.

#### **11.11.4.6—Overall Stability**

The provisions of Article 11.6.2.3 shall apply.

#### **11.11.4.7—Passive Resistance and Sliding**

The provisions of Articles 10.6.3.4 and 11.6.3.6 shall apply, as applicable.

#### **11.11.5—Safety Against Structural Failure**

##### **11.11.5.1—Module Members**

Prefabricated modular units shall be designed for the factored earth pressures behind the wall and for factored pressures developed inside the modules. Rear face surfaces shall be designed for both the factored earth pressures developed inside the modules during construction and the difference between the factored earth pressures behind and inside the modules after construction. Strength and reinforcement requirements for concrete modules shall be in accordance with Section 5.

Strength requirements for steel modules shall be in accordance with Section 6. The net section used for design shall be reduced in accordance with Article 11.10.6.4.2a.

Factored bin pressures shall be the same for each module and shall not be less than:

$$P_b = \gamma \gamma_s b \quad (11.11.5.1-1)$$

where:

$P_b$  = factored pressure inside bin module (ksf)

$\gamma_s$  = soil unit weight (kcf)

$\gamma$  = load factor for vertical earth pressure specified in Table 3.4.1-2

$b$  = width of bin module (ft)

Steel reinforcing shall be symmetrical on both faces unless positive identification of each face can be ensured to preclude reversal of units. Corners shall be adequately reinforced.

##### **C11.11.5.1**

Structural design of module members is based on the difference between pressures developed inside the modules (bin pressures) and those resulting from the thrust of the backfill. The recommended bin pressure relationships are based on relationships obtained for long trench geometry, and are generally conservative.

#### **11.11.6—Seismic Design**

The provisions of Article 11.6.5 shall apply.

### 11.11.7—Abutments

Abutment seats constructed on modular units shall be designed by considering earth pressures and supplemental horizontal pressures from the abutment seat beam and earth pressures on the backwall. The top module shall be proportioned to be stable under the combined actions of normal and supplementary earth pressures. The minimum width of the top module shall be 6.0 ft. The centerline of bearing shall be located a minimum of 2.0 ft from the outside face of the top precast module. The abutment beam seat shall be supported by, and cast integrally with, the top module. The front face thickness of the top module shall be designed for bending forces developed by supplemental earth pressures. Abutment beam-seat loadings shall be carried to foundation level and shall be considered in the design of footings.

Differential settlement provisions, specified in Article 11.10.4, shall apply.

### 11.11.8—Drainage

In cut and side-hill fill areas, prefabricated modular units shall be designed with a continuous subsurface drain placed at, or near, the footing grade and outletted as required. In cut and side-hill fill areas with established or potential groundwater levels above the footing grade, a continuous drainage blanket shall be provided and connected to the longitudinal drain system.

For systems with open front faces, a surface drainage system shall be provided above the top of the wall.

## APPENDIX A11—SEISMIC DESIGN OF ABUTMENTS AND GRAVITY RETAINING STRUCTURES

### A11.1—GENERAL

The numerous case histories of damage to or failure of bridges induced by abutment failure or displacement during earthquakes have clearly demonstrated the need for careful attention to abutment design and detailing in seismic areas. Damage is typically associated with fill settlement or slumping, displacements induced by high seismically caused lateral earth pressures, or the transfer of high longitudinal or transverse inertia forces from the bridge structure itself. Settlement of abutment backfill, severe abutment damage, or bridge deck damage induced by the movement of abutments may cause loss of bridge access; hence abutments must be considered a vital link in the overall seismic design process for bridges.

The nature of abutment movement or damage during past earthquakes has been well documented in the literature. Evans (1971) examined the abutments of 39 bridges within 30 miles (48.3 km) of the 1968 M7 Inangahua earthquake in New Zealand, of which 23 showed measurable movement and 15 were damaged. Movements of free-standing abutments followed the general pattern of outward motion and rotation about the top after contact with and restraint by the superstructures. Fill settlements were observed to be 10 to 15 percent of the fill height. Damage effects on bridge abutments in the M7.1 Madang earthquake in New Guinea, reported by Ellison (1971), were similar; abutment movement, as much as 20.0 in. (500 mm), was noted. Damage to abutments in the 1971 San Fernando earthquake is described by Fung et al. (1971). Numerous instances of abutment displacement and associated damage have been reported in publications on Niigata and Alaskan earthquakes. However, these failures were primarily associated with liquefaction of foundation soils.

Design features of abutments vary tremendously and depend on the nature of the bridge site, foundation soils, bridge span length, and load magnitudes. Abutment types include free-standing gravity walls, cantilever walls, tied back walls, and monolithic diaphragms. Foundation support may use spread footings, vertical piles, or battered piles, whereas connection details to the superstructure may incorporate roller supports, elastomeric bearings, or fixed bolted connections. Considering the number of potential design variables, together with the complex nature of soil abutment superstructure interaction during earthquakes, it is clear that the seismic design of abutments necessitates many simplifying assumptions.

#### A11.1.1—Free-Standing Abutments

For free-standing abutments, such as gravity or cantilever walls, which are able to yield laterally during an earthquake, i.e., superstructure supported by bearings that are able to slide freely, the well-established Mononobe-Okabe pseudo-static approach, outlined below, is widely used to compute earth pressures induced by earthquakes.

For free-standing abutments in highly seismic areas, design of abutments to provide zero displacement under peak ground accelerations may be unrealistic, and design for an acceptable small lateral displacement may be preferable. A recently developed method for computing the magnitude of relative wall displacement during a given earthquake is outlined in this Article. On the basis of this simplified approach, recommendations are made for the selection of a pseudo-static seismic coefficient and the corresponding displacement level for a given peak ground acceleration.

##### A11.1.1.1—Mononobe-Okabe Analysis

The method most frequently used for the calculation of the seismic soil forces acting on a bridge abutment is a static approach developed in the 1920s by Mononobe (1929) and Okabe (1926). The Mononobe-Okabe analysis is an extension of the Coulomb sliding-wedge theory, taking into account horizontal and vertical inertia forces acting on the soil. The analysis is described in detail by Seed and Whitman (1970) and Richards and Elms (1979). The following assumptions are made:

1. The abutment is free to yield sufficiently to enable full soil strength or active pressure conditions to be mobilized. If the abutment is rigidly fixed and unable to move, the soil forces will be much higher than those predicted by the Mononobe-Okabe analysis.
2. The backfill is cohesionless, with a friction angle of  $\phi$ .
3. The backfill is unsaturated, so that liquefaction problems will not arise.

Equilibrium considerations of the soil wedge behind the abutment, as shown in Figure A11.1.1.1-1, then lead to a value,  $E_{AE}$ , of the active force exerted on the soil mass by the abutment and vice versa. When the abutment is at the point of failure  $E_{AE}$  is given by the expression:

$$E_{AE} = \frac{1}{2} \gamma H^2 (1 - k_v) K_{AE} \quad (\text{A11.1.1.1-1})$$

where the seismic active pressure coefficient  $K_{AE}$  is:

$$K_{AE} = \frac{\cos^2(\phi - \theta - \beta)}{\cos \theta \cos^2 \beta \cos(\delta + \beta + \theta)} \times \left[ 1 + \sqrt{\frac{\sin(\phi + \delta) \sin(\phi - \theta - i)}{\cos(\delta + \beta + \theta) \cos(i - \beta)}} \right]^{-2} \quad (\text{A11.1.1.1-2})$$

and where:

$\gamma$  = unit weight of soil (kcf)

$H$  = height of soil face (ft)

$\phi$  = angle of friction of soil (degrees)

$\theta$  =  $\arctan(k_h / (1 - k_v))$  (degrees)

$\delta$  = angle of friction between soil and abutment (degrees)

$k_h$  = horizontal acceleration coefficient (dim.)

$k_v$  = vertical acceleration coefficient (dim.)

$i$  = backfill slope angle (degrees)

$\beta$  = slope of wall to the vertical, negative as shown (degrees)

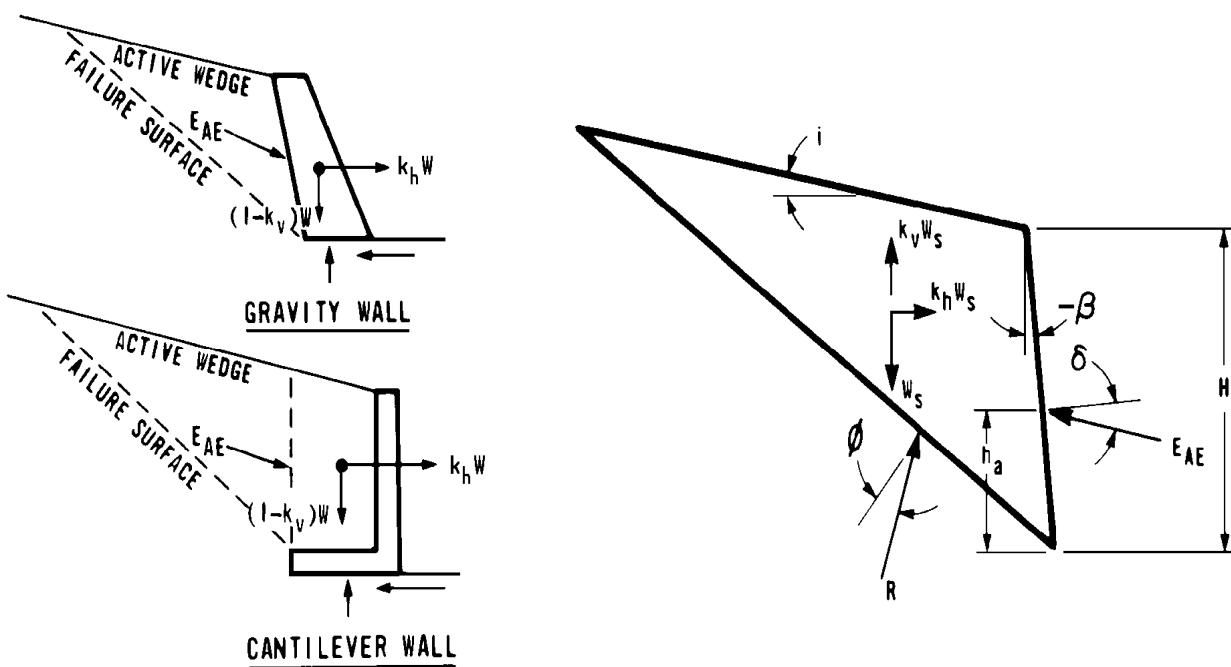

Figure A11.1.1.1—Active Wedge Force Diagram

The equivalent expression for passive force if the abutment is being pushed into the backfill is:

$$E_{PE} = \frac{1}{2} \gamma H^2 (1 - k_v) K_{PE} \quad (\text{A11.1.1.1-3})$$

where:

$$K_{PE} = \frac{\cos^2(\phi - \theta + \beta)}{\cos \theta \cos^2 \beta \cos(\delta - \beta + \theta)} \times \left[ 1 - \sqrt{\frac{\sin(\phi + \delta) \sin(\phi - \theta + i)}{\cos(\delta - \beta + \theta) \cos(i - \beta)}} \right]^{-2} \quad (\text{A11.1.1.1-4})$$

As the seismic inertial angle  $\theta$  increases, the values of  $K_{AE}$  and  $K_{PE}$  approach each other and, for vertical backfill, become equal when  $\theta = \phi$ .

Despite the relative simplicity of the approach, the accuracy of Eq. A11.1.1.1-1 has been substantiated by model tests (*Seed and Whitman 1970*), and back calculation from observed failures of flood channels walls (*Clough and Fragaszy 1977*). In the latter case, however, the displacements were large; and this, as will be seen, can modify the effective values of  $k_h$  at which failure occurs.

The value of  $h_a$ , the height at which the resultant of the soil pressure acts on the abutment, may be taken as  $H/3$  for the static case with no earthquake effects involved. However, it becomes greater as earthquake effects increase. This has been shown empirically by tests and theoretically by Wood (1973), who found that the resultant of the dynamic pressure acted approximately at midheight. Seed and Whitman have suggested that  $h$  could be obtained by assuming that the static component of the soil force (computed from Eq. A11.1.1.1-1 with  $\theta = k_v = 0$ ) acts at  $H/3$  from the bottom of the abutment, whereas the additional dynamic effect should be taken to act at a height of  $0.6H$ . For most purposes, it is sufficient to assume  $h = H/2$  with a uniformly distributed pressure.

Although the Mononobe-Okabe expression for active thrust is easily evaluated for any particular geometry and friction angle, the significance of the various parameters is not obvious. Figure A11.1.1.1-2 shows the variation of  $K_{AE}$  against  $k_h$  for different values of  $\phi$  and  $k_v$ ; obviously  $K_{AE}$  is very sensitive to the value of  $\phi$ . Also, for a constant value of  $\phi$ ,  $K_{AE}$  doubles as  $k_h$  increases from 0.0 to 0.35 for 0.0 vertical acceleration, and thereafter it increases more rapidly.

In order to evaluate the increase in soil active pressure due to earthquake effects more easily,  $K_{AE}$  can be normalized by dividing by its static value  $K_A$  to give a thrust factor

$$F_T = \frac{K_{AE}}{K_A} \quad (\text{A11.1.1.1-5})$$

Whereas Figure A11.1.1.1-2 shows that  $K_{AE}$  is sensitive to changes in the soil friction angle, the plots of  $F_T$  against  $\phi$  in Figure A11.1.1.1-3 indicate that the value of  $\phi$  has little effect on the thrust factor until quite suddenly, over a short range of  $\phi$ ,  $F_T$  increases rapidly and becomes infinite for specific critical values of  $\phi$ . The reason for this behavior may be determined by examining Eq. A11.1.1.1-2. The contents of the radical must be positive for a real solution to be possible, and, for this, it is necessary that:

$$\phi \geq i + \theta = i + \arctan \left( \frac{k_h}{1 - k_v} \right) \quad (\text{A11.1.1.1-6})$$

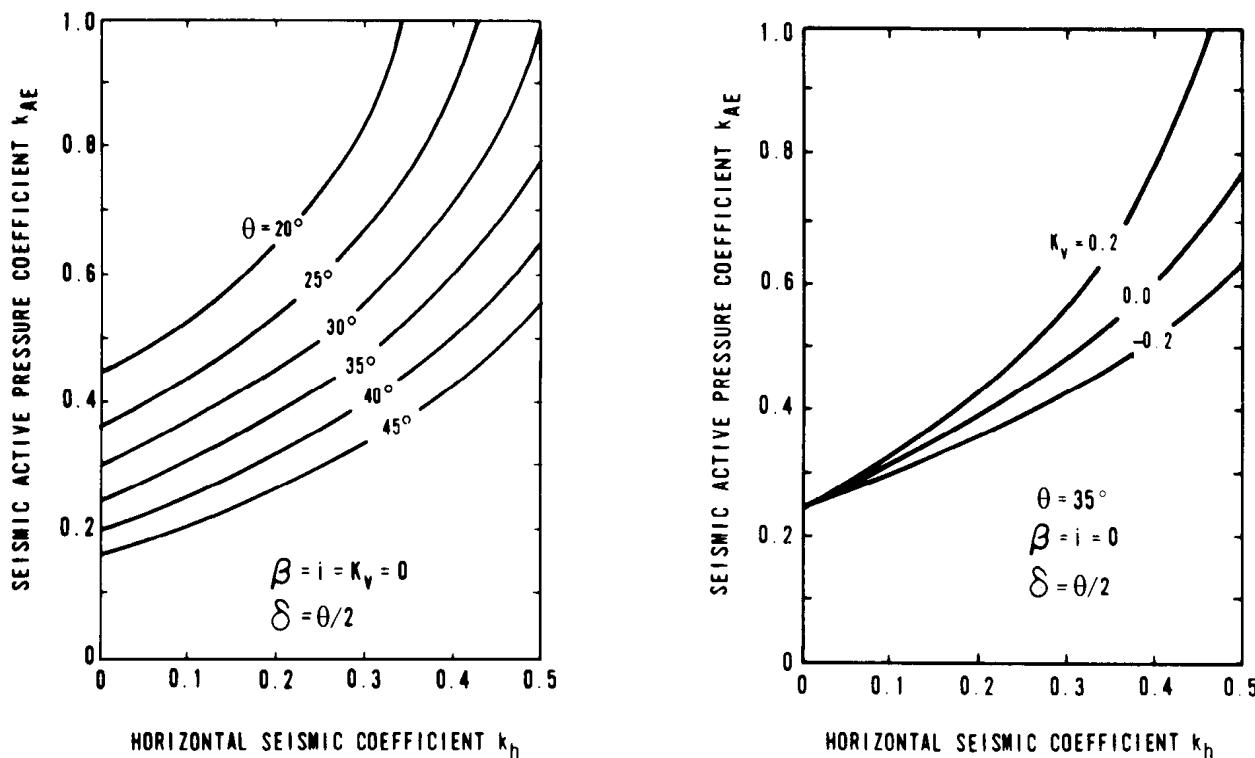

Figure A11.1.1.1-2—Effects of Seismic Coefficient and Soil Friction Angle on Seismic Active Pressure Coefficient

This condition could also be thought of as specifying a limit to the horizontal acceleration coefficient that could be sustained by any structure in a given soil. The limiting condition is:

$$k_h \leq (1 - k_v) \tan(\phi - i) \quad (\text{A11.1.1.1-7})$$

For 0.0 vertical acceleration and backfill angle and for a soil friction angle of 35 degrees, the limiting value of  $k_h$  is 0.7. This is a figure of some interest in that it provides an absolute upper-bound for the seismic acceleration that can be transmitted to any structure whatsoever built on soil with the given strength characteristics.

Figure A11.1.1.1-4 shows the effect on  $F_T$  of changes in the vertical acceleration coefficient  $k_v$ . Positive values of  $k_v$  have a significant effect for values of  $k_h$  greater than 0.2. The effect is greater than ten percent above and to the right of the dashed line. As is to be expected from Eq. A11.1.1.1-4,  $K_{AE}$  and  $F_T$  are also sensitive to variations in backfill slope, particularly for higher values of horizontal acceleration coefficient when the limit, implied by Eq. A11.1.1.1-4, is approached. This effect is shown in Figure A11.1.1.1-5.

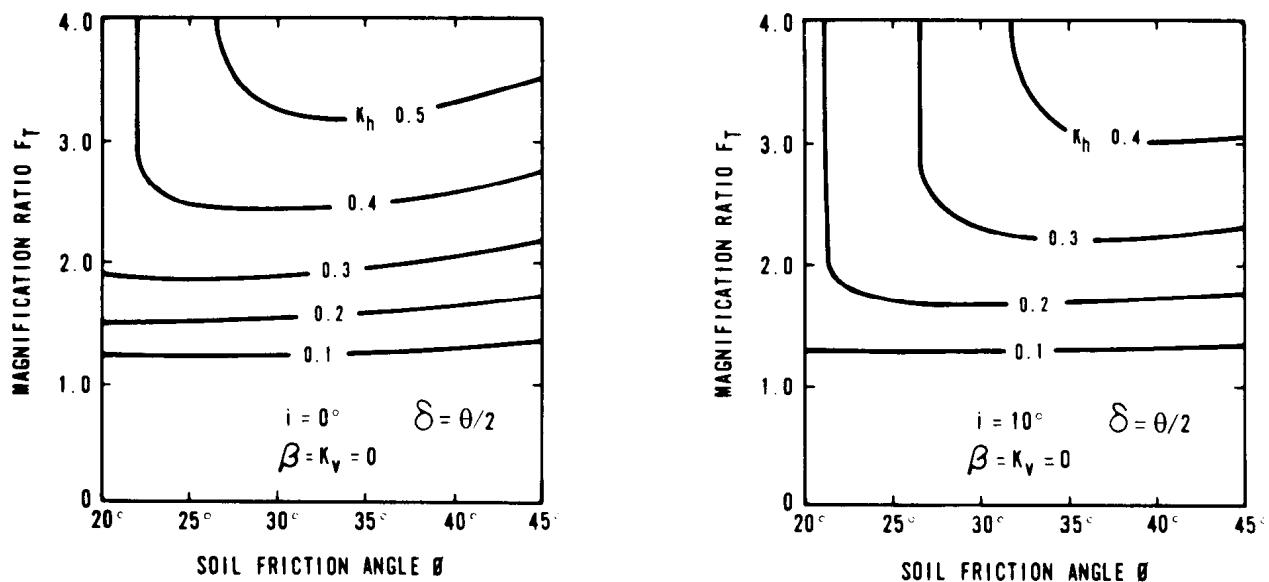

Figure A11.1.1.1-3—Influence of Soil Friction Angle on Magnification Ratio

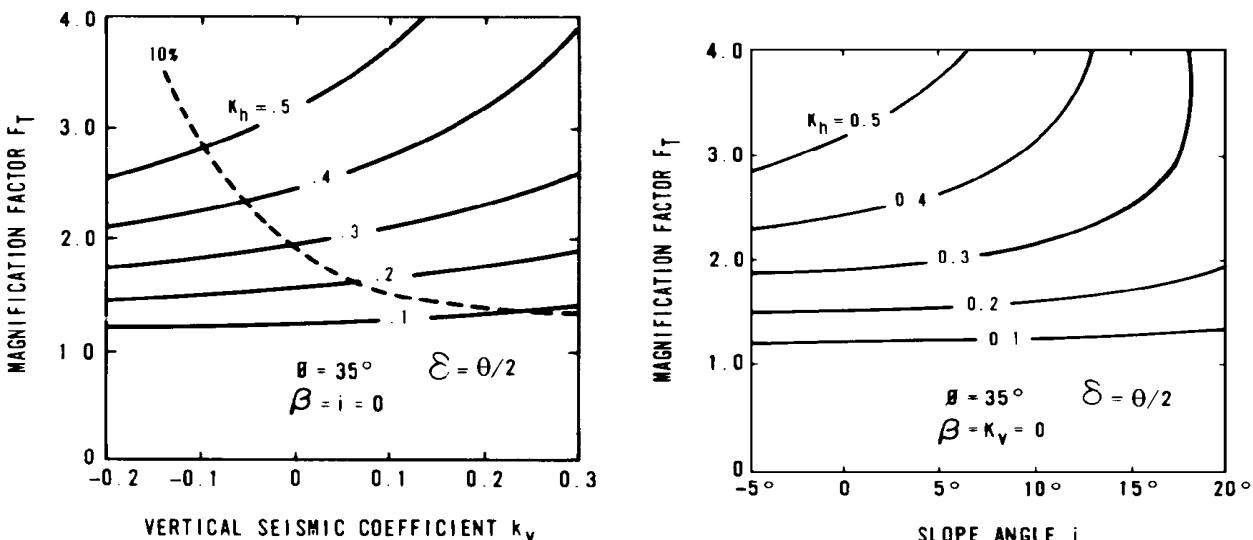

Figure A11.1.1.1-4—Influence of Vertical Seismic Coefficient on Magnification Ratio

Figure A11.1.1.1-5—Influence of Backfill Slope Angle on Magnification Ratio

The effects of abutment inertia are not taken into account in the Mononobe-Okabe analysis. Many current procedures assume that the inertia forces due to the mass of the abutment itself may be neglected in considering seismic behavior and seismic design. This is not a conservative assumption, and for those abutments relying on their mass for stability, it is also an unreasonable assumption in that to neglect the mass is to neglect a major aspect of their behavior. The effects of wall inertia are discussed further by Richards and Elms (1979), who show that wall inertia forces should not be neglected in the design of gravity-retaining walls.

### A11.1.1.2—Design for Displacement

If peak ground accelerations are used in the Mononobe-Okabe analysis method, the size of gravity-retaining structures will often be excessively great. To provide a more economic structure, design for a small tolerable displacement, instead of no displacement, may be preferable.

Tests have shown that a gravity-retaining wall fails in an incremental manner in an earthquake. For any earthquake ground motion, the total relative displacement may be calculated using the sliding block method suggested by Newmark (1965). The method assumes a displacement pattern similar to that of a block resting on a plane rough horizontal surface subjected to an earthquake, with the block being free to move against frictional resistance in one direction only. Figure A11.1.1.2-1 shows how the relative displacement relates to the acceleration and velocity time histories of soil and wall. At a critical value of  $k_h$ , the wall is assumed to begin sliding; relative motion will continue until wall and soil velocities are equal. Figures A11.1.1.2-2 and A11.1.1.2-3 show the results by Richards and Elms (1979) of a computation of wall displacement for  $k_h = 0.1$  for the El Centro 1940 N-S record.

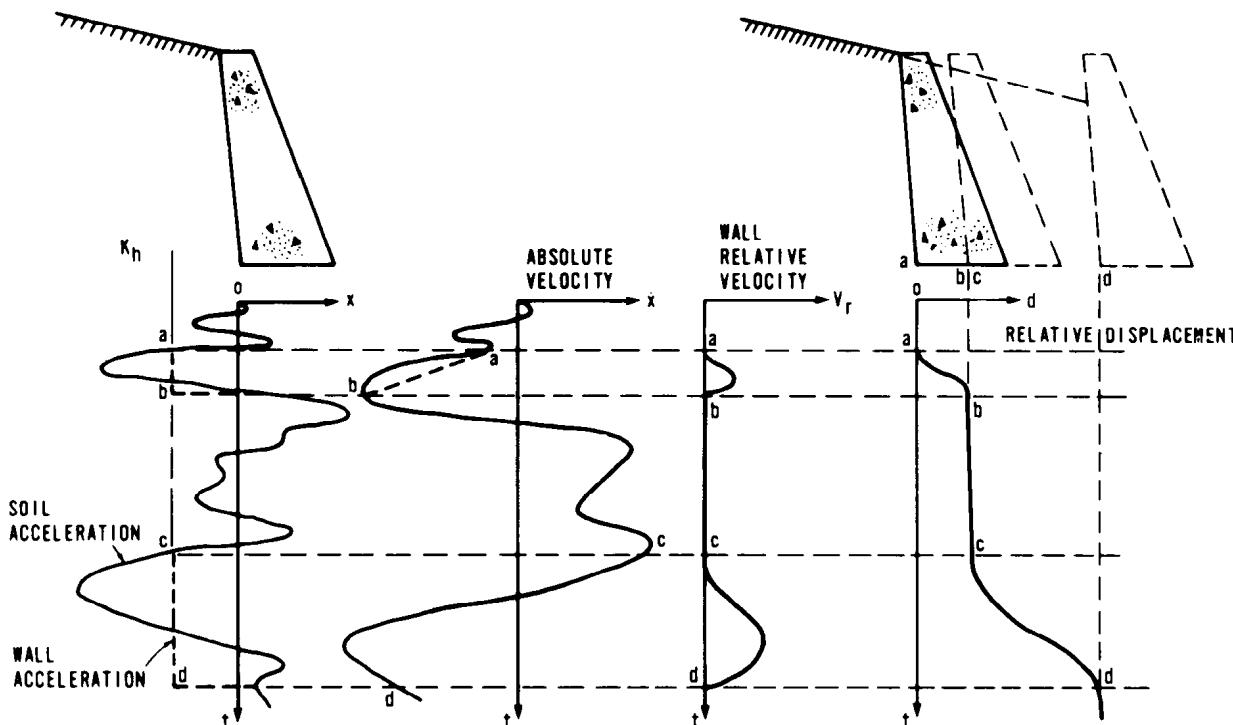

Newmark computed the maximum displacement response for four earthquake records and plotted the results after scaling the earthquakes to a common maximum acceleration and velocity. Franklin and Chang (1977) repeated the analysis for a large number of both natural and synthetic records and added their results to the same plot. Upper-bound envelopes for their results are shown in Figure A11.1.1.2-4. All records were scaled to a maximum acceleration coefficient of 0.5 and a maximum velocity,  $V$ , of 30.0 in./sec. The maximum resistance of coefficient  $N$  is the maximum acceleration coefficient sustainable by a sliding block before it slides. In the case of a wall designed using the Mononobe-Okabe method, the maximum coefficient is, of course,  $k_h$ .

Figure A11.1.1.2-4 shows that the displacement envelopes for all the scaled records have roughly the same shape.

An approximation of the curves for relatively low displacements is given by the relations, expressed in any consistent set of units:

$$d = 0.087 \frac{V^2}{Ag} \left( \frac{N}{A} \right)^{-4} \quad (\text{A11.1.1.2-1})$$

where  $d$  is the total relative displacement of a wall subjected to an earthquake ground motion whose maximum acceleration coefficient and maximum velocity are  $A$  and  $V$ , respectively. This displacement is drawn as a straight line on Figure A11.1.1.2-4. Because this expression has been derived from envelope curves, it will overestimate  $d$  for most earthquakes.

**Figure A11.1.1.2-1—Relation between Relative Displacement and Acceleration and Velocity Time Histories of Soil and Wall**

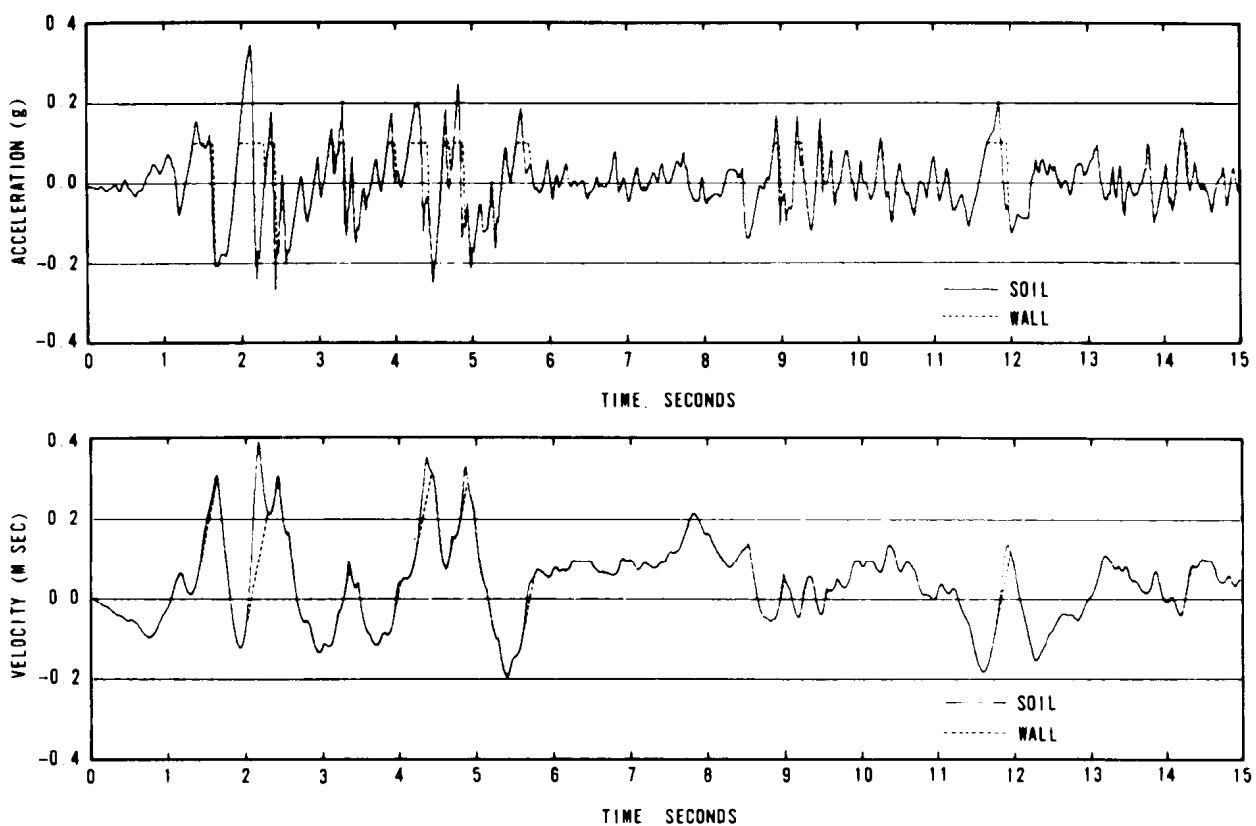

Figure A11.1.1.2-2—Acceleration and Velocity Time Histories of Soil and Wall (El Centro 1940 N-S Record)

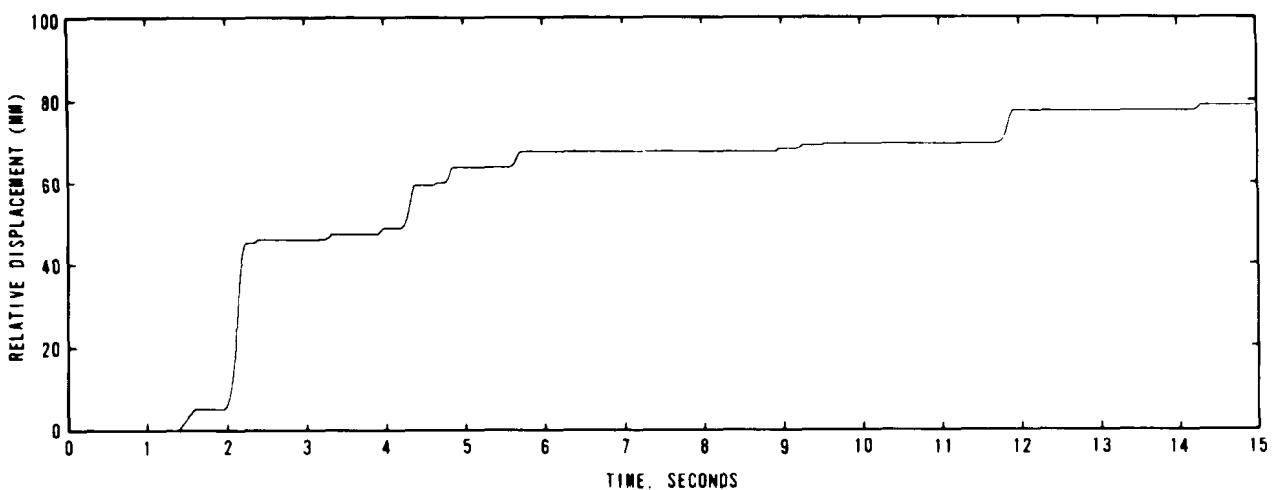

Figure A11.1.1.2-3—Relative Displacement of Wall (El Centro 1940 N-S Record)

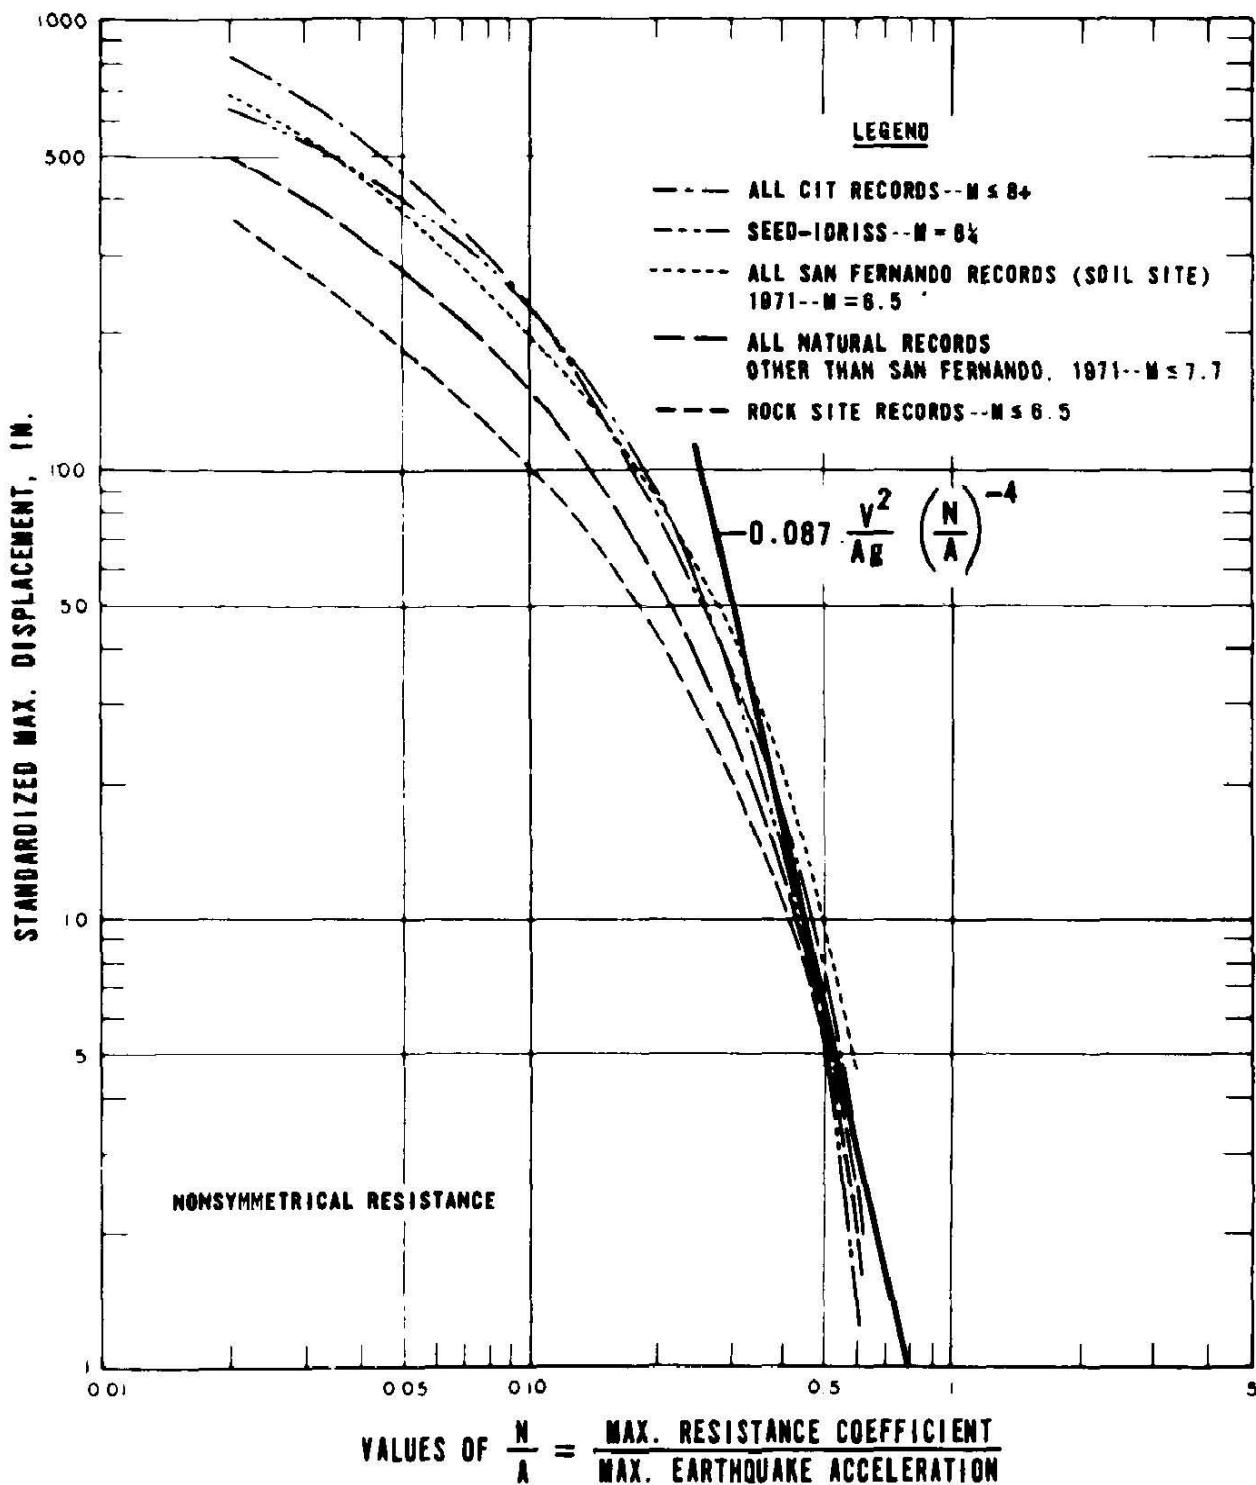

Figure A11.1.1.2-4—Upper-Bound Envelope Curves of Permanent Displacements for All Natural and Synthetic Records Analyzed by Franklin and Chang (1977)

One possible design procedure would be to choose a desired value of maximum wall displacement,  $d$ , together with appropriate earthquake parameters and to use Eq. A11.1.1.2-1 to derive a value of the seismic acceleration coefficient for which the wall should be designed. The wall connections, if any, could then be detailed to allow for this displacement.

By applying the above procedure to several simplified examples, Elms and Martin (1979) have shown that a value of  $k_h = A_s/2$  is adequate for most design purposes, provided that allowance is made for an outward displacement of the abutment of up to  $10A_s$  in.

For bridges classified as Seismic Zones 2, 3, or 4, more detailed consideration of the mechanism of transfer of structural inertia forces through bridge bearings to free-standing abutments is required, particularly for bridges classified as Seismic Zone 4, where continued bridge accessibility after a major earthquake is required.

For sliding steel bearings or pot bearings, force diagrams describing limiting equilibrium conditions for simple abutments are shown in Figure A11.1.1.2-5. Where bearings comprise unconfined elastomeric pads, the nature of the forces transferred to the abutment becomes more complex because such bearings are capable of transferring significant force. The magnitude of the force initially depends on the relative movement between the superstructure and the abutment, and force magnitudes can become quite large before slip will occur.

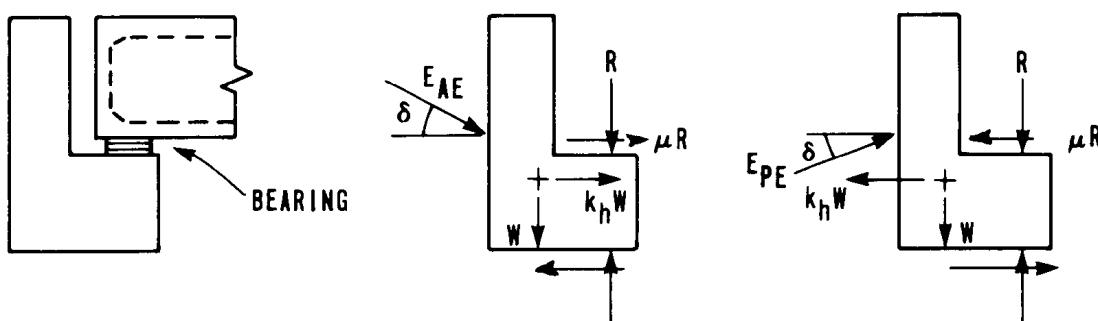

Figure A11.1.1.2-5—Force Diagrams Including Bearing Friction

For bridges classified as Seismic Zone 4, additional consideration should be given to the use of linkage bolts and buffers to minimize damage. A typical abutment support detail used by the New Zealand Ministry of Works is shown in Figure A11.1.1.2-6. It may be seen that linkage bolts are incorporated to prevent spans from dropping off supports. The rubber rings act as buffers to prevent impact damage in the event that the lateral displacement clearance provided is inadequate. The knock-off backwall accommodates differential displacement between the abutment and superstructure, with minimum structural damage. A more typical design provision in United States practice is to seal the gap between superstructure and abutment with bitumen to minimize impact damage. It must be recognized, however, that in this case some damage and possible abutment rotation will occur in strong earthquakes.

In Figures A11.1.1.2-6 and A11.1.1.2-7, the use of a settlement or approach slab, which has the effect of providing bridge access in the event of backfill settlement, is also noted. The slab also provides an additional abutment friction anchorage against lateral movement.

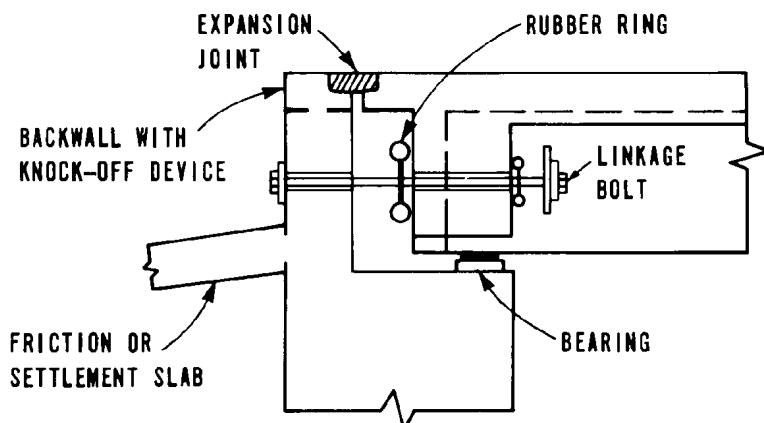

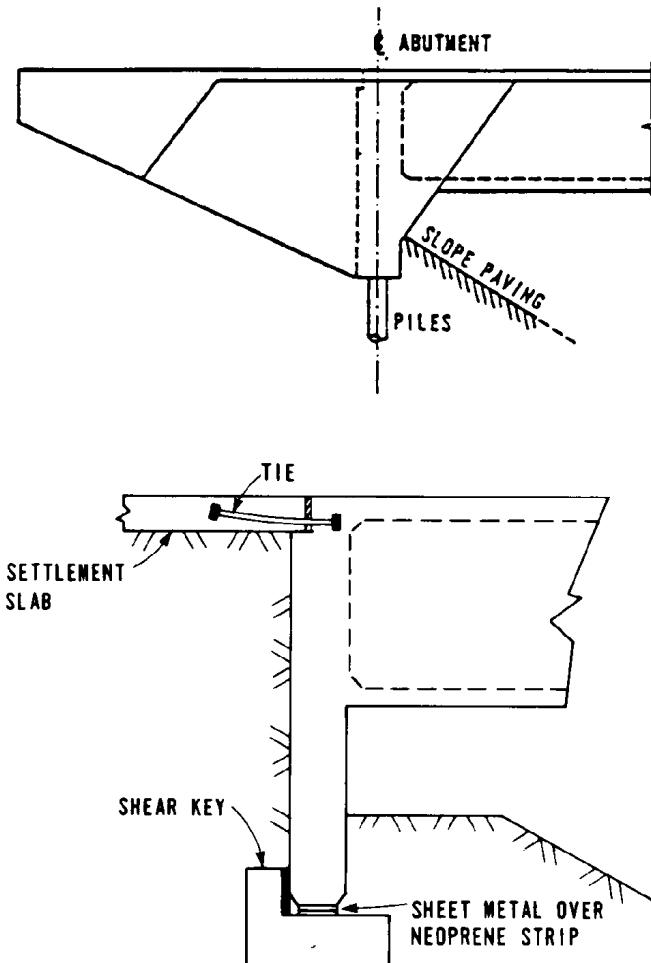

Figure A11.1.1.2-6—Possible Abutment Details

**Figure A11.1.1.2-7—Typical Monolithic Abutment**

### A11.1.1.3—Nonyielding Abutments

As previously noted, the Mononobe-Okabe analysis assumes that the abutment is free to laterally yield a sufficient amount to mobilize peak soil strengths in the soil backfill. For granular soils, peak strengths can be assumed to be mobilized if deflections at the top of the wall are about 0.5 percent of the abutment height. For abutments restrained against lateral movement by tiebacks or batter piles, lateral pressures induced by inertia forces in the backfill will be greater than those given by a Mononobe-Okabe analysis. Simplified elastic solutions presented by Wood (1973) for rigid nonyielding walls also indicate that pressures are greater than those given by Mononobe-Okabe. The use of a factor of 1.5 in conjunction with peak ground accelerations is suggested for design where doubt exists that an abutment can yield sufficiently to mobilize soil strengths.

### A11.1.2—Monolithic Abutments

Monolithic or end diaphragm abutments, such as shown in Figure A11.1.1.2-7, are commonly used for single and for two span bridges in California. As shown, the end diaphragm is cast monolithically with the superstructure and may be directly supported on piles, or provision may be made for beam shortening during post-tensioning. The diaphragm acts as a retaining wall with the superstructure acting as a prop between abutments.

Such abutments have performed well during earthquakes, avoiding problems such as backwall and bearing damage associated with yielding abutments and reducing the lateral load taken by columns or piers. On the other hand, higher longitudinal and transverse superstructure inertia forces are transmitted directly into the backfill, and provision must be made for adequate passive resistance to avoid excessive relative displacements.

Although free-standing or seat-type abutments allow the engineer more control over development of soil forces, the added joint introduces a potential collapse mechanism into the structure. To avoid this collapse mechanism, monolithic abutments are particularly recommended for bridges classified as Seismic Zone 4. Although damage may be heavier than that for free-standing abutments because of the higher forces transferred to backfill soils, with adequate abutment reinforcement, the collapse potential is low. In making estimates of monolithic abutment stiffness and associated longitudinal displacements during transfer of peak earthquake forces from the structure, it is recommended that abutments be proportioned to restrict displacements to 3.5 in. or less in order to minimize damage.

## SECTION 12

# BURIED STRUCTURES AND TUNNEL LINERS

### 12.1—SCOPE

This Section provides requirements for the selection of structural properties and dimensions of buried structures, e.g., culverts, and steel plate used to support tunnel excavations in soil.

Buried structure systems considered herein are metal pipe, structural plate pipe, long-span structural plate, deep corrugated plate, structural plate box, reinforced concrete pipe, reinforced concrete cast-in-place and precast arch, box and elliptical structures, and thermoplastic pipe.

The type of liner plate considered is cold-formed steel panels.

### 12.2—DEFINITIONS

*Abrasion*—Loss of section or coating of a culvert by the mechanical action of water conveying suspended bed load of sand, gravel, and cobble-size particles at high velocities with appreciable turbulence.

*Buried Structure*—A generic term for a structure built by embankment or trench methods.

*Corrosion*—Loss of section or coating of a buried structure by chemical and/or electrochemical processes.

*Culvert*—A curved or rectangular buried conduit for conveyance of water, vehicles, utilities, or pedestrians.

*Deep Corrugated Plate*—Structural Plate in AASHTO M 167 with a corrugation depth greater than 5 in.

*FEM*—Finite Element Method

*Narrow Trench Width*—The outside span of rigid pipe, plus 1.0 ft.

*Projection Ratio*—Ratio of the vertical distance between the outside top of the pipe and the ground or bedding surface to the outside vertical height of the pipe, applicable to reinforced concrete pipe only.

*Side Radius*—For deep corrugated plate structures, the side radius is the radius of the plate in the section adjacent to crown (top) section of the structure. In box shaped structures, this is often called the haunch radius.

*Soil Envelope*—Zone of controlled soil backfill around culvert structure required to ensure anticipated performance based on soil-structure interaction considerations.

*Soil-Structure Interaction System*—A buried structure whose structural behavior is influenced by interaction with the soil envelope.

*Tunnel*—A horizontal or near horizontal opening in soil excavated to a predesigned geometry by tunneling methods exclusive of cut-and-cover methods.

### 12.3—NOTATION

$A$	=	wall area (in. <sup>2</sup> /ft) (12.7.2.3)
$A_{eff}$	=	effective wall area (in. <sup>2</sup> /ft) (12.12.3.5.2)
$A_g$	=	gross wall area within a length of one period (in. <sup>2</sup> ) (12.12.3.5.3c)
$A_L$	=	axle load, taken as 50 percent of all axle loads that can be placed on the structure at one time (kip); sum of all axle loads in an axle group (kip); total axle load on single axle or tandem axles (kip) (12.8.4.2) (12.9.4.2) (12.9.4.3)
$A_s$	=	tension reinforcement area on cross-section width, $b$ (in. <sup>2</sup> /ft) (C12.10.4.2.4a) (C12.11.3) (C12.11.4)
$A_{smax}$	=	minimum flexural reinforcement area without stirrups (in. <sup>2</sup> /ft) (12.10.4.2.4c)
$A_T$	=	area of the top portion of the structure above the springline (ft <sup>2</sup> ) (12.8.4.2)

$A_{vr}$	= stirrup reinforcement area to resist radial tension forces on cross-section width, $b$ in each line of stirrups at circumferential spacing, $s_v$ (in. <sup>2</sup> /ft) (12.10.4.2.6)
$A_{vs}$	= required area of stirrups for shear reinforcement (in. <sup>2</sup> /ft) (12.10.4.2.6)
$B$	= width of culvert (ft) (C12.6.2.2.5)
$B'$	= nonuniform stress distribution factor (12.12.3.5.2)
$B_c$	= outside diameter or width of the structure (ft) (12.6.6.3)
$B'_c$	= out-to-out vertical rise of pipe (ft) (12.6.6.3)
$B_d$	= horizontal width of trench at top of pipe (ft) (12.11.2.2)
$B_{FE}$	= earth load bedding factor (12.10.4.3.1)
$B_{FLL}$	= live load bedding factor (12.10.4.3.1)
$B_1$	= crack control coefficient for effect of cover and spacing of reinforcement (C12.10.4.2.4d)
$b$	= width of section resisting $M$ , $N$ , and $V$ ; usually $b = 12.0$ in.; element effective width (12.10.4.2.4c) (12.12.3.5.3c)
$C_A$	= constant corresponding to the shape of the pipe (12.10.4.3.2a)
$C_c$	= load coefficient for positive pipe projection (12.10.4.3.2a)
$C_d$	= load coefficient for trench installation (12.11.2.2)
$C_{dt}$	= load coefficient for tunnel installation (12.13.2.1)
$C_H$	= adjustment factor for shallow cover heights over metal box culverts (12.9.4.4)
$C_L$	= live load distribution coefficient (12.12.3.4)
$C_{\ell\ell}$	= live load adjusted for axle loads, tandem axles, and axles with other than four wheels; $C_1 C_2 A_L$ (kip) (12.9.4.2)
$C_N$	= parameter that is a function of the vertical load and vertical reaction (12.10.4.3.2a)
$C_s$	= construction stiffness for tunnel liner plate (kip/in.) (12.5.6.4)
$C_1$	= 1.0 for single axles and $0.5 + S/50 \leq 1.0$ for tandem axles; adjustment coefficient for number of axles; crack control coefficient for various types of reinforcement (12.9.4.2) (12.9.4.3) (C12.10.4.2.4d)
$C_2$	= adjustment factor for number of wheels on a design axle as specified in Table 12.9.4.2-1; adjustment coefficient for number of wheels per axle (12.9.4.2) (12.9.4.3)
$c$	= distance from inside face to neutral axis of thermoplastic pipe (in.); distance from inside surface to neutral axis (in.); distance from neutral axis to extreme fiber (in.) (12.12.3.6) (12.12.3.5.2) (12.12.3.5.4b)
$D$	= straight leg length of haunch (in.); pipe diameter (in.); required D-load capacity of reinforced concrete pipe (klf); diameter to centroid of pipe wall (in.) (12.9.4.1) (12.6.6.2) (12.10.4.3.1) (12.12.3.5.4b)
$D\text{-load}$	= resistance of pipe from three-edge bearing test load to produce a 0.01-in. crack (klf) (12.10.4.3)
$D_e$	= effective diameter of thermoplastic pipe (in.) (12.12.3.6)
$D_f$	= shape factor (12.12.3.5.4b)
$D_i$	= inside diameter of pipe (in.) (12.10.4.3.1)
$D_o$	= outside diameter of pipe (ft) (12.12.3.4)
$d$	= required envelope width adjacent to the structure (ft); distance from compression face to centroid of tension reinforcement (in.) (12.8.5.3) (12.10.4.2.4a) (C12.11.3)
$d'$	= width of warped embankment fill to provide adequate support for skewed installation (ft) (C12.6.8.2)
$d_1$	= distance from the structure (ft) (12.8.5.3)
$E$	= modulus of elasticity of the plastic (ksi) (12.12.3.3)
$E_m$	= modulus of elasticity of metal (ksi) (12.7.2.4)
$E(x)$	= lateral unbalanced distributed load on culvert below sloping ground and skewed at end wall (lbs.) (C12.6.2.2.5)
$E_{50}$	= 50-yr modulus of elasticity (ksi) (12.12.3.5.3c)
$F$	= concentrated load acting at the crown of a culvert (kip) (C12.6.2.2.5)
$F_c$	= curvature correction factor (12.10.4.2.5)
$F_{cr}$	= factor for adjusting crack control relative to average maximum crack width of 0.01 in. corresponding to $F_{cr} = 1.0$ (12.10.4.2.4d)
$F_d$	= factor for crack depth effect resulting in increase in diagonal tension, shear, and strength with decreasing $d$ (12.10.4.2.5)
$F_e$	= soil-structure interaction factor for embankment installations (12.10.2.1)
$FF$	= flexibility factor (in./kip) (12.5.6.3) (12.7.2.6)
$F_n$	= coefficient for effect of thrust on shear strength (12.10.4.2.5)
$F_{rp}$	= factor for process and local materials affecting radial tension strength of pipe (12.10.4.2.3)
$F_{rt}$	= factor for pipe size effect on radial tension strength (12.10.4.2.4c)
$F_t$	= soil-structure interaction factor for trench installations (12.10.2.1)
$F_u$	= specified minimum tensile strength (ksi) (12.7.2.4)

$F_{vp}$	= factor for process and local materials that affect the shear strength of the pipe (12.10.4.2.3)
$F_y$	= yield strength of metal (ksi) (12.7.2.3)
$f'_c$	= compressive strength of concrete (ksi) (12.4.2.2)
$f_{cr}$	= critical buckling stress (ksi) (12.7.2.4) (12.12.3.5.2)
$f_s$	= maximum stress in reinforcing steel at service limit state (ksi) (C12.11.3)
$f_y$	= specified minimum yield point for reinforcing steel (ksi) (12.10.4.2.4a)
$H$	= rise of culvert (ft); height of cover from the box culvert rise to top of pavement (ft); height of cover over crown (ft); height of fill above top of pipe (ft) (C12.6.2.2.5) (12.9.4.2) (12.9.4.4) (12.10.2.1)
$HAF$	= horizontal arching factor (12.10.2.1)
$H_D$	= vertical distance from mid-depth of corrugation to top grade (12.8.9.4)
$H_{design}$	= design height of cover above top of culvert or above crown of arches or pipes (ft) (C12.6.2.2.5)
$H_L$	= headwall strip reaction (kip) (C12.6.2.2.5)
$H_s$	= depth of water table above springline of pipe (ft) (12.12.3.4)
$H_1$	= depth of crown of culvert below ground surfaces (ft); height of cover above the footing to traffic surface (ft) (C12.6.2.2.5) (12.8.4.2)
$H_2$	= actual height of cover above top of culvert or above crown of arches or pipes (ft); height of cover from the structure springline to traffic surface (ft) (C12.6.2.2.5) (12.8.4.2)
$h$	= vertical distance from the top of cover for design height to point of horizontal load application (ft); wall thickness of pipe or box culvert (in.); height of ground surface above top of pipe (ft) (C12.6.2.2.5) (12.10.4.2.4a) (C12.11.3)
$h_w$	= height of water surface above top of pipe (ft) (12.12.3.5.2)
$I$	= moment of inertia ( $\text{in.}^4/\text{in.}$ ) (12.7.2.6)
$ID$	= inside diameter (in.) (12.6.6.3)
$i$	= coefficient for effect of axial force at service limit state, $f_s$ (12.10.4.2.4d) (C12.11.3)
$j$	= coefficient for moment arm at service limit state, $f_s$ (12.10.4.2.4d) (C12.11.3)
$K$	= ratio of the unit lateral effective soil pressure to unit vertical effective soil pressure, i.e., Rankine coefficient of active earth pressure (12.10.4.2)
$K_h$	= lateral earth pressure for culvert under sloping ground (psf/lf) (C12.6.2.2.5)
$K_{h1}$	= lateral earth pressure distribution acting on upslope surface of culvert (psf/lf) (C12.6.2.2.5)
$K_{h2}$	= lateral earth pressure distribution acting on downslope surface of culvert (psf/lf) (C12.6.2.2.5)
$k$	= soil stiffness factor; edge support coefficient (12.7.2.4) (12.13.3.3) (12.12.3.5.3c)
$L$	= distance along length of culvert from expansion joint to the centerline of the headwall (ft); length of stiffening rib on leg (in.) (C12.6.2.2.5) (12.9.4.1)
$L_w$	= lane width (ft); horizontal live load distribution width in the circumferential direction, at the elevation of the crown (ft) (12.8.4.2) (12.12.3.4)
$M_{dl}$	= dead load moment (kip-ft/ft); sum of the nominal crown and haunch dead load moments (kip-ft/ft) (12.9.4.2)
$M_{dlu}$	= factored dead load moment as specified in Article 12.9.4.2 (kip-ft) (12.9.4.3)
$M_{\ell\ell}$	= live load moment (kip-ft/ft); sum of the nominal crown and haunch live load moments (kip-ft/ft) (12.9.4.2)
$M_{\ell\ell u}$	= factored live load moment as specified in Article 12.9.4.2 (kip-ft) (12.9.4.3)
$M_{nu}$	= factored moment acting on cross-section width, $b$ , as modified for effects of compressive or tensile thrust (kip-in./ft) (12.10.4.2.6)
$M_P$	= plastic moment capacity of deep corrugated structure (k-ft/ft) (12.8.9.4)
$M_{pc}$	= crown plastic moment capacity (kip-ft/ft) (12.9.4.3)
$M_{ph}$	= haunch plastic moment capacity (kip-ft/ft) (12.9.4.3)
$M_s$	= bending moment at service limit state (kip-in./ft); moment acting on a cross-section of width, $b$ , at service limit state taken as an absolute value in design equations (kip-in./ft); constrained soil modulus specified in Table 12.12.3.4-1 (ksi); soil modulus (ksi) (12.10.4.2.4d) (C12.11.3) (12.12.3.4) (12.12.3.5.2)
$M_u$	= ultimate moment acting on cross-section width, $b$ (kip-in./ft) (12.10.4.2.4a)
$N_s$	= axial thrust acting on a cross-section width, $b$ , at service limit state taken as positive when compressive and negative when tensile (kip/ft) (12.10.4.2.4d) (C12.11.3)
$N_u$	= axial thrust acting on cross-section width, $b$ , at strength limit state (kip/ft) (12.10.4.2.4a)
$n$	= number of adjoining traffic lanes (12.8.4.2)
$P_{Brg}$	= allowable bearing pressure to limit compressive strain in the trench wall or embankment (ksf) (12.8.5.3)
$P_c$	= proportion of total moment carried by crown of metal box culvert (12.9.4.3)
$P_F$	= factored vertical crown pressure (ksf) (12.12.3.4)
$P_L$	= factored design crown pressure (ksf); pressure due to live load ( $LL$ ) and dynamic load allowance ( $IM$ ) (ksf) (12.7.2.2) (12.12.3.4)

$P_{sp}$	= geostatic earth pressure ( $EV$ ), does not include hydrostatic pressure (ksf) (12.12.3.4)
$P_w$	= hydrostatic water pressure (ksf) (12.12.3.4)
$P_1$	= horizontal pressure from the structure at a distance, $d_1$ (ksf) (12.8.5.3)
$p$	= positive projection ratio (12.10.4.3.2a)
$p'$	= negative projection ratio (12.10.4.3.2a)
$q$	= ratio of the total lateral pressure to the total vertical pressure (12.10.4.3.2a)
$R$	= rise of structure (ft); rise of box culvert or long-span structural plate structures (ft); radius of centroid of culvert wall (in.); radius of pipe (in.); radius to centroid of pipe wall profile (in.) (12.8.4.1) (12.9.4.1) (12.12.3.4) (12.12.3.5.2) (12.12.3.5.4b)
$R_{AL}$	= axle load correction factor (12.9.4.6)
$R_c$	= corner radius of the structure (ft); concrete strength correction factor (12.8.5.3) (12.9.4.6)
$R_d$	= ratio of resistance factors specified in Article 5.5.4.2 for shear and moment (12.10.4.2.4c)
$R_f$	= factor related to required relieving slab thickness, applicable for box structures where the span is less than 26.0 ft (12.9.4.6)
$R_H$	= horizontal footing reaction component (kip/ft) (12.8.4.2)
$R_h$	= haunch moment reduction factor (12.9.4.3)
$R_n$	= nominal resistance (klf) (12.5.1)
$R_r$	= factored resistance (klf); factored resistance to thrust (kip/ft) (12.5.1) (12.12.3.5)
$R_T$	= top arc radius of long-span structural plate structures (ft) (12.8.3.2)
$R_V$	= vertical footing reaction component (kip/ft) (12.8.4.2)
$R_w$	= water buoyancy factor (12.12.3.5.2)
$r$	= radius of gyration (in.); radius to centerline of concrete pipe wall (in.) (12.7.2.4) (12.10.4.2.5)
$r_c$	= radius of crown (ft) (12.9.4.1)
$r_h$	= radius of haunch (ft) (12.9.4.1)
$r_s$	= radius of the inside reinforcement (in.) (12.10.4.2.4c)
$r_{sd}$	= settlement ratio parameter (12.10.4.3.2a)
$S$	= pipe, tunnel, or box diameter or span (in.) or (ft) as indicated; span of structure between springlines of long-span structural plate structures (ft); box culvert span (ft) (12.6.6.3) (12.8.4.1) (12.9.4.2)
$S_H$	= hoop stiffness factor (12.12.3.4)
$S_i$	= internal diameter or horizontal span of the pipe (in.) (12.10.4.2.4b)
$S_f$	= spacing of circumferential reinforcement (in.) (12.10.4.2.4d)
$S_1, S_2$	= shear forces acting along culvert bearing lines (lbs.) (C12.6.2.2.5)
$s_v$	= spacing of stirrups (in.) (12.10.4.2.6)
$T$	= total dead load and live load thrust in the structure (kip/ft) (12.8.5.3)
$T_L$	= factored thrust (kip/ft) (12.7.2.2)
$t$	= required thickness of cement concrete relieving slab (in.); thickness of element (in.) (12.9.4.6) (12.12.3.5.3c)
$t_b$	= basic thickness of cement concrete relieving slab (in.); clear cover over reinforcement (in.) (12.9.4.6) (12.10.4.2.4d)
$V$	= unfactored footing reaction (kip/ft) (12.9.4.5)
$VAF$	= vertical arching factor (12.10.2.1)
$V_c$	= factored shear force acting on cross-section width, $b$ , which produces diagonal tension failure without stirrup reinforcement (kip/ft) (12.10.4.2.6)
$V_{DL}$	= $[H_2(S) - A_T] \gamma_s/2$ (kip/ft) (12.8.4.2)
$V_L$	= headwall strip reaction (kip) (C12.6.2.2.5)
$V_{LL}$	= $n(A_L)/(8 + 2 H_1)$ (kip/ft) (12.8.4.2)
$V_n$	= nominal shear resistance of pipe section without radial stirrups per unit length of pipe (kip/ft) (12.10.4.2.5)
$V_r$	= factored shear resistance per unit length (kip/ft) (12.10.4.2.5)
$V_u$	= ultimate shear force acting on cross-section width, $b$ (kip/ft) (12.10.4.2.5)
$W_E$	= total earth load on pipe or liner (kip/ft) (12.10.2.1)
$W_F$	= fluid load in the pipe (kip/ft) (12.10.4.3.1)
$W_L$	= total live load on pipe or liner (kip/ft) (12.10.4.3.1)
$W_T$	= total dead and live load on pipe or liner (kip/ft) (12.10.4.3.1)
$w$	= unit weight of soil (pcf); total clear width of element between supporting elements (in.) (12.10.2.1) (12.12.3.5.3c)
$x$	= parameter which is a function of the area of the vertical projection of the pipe over which active lateral pressure is effective (12.10.4.3.2a)

$\alpha$	= skew angle between the highway centerline or tangent thereto and the culvert headwall (degrees) (C12.6.2.2.5)
$\beta$	= angle of fill slope measured from horizontal (degrees) (C12.6.2.2.5)
$\gamma_{EV}$	= load factor for vertical pressure from dead load of earth fill (12.12.3.4)
$\gamma_{LL}$	= load factor for live load (12.12.3.4)
$\gamma_p$	= maximum load factor for permanent load resulting from Vertical Earth Pressure ( <i>EV</i> ) for the case of flexible buried structures other than metal box culverts, specified in Table 3.4.1-2 (12.12.3.5.4a)
$\gamma_s$	= unit weight of backfill (kcf); soil unit weight (kcf) (C12.9.2) (12.9.4.2)
$\gamma_w$	= unit weight of water (kcf) (12.12.3.4)
$\gamma_{WA}$	= load factor for hydrostatic pressure (12.12.3.4)
$\Delta$	= return angle of the structure (degrees); haunch radius included angle (degrees); allowable deflection of pipe, reduction of vertical diameter due to bending (in.) (12.8.4.2) (12.9.4.1) (12.12.3.5.4b)
$\epsilon_{bu}$	= factored bending strain = $\gamma_B \epsilon_b$ (in./in.) (12.12.3.5.4a)
$\epsilon_{tt}$	= factored long-term tension strain (in./in.) (12.12.3.5.4a)
$\epsilon_t$	= allowable tension strain (12.12.3.5.4a)
$\eta_{EV}$	= load modifier, specified in Article 1.3.2, as they apply to vertical earth loads on culverts (12.12.3.4)
$\eta_{LL}$	= load modifier as they apply to live loads on culverts (12.12.3.4)
$\lambda$	= slenderness factor (12.12.3.5.3c)
$\mu$	= coefficient of friction between the pipe and soil (12.10.2.1)
$\rho$	= effective width factor (12.12.3.5.3c)
$\phi$	= resistance factor (12.5.1)
$\phi_f$	= resistance factor for flexure (12.10.4.2.4c)
$\phi_{fs}$	= coefficient of friction between the fill material and the sides of the trench (12.10.4.3.2a)
$\phi_r$	= resistance factor for radial tension (12.10.4.2.4c)
$\phi_s$	= resistance factor for soil stiffness, $\phi_s = 0.9$ (12.12.3.4)
$\Psi$	= central angle of pipe subtended by assumed distribution of external reactive force (degrees) (12.10.4.2.1)
$\omega$	= spacing of corrugation (in.) (12.12.3.5.3c)

## 12.4—SOIL AND MATERIAL PROPERTIES

### 12.4.1—Determination of Soil Properties

#### 12.4.1.1—General

Subsurface exploration shall be carried out to determine the presence and influence of geologic and environmental conditions that may affect the performance of buried structures. For buried structures supported on footings and for pipe arches and large diameter pipes, a foundation investigation should be conducted to evaluate the capacity of foundation materials to resist the applied loads and to satisfy the movement requirements of the structure.

#### C12.4.1.1

The following information may be useful for design:

- Strength and compressibility of foundation materials;
- Chemical characteristics of soil and surface waters, e.g., pH, resistivity, and chloride content of soil and pH, resistivity, and sulfate content of surface water;
- Stream hydrology, e.g., flow rate and velocity, maximum width, allowable headwater depth, and scour potential; and
- Performance and condition survey of culverts in the vicinity.

#### C12.4.1.2

Refer to Article 10.4 for general guidance regarding foundation soil properties. The performance of rigid pipes is dependent on foundation and bedding stability.

#### 12.4.1.2—Foundation Soils

The type and anticipated behavior of the foundation soil shall be considered for stability of bedding and settlement under load.

### 12.4.1.3—Envelope Backfill Soils

The type, compacted density and strength properties of the soil envelope adjacent to the buried structure shall be established. The backfill soils comprising the soil envelope shall conform to the requirements of AASHTO M 145 as follows:

- For standard flexible pipes and concrete structures: A-1, A-2, or A-3 (GW, GP, SW, SP, GM, SM, SC, GC),
- For metal box culverts and long-span structures with cover less than 12.0 ft: A-1, A-2-4, A-2-5, or A-3 (GW, GP, SW, SP, GM, SM, SC, GC),
- For long-span metal structures with cover not less than 12.0 ft: A-1 or A-3 (GW, GP, SW, SP, GM, SM), and
- For structural plate culverts with deep corrugations: A-1, A-2-4, A-2-5, or A-3 ([ASTM D2487](#)) (GW, GP, SW, SP, GM, SM, SC, GC) and the culvert manufacturer's requirements.

### C12.4.1.3

Refer to Sections 26 and 27, *AASHTO LRFD Bridge Construction Specifications*, for compaction criteria of soil backfill for flexible and rigid culverts, respectively.

Wall stresses in buried structure are sensitive to the relative stiffness of the soil and pipe. Buckling stability of flexible culverts is dependant on soil stiffness.

In the selection of a type of backfill for the envelope, the quality of the material and its suitability for achieving the requirements of the design should be considered. The order of preference for selecting envelope backfill based on quality may be taken as follows:

- Angular, well-graded sand and gravel;
- Nonangular, well-graded sand and gravel;
- Flowable materials, e.g., cement-soil-fly ash mixtures, which result in low density/low strength backfill, for trench applications only;
- Uniform sand or gravel, provided that placement is confirmed to be dense and stable, but which may require a soil or geofabric filter to prevent the migration of fines;
- Clayey sand or gravel of low plasticity; and
- Stabilized soil, which should be used only under the supervision of an Engineer familiar with the behavior of the material.

### 12.4.2—Materials

#### 12.4.2.1—Aluminum Pipe and Structural Plate Structures

Aluminum for corrugated metal pipe and pipe-arches shall comply with the requirements of AASHTO M 196 ([ASTM B745](#)). Aluminum for structural plate pipe, pipe-arch, arch, and box structures shall meet the requirements of AASHTO M 219 ([ASTM B746](#)).

#### 12.4.2.2—Concrete

Concrete shall conform to Article 5.4, except that  $f'c$  may be based on cores.

#### 12.4.2.3—Precast Concrete Pipe

Precast concrete pipe shall comply with the requirements of AASHTO M 170 ([ASTM C76](#)) and M 242/M 242 ([ASTM C655M](#) and [C655](#)). Design wall thickness, other than the standard wall dimensions, may be used, provided that the design complies with all applicable requirements of this Section.

#### 12.4.2.4—Precast Concrete Structures

Precast concrete arch, elliptical, and box structures shall comply with the requirements of AASHTO M 206/M 206 ([ASTM C506M](#) and [C506](#)), M 207/M 207 ([ASTM C507M](#) and [C507](#)), M 259 ([ASTM C789](#)), and M 273 ([ASTM C850](#)).

#### 12.4.2.5—Steel Pipe and Structural Plate Structures

Steel for corrugated metal pipe and pipe-arches shall comply with the requirements of AASHTO M 36 ([ASTM A760](#)). Steel for structural plate pipe, pipe-arch, arch, and box structures shall meet the requirements of AASHTO M 167/M 167 ([ASTM A761/A761M](#)).

#### 12.4.2.6—Deep Corrugated Structures

Steel for deep corrugated structural plate shall comply with the requirements of AASHTO M 167. Deep corrugated structural plate may be reinforced.

#### C12.4.2.6

Reinforcement for deep corrugated structures may consist of structural shapes, or deep corrugated structural plate meeting the requirements of AASHTO M 167, with or without nonshrink grout, complete with shear studs.

#### 12.4.2.7—Steel Reinforcement

Reinforcement shall comply with the requirements of Article 5.4.3, and shall conform to one of the following: AASHTO M 31/M 31 ([ASTM A615/A615M](#)), M 32/M 32 ([ASTM A82/A82M](#)), M 55/M 55 ([ASTM A185/A185M](#)), M 221/M 221 ([ASTM A497](#)), or M 225/M 225 ([ASTM A496/A496M](#)).

For smooth wire and smooth welded wire fabric, the yield strength may be taken as 65.0 ksi. For deformed welded wire fabric, the yield strength may be taken as 70.0 ksi.

#### 12.4.2.8—Thermoplastic Pipe

Plastic pipe may be solid wall, corrugated, or profile wall and may be manufactured of polyethylene (PE) or polyvinyl chloride (PVC).

PE pipe shall comply with the requirements of [ASTM F714](#) for solid wall pipe, AASHTO M 294 for corrugated pipe, and [ASTM F894](#) for profile wall pipe.

PVC pipe shall comply with the requirements of AASHTO M 278 for solid wall pipe, [ASTM F679](#) for solid wall pipe, and AASHTO M 304 for profile wall pipe.

## 12.5—LIMIT STATES AND RESISTANCE FACTORS

### 12.5.1—General

Buried structures and their foundations shall be designed by the appropriate methods specified in Articles 12.7 through 12.12 so that they resist the factored loads given by the load combinations specified in Articles 12.5.2 and 12.5.3.

The factored resistance,  $R_r$ , shall be calculated for each applicable limit state as:

$$R_r = \phi R_n \quad (12.5.1-1)$$

where:

$R_n$  = the nominal resistance

$\phi$  = the resistance factor specified in Table 12.5.5-1

### 12.5.2—Service Limit State

Buried structures shall be investigated at Service Load Combination I, as specified in Table 3.4.1-1.

- Deflection of metal structures, tunnel liner plate, and thermoplastic pipe, and
- Crack width in reinforced concrete structures.

### 12.5.3—Strength Limit State

Buried structures and tunnel liners shall be investigated for construction loads and at Strength Load Combinations I and II, as specified in Table 3.4.1-1, as follows:

- For metal structures:
  - Wall area
  - Buckling
  - Seam failure
  - Flexibility limit for construction
  - Flexure of box and deep corrugated structures only
- For concrete structures:
  - Flexure
  - Shear
  - Thrust
  - Radial tension
- For thermoplastic pipe:
  - Wall area
  - Buckling

### C12.5.1

Procedures for determining nominal resistance are provided in Articles 12.7 through 12.12 for:

- Metal pipe, pipe arches, and arch structures;
- Long-span structural plate;
- Structural plate box structures;
- Reinforced precast concrete pipe;
- Reinforced concrete cast-in-place and precast box structures
- Thermoplastic pipe; and
- Deep corrugated structural plate structures.

### C12.5.2

Deflection of a tunnel liner depends significantly on the amount of overexcavation of the bore and is affected by delay in backpacking or inadequate backpacking. The magnitude of deflection is not primarily a function of soil modulus or the liner plate properties, so it cannot be computed with usual deflection formulae.

Where the tunnel clearances are important, the designer should oversize the structure to allow for deflection.

### C12.5.3

Strength Load Combinations III and IV and the extreme event limit state do not control due to the relative magnitude of loads applicable to buried structures as indicated in Article 12.6.1. Buried structures have been shown not to be controlled by fatigue.

Flexibility limit requirement is waived for some metal structures. See design provisions in Article 12.8.

Thermoplastic pipe have many profile wall geometries and some of these are made up of thin sections that may be limited based on local buckling. The strength limit state for wall area includes evaluating the section capacity for local buckling.

- Flexibility limit
- For tunnel liner plate:
  - Wall area
  - Buckling
  - Seam strength
  - Construction stiffness

#### 12.5.4—Load Modifiers and Load Factors

Load modifiers shall be applied to buried structures and tunnel liners as specified in Article 1.3, except that the load modifiers for construction loads should be taken as 1.0. For strength limit states, buried structures shall be considered nonredundant under earth fill and redundant under live load and dynamic load allowance loads. Operational classification shall be determined on the basis of continued function and/or safety of the roadway.

#### 12.5.5—Resistance Factors

Resistance factors for buried structures shall be taken as specified in Table 12.5.5-1. Values of resistance factors for the geotechnical design of foundations for buried structures shall be taken as specified in Section 10.

#### C12.5.5

The standard installations for direct design of concrete pipe were developed based on extensive parameter studies using the soil structure interaction program, SPIDA. Although past research validates that SPIDA soil structure models correlate well with field measurements, variability in culvert installation methods and materials suggests that the design for Type I installations be modified. This revision reduces soil structure interaction for Type I installations by ten percent until additional performance documentation on installation in the field is obtained.

**Table 12.5.5-1—Resistance Factors for Buried Structures**

Structure Type	Resistance Factor
Metal Pipe, Arch, and Pipe Arch Structures	
Helical pipe with lock seam or fully welded seam:	
• Minimum wall area and buckling	1.00
Annular pipe with spot-welded, riveted, or bolted seam:	
• Minimum wall area and buckling	1.00
• Minimum longitudinal seam strength	0.67
• Bearing resistance to pipe arch foundations	Refer to Section 10
Structural plate pipe:	
• Minimum wall area and buckling	1.00
• Minimum longitudinal seam strength	0.67
• Bearing resistance to pipe arch foundations	Refer to Section 10
Long-Span Structural Plate and Tunnel Liner Plate Structures	
• Minimum wall area	0.67
• Minimum seam strength	0.67
• Bearing resistance of pipe arch foundations	Refer to Section 10
Structural Plate Box Structures	
• Plastic moment strength	1.00
• Bearing resistance of pipe arch foundations	Refer to Section 10
Reinforced Concrete Pipe	
Direct design method:	
Type 1 installation:	
• Flexure	0.90
• Shear	0.82
• Radial tension	0.82
Other type installations:	
• Flexure	1.00
• Shear	0.90
• Radial tension	0.90
Reinforced Concrete Cast-in-Place Box Structures	
• Flexure	0.90
• Shear	0.85
Reinforced Concrete Precast Box Structures	
• Flexure	1.00
• Shear	0.90
Reinforced Concrete Precast Three-Sided Structures	
• Flexure	0.95
• Shear	0.90
Thermoplastic Pipe	
PE and PVC pipe:	
• Minimum wall area and buckling	1.00
• Flexure	1.00
Deep Corrugated Structural Plate Structures	
• Minimum wall area and general buckling, $\phi_b$	0.70
• Plastic hinge, $\phi_h$	0.85
• Soil, $\phi_s$	0.90

### 12.5.6—Flexibility Limits and Construction Stiffness

#### 12.5.6.1—Corrugated Metal Pipe and Structural Plate Structures

Flexibility factors for corrugated metal pipe and structural plate structures shall not exceed the values specified in Table 12.5.6.1-1.

#### C12.5.6.1

Limits on construction stiffness and plate flexibility are construction requirements that do not represent any limit state in service.

**Table 12.5.6.1-1—Flexibility Factor Limit**

Type of Construction Material	Corrugation Size (in.)	Flexibility Factor (in./kip)
Steel Pipe	0.25	43
	0.5	43
	1.0	33
Aluminum Pipe	0.25 and 0.50	
	0.060 Material Thk.	31
	0.075 Material Thk.	61
	All Others	92
Steel Plate	1.0	60
	6.0 × 2.0	
	Pipe	20
	Pipe-Arch	30
Aluminum Plate	Arch	30
	9.0 × 2.5	
	Pipe	25
	Pipe-Arch	36
	Arch	36

#### 12.5.6.2—Spiral Rib Metal Pipe and Pipe Arches

Flexibility factors for spiral rib metal pipe and pipe arches shall not exceed the values, specified in Table 12.5.6.2-1, for embankment installations conforming to the provisions of Articles 12.6.6.2 and 12.6.6.3 and for trench installations conforming to the provisions of Articles 12.6.6.1 and 12.6.6.3.

**Table 12.5.6.2-1—Flexibility Factor Limits**

Material	Condition	Corrugation Size (in.)	Flexibility Factor (in./kip)
Steel	Embankment	0.75 × 0.75 × 7.5	217I <sup>1/3</sup>
		0.75 × 1.0 × 11.5	140I <sup>1/3</sup>
	Trench	0.75 × 0.75 × 7.5	263I <sup>1/3</sup>
		0.75 × 1.0 × 11.5	163I <sup>1/3</sup>
Aluminum	Embankment	0.75 × 0.75 × 7.5	340I <sup>1/3</sup>
		0.75 × 1.0 × 11.5	175I <sup>1/3</sup>
	Trench	0.75 × 0.75 × 7.5	420I <sup>1/3</sup>
		0.75 × 1.0 × 11.5	215I <sup>1/3</sup>

Values of inertia,  $I$ , for steel and aluminum pipes and pipe arches shall be taken as tabulated in Tables A12-2 and A12-5.

### 12.5.6.3—Thermoplastic Pipe

Flexibility factor,  $FF$ , of thermoplastic pipe shall not exceed 95.0 in./kip.

### C12.5.6.3

PE and PVC are thermoplastic materials that exhibit higher flexibility factors at high temperatures and lower flexibility factors at low temperatures. The specified flexibility factor limits are defined in relation to pipe stiffness values in accordance with [ASTM D2412](#) at 73.4°F.

### 12.5.6.4—Steel Tunnel Liner Plate

Construction stiffness,  $C_s$ , in kip/in., shall not be less than the following:

- Two-flange liner plate

$$C_s \geq 0.050 \text{ (kip/in.)}$$

- Four-flange liner plate

$$C_s \geq 0.111 \text{ (kip/in.)}$$

### C12.5.6.4

Assembled liner using two- and four-flange liner plates does not provide the same construction stiffness as a full steel ring with equal stiffness.

## 12.6—GENERAL DESIGN FEATURES

### 12.6.1—Loading

Buried structures shall be designed for force effects resulting from horizontal and vertical earth pressure, pavement load, live load, and vehicular dynamic load allowance. Earth surcharge, live load surcharge, downdrag loads, and external hydrostatic pressure shall be evaluated where construction or site conditions warrant. Water buoyancy loads shall be evaluated for buried structures with inverts below the water table to control flotation, as indicated in Article 3.7.2. Earthquake loads should be considered only where buried structures cross active faults.

For vertical earth pressure, the maximum load factor from Table 3.4.1-2 shall apply.

Wheel loads shall be distributed through earth fills according to the provisions of Article 3.6.1.2.6.

### C12.6.1

Buried structures benefit from both earth shelter and support that reduce or eliminate from concern many of the loads and load combinations of Article 3.4. Wind, temperature, vehicle braking, and centrifugal forces typically have little effect due to earth protection. Structure dead load, pedestrian live load, and ice loads are insignificant in comparison with force effects due to earth fill loading. External hydrostatic pressure, if present, can add significantly to the total thrust in a buried pipe.

Vehicular collision forces are applicable to appurtenances such as headwalls and railings only. Water, other than buoyancy and vessel collision loads, can act only in the noncritical longitudinal direction of the culvert.

Due to the absence or low magnitude of these loadings, Service Load Combination I, Strength Load Combinations I and II, or construction loads control the design.

The finite element analyses used in the preparation of these metal box structure provisions are based on conservative soil properties of low plasticity clay (CL) compacted to 90 percent density as specified in AASHTO T 99. Although low plasticity clay is not considered an acceptable backfill material, as indicated in Article 12.4.1.3, the FEM results have been shown to yield conservative, upperbound moments.

The loading conditions that cause the maximum flexural moment and thrust are not necessarily the same, nor are they necessarily the conditions that will exist at the final configuration.

## 12.6.2—Service Limit State

### 12.6.2.1—Tolerable Movement

Tolerable movement criteria for buried structures shall be developed based on the function and type of structure, anticipated service life, and consequences of unacceptable movements.

### 12.6.2.2—Settlement

#### 12.6.2.2.1—General

Settlement shall be determined as specified in Article 10.6.2. Consideration shall be given to potential movements resulting from:

- Longitudinal differential settlement along the length of the pipe,
- Differential settlement between the pipe and backfill, and
- Settlement of footings and unbalanced loading of skewed structures extending through embankment slopes.

#### 12.6.2.2.2—Longitudinal Differential Settlement

Differential settlement along the length of buried structures shall be determined in accordance with Article 10.6.2.4. Pipes and culverts subjected to longitudinal differential settlements shall be fitted with positive joints to resist disjointing forces meeting the requirements of Sections 26 and 27, *AASHTO LRFD Bridge Construction Specifications*.

Camber may be specified for an installation to ensure hydraulic flow during the service life of the structure.

#### 12.6.2.2.3—Differential Settlement between Structure and Backfill

#### C12.6.2.2.3

Where differential settlement of arch structures is expected between the structure and the side fill, the foundation should be designed to settle with respect to the backfill.

Pipes with invert shall not be placed on foundations that will settle much less than the adjacent side fill, and a uniform bedding of loosely compacted granular material should be provided.

The purpose of this provision is to minimize downdrag loads.

*12.6.2.2.4—Footing Settlement*

Footings shall be designed to provide uniform longitudinal and transverse settlement. The settlement of footings shall be large enough to provide protection against possible downdrag forces caused by settlement of adjacent fill. If poor foundation materials are encountered, consideration shall be given to excavation of all or some of the unacceptable material and its replacement with compacted acceptable material.

Footing design shall comply with the provisions of Article 10.6.

Footing reactions for metal box culvert structures shall be determined as specified in Article 12.9.4.5.

The effects of footing depth shall be considered in the design of arch footings. Footing reactions shall be taken as acting tangential to the arch at the point of connection to the footing and to be equal to the thrust in the arch at the footing.

*12.6.2.2.5—Unbalanced Loading*

Buried structures skewed to the roadway alignment and extending through an embankment fill shall be designed in consideration of the influence of unsymmetrical loading on the structure section.

*C12.6.2.2.4*

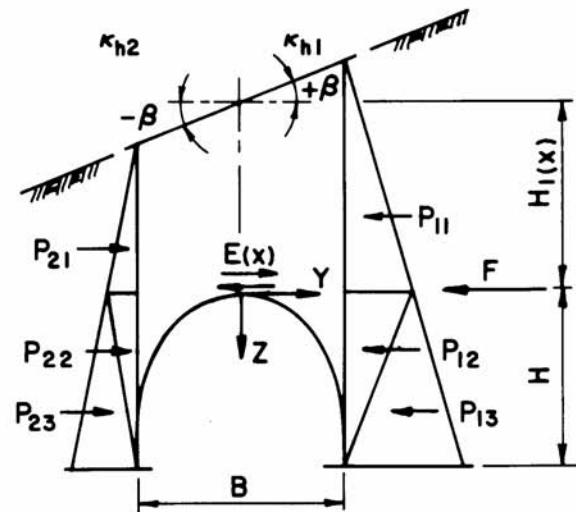

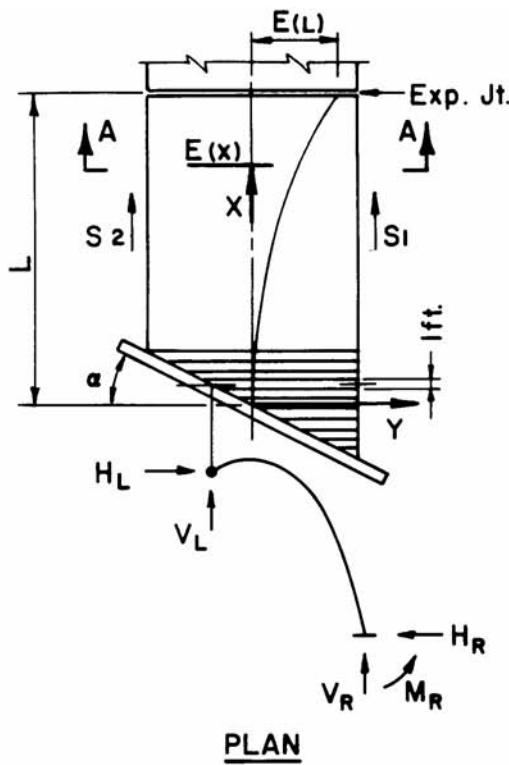

Metal pipe arch structures, long-span arch structures, and box culvert structures should not be supported on foundation materials that are relatively unyielding compared with the adjacent sidefill. The use of massive footings or piles to prevent settlement of such structures is not recommended.

In general, provisions to accommodate uniform settlement between the footings are desirable, provided that the resulting total settlement is not detrimental to the function of the structure.

*C12.6.2.2.5*

Disregard of the effect of lateral unbalanced forces in the headwall design can result in failure of the headwall and adjacent culvert sections.

Due to the complexity of determining the actual load distribution on a structure subjected to unbalanced loading, the problem can be modeled using numerical methods or the following approximate method. The approximate method consists of analyzing 1.0-ft wide culvert strips for the unbalanced soil pressures wherein the strips are limited by planes perpendicular to the culvert centerline. Refer to Figure C12.6.2.2.5-1 for this method of analysis for derivation of force  $F$ . For semicomplete culvert strips, the strips may be assumed to be supported as shown in the lower part of the plan. The headwall shall be designed as a frame carrying the strip reactions,  $V_L$  and  $H_L \cos \theta$ , in addition to the concentrated force,  $F$ , assumed to be acting on the crown. Force  $F$  is determined using the equations given herein.

SECTION A - A

**Figure C12.6.2.2.5-1—Forces on Culvert—Approximate Analysis**

The unbalanced distributed load may be estimated by the following relationships:

$$E(x) = (P_{11} - P_{21}) + \frac{2}{3}(P_{12} - P_{22}) + \frac{1}{3}(P_{13} - P_{23}) \quad (\text{C12.6.2.2.5-1})$$

in which:

$$\begin{aligned}
 P_{11} &= \frac{1}{2} K_{h1} \left( H_{l(x)} + \frac{B}{2} \tan \beta \right)^2 \\
 P_{21} &= \frac{1}{2} K_{h2} \left( H_{l(x)} - \frac{B}{2} \tan \beta \right)^2 \\
 P_{12} &= \frac{1}{2} K_{h1} H \left( H_{l(x)} + \frac{B}{2} \tan \beta \right) \\
 P_{22} &= \frac{1}{2} K_{h2} H \left( H_{l(x)} - \frac{B}{2} \tan \beta \right) \\
 P_{13} &= \frac{1}{2} K_{h1} H \left( H + H_{l(x)} + \frac{B}{2} \tan \beta \right) \\
 P_{23} &= \frac{1}{2} K_{h2} H \left( H + H_{l(x)} - \frac{B}{2} \tan \beta \right)
 \end{aligned} \tag{C12.6.2.2.5-2}$$

When the pressures are substituted into Eq. C12.6.2.2.5-1, the following results:

$$E(x) = A_2 x^2 + A_1 x + A_0 \tag{C12.6.2.2.5-3}$$

in which:

$$\begin{aligned}
 A_2 &= \frac{1}{2} \left( \frac{H_{l(L)}}{L} \right)^2 (K_{h1} - K_{h2}) \\
 A_1 &= \frac{1}{2} \left( \frac{H_{l(L)}}{L} \right) [B(K_{h1} + K_{h2}) \tan \beta + H(K_{h1} - K_{h2})] \\
 A_0 &= \frac{1}{24} [(3B^2 \tan^2 \beta + 4H^2)(K_{h1} - K_{h2}) \\
 &\quad + 6HB(K_{h1} + K_{h2}) \tan \beta]
 \end{aligned} \tag{C12.6.2.2.5-4}$$

The support forces for the unbalanced distribution load,  $E(x)$ , are:

$$\begin{aligned}
 F &= \frac{1}{6} L \sec \alpha (2A_2 L^2 + 3A_1 L + 6A_0) \\
 S_1 &= -\frac{1}{12} \frac{L}{B} [A_2 L^2 (3L - 2B \tan \alpha) + A_1 L (4L \\
 &\quad - 3B \tan \alpha) + 6A_0 (L - B \tan \alpha)] \\
 S_2 &= \frac{1}{12} \frac{L}{B} [A_2 L^2 (3L + 2B \tan \alpha) + A_1 L (4L \\
 &\quad + 3B \tan \alpha) + 6A_0 (L + B \tan \alpha)]
 \end{aligned} \tag{C12.6.2.2.5-5}$$

For values of  $K_h$ , see Figure C12.6.2.2.5-2.

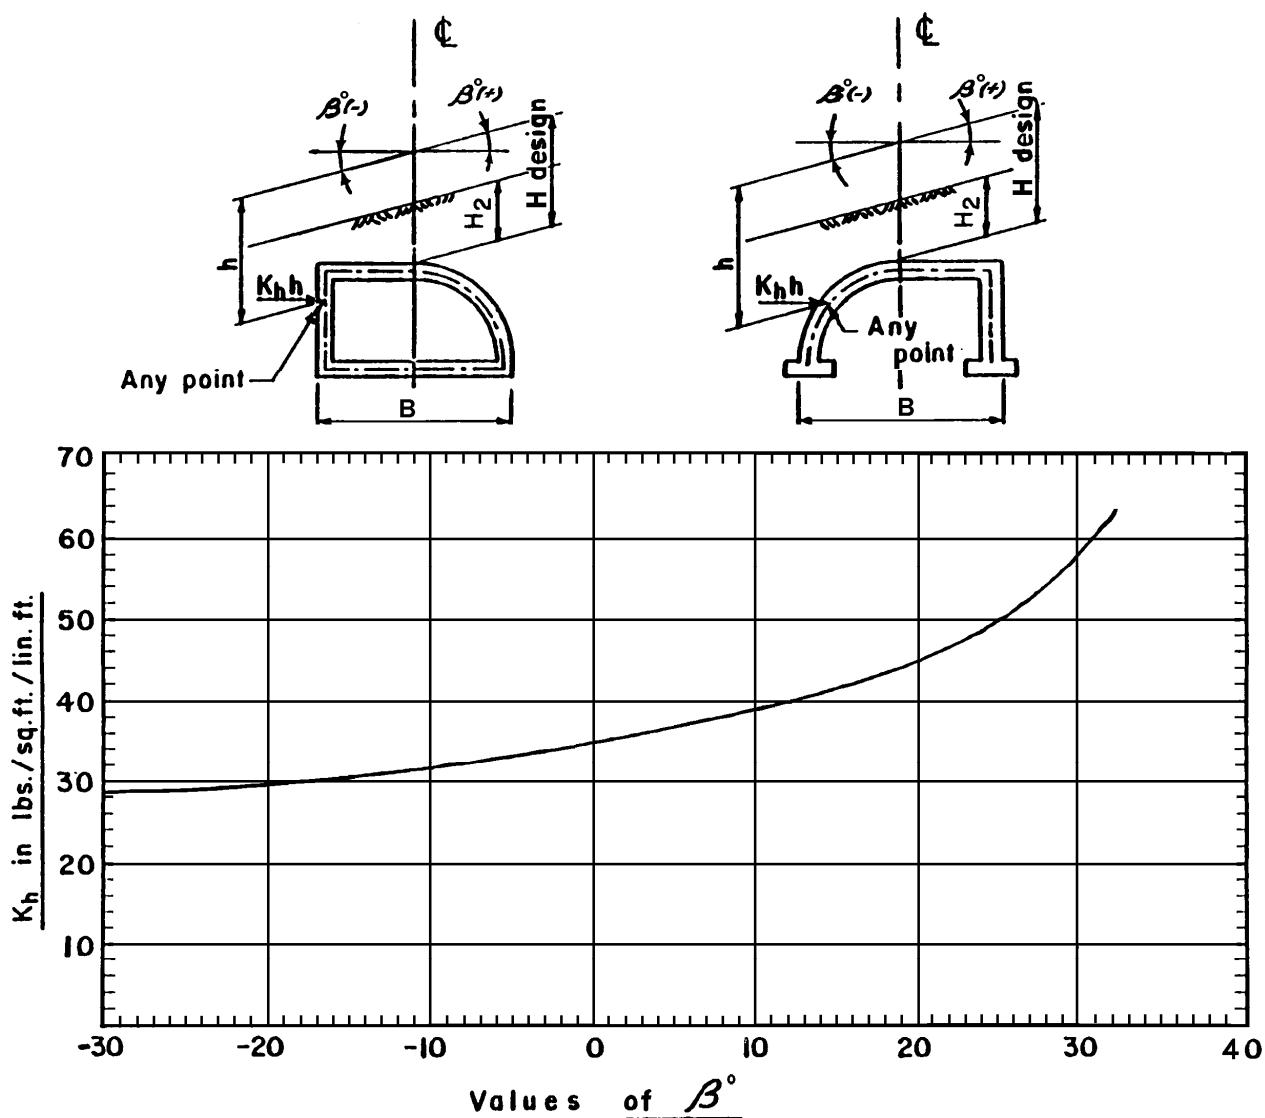

Figure C12.6.2.2.5-2—Lateral Earth Pressure as a Function of Ground Slope

### 12.6.2.3—Uplift

Uplift shall be considered where structures are installed below the highest anticipated groundwater level.

### C12.6.2.3

To satisfy this provision, the dead load on the crown of the structure should exceed the buoyancy of the culvert, using load factors as appropriate.

### 12.6.3—Safety against Soil Failure

#### 12.6.3.1—Bearing Resistance and Stability

Pipe structures and footings for buried structures shall be investigated for bearing capacity failure and erosion of soil backfill by hydraulic gradients.

### 12.6.3.2—Corner Backfill for Metal Pipe Arches

The corner backfill for metal pipe arches shall be designed to account for corner pressure taken as the arch thrust divided by the radius of the pipe-arch corner. The soil envelope around the corners of pipe arches shall resist this pressure. Placement of select structural backfill compacted to unit weights higher than normal may be specified.

### 12.6.4—Hydraulic Design

Design criteria, as specified in Article 2.6 and "Hydraulic Design of Highway Culverts," FHWA (1985), for hydraulic design considerations shall apply.

### 12.6.5—Scour

Buried structures shall be designed so that no movement of any part of the structure will occur as a result of scour.

In areas where scour is a concern, the wingwalls shall be extended far enough from the structure to protect the structural portion of the soil envelope surrounding the structure. For structures placed over erodible deposits, a cut-off wall or scour curtain, extending below the maximum anticipated depth of scour or a paved invert, shall be used. The footings of structures shall be placed not less than 2.0 ft below the maximum anticipated depth of scour.

### 12.6.6—Soil Envelope

#### 12.6.6.1—Trench Installations

The minimum trench width shall provide sufficient space between the pipe and the trench wall to ensure sufficient working room to properly and safely place and compact backfill material.

The contract documents shall require that stability of the trench be ensured by either sloping the trench walls or providing support of steeper trench walls in conformance with OSHA or other regulatory requirements.

#### C12.6.6.1

As a guide, the minimum trench width should not be less than the greater of the pipe diameter plus 16.0 in. or the pipe diameter times 1.5 plus 12.0 in. The use of specially designed equipment may enable satisfactory installation and embedment even in narrower trenches. If the use of such equipment provides an installation meeting the requirements of this Article, narrower trench widths may be used as approved by the Engineer.

For trenches excavated in rock or high-bearing soils, decreased trench widths may be used up to the limits required for compaction. For these conditions, the use of a flowable backfill material, as specified in Article 12.4.1.3, allows the envelope to be decreased to within 6.0 in. along each side of the pipe.

### 12.6.6.2—Embankment Installations

The minimum width of the soil envelope shall be sufficient to ensure lateral restraint for the buried structure. The combined width of the soil envelope and embankment beyond shall be adequate to support all the loads on the culvert and to comply with the movement requirements specified in Article 12.6.2.

### C12.6.6.2

As a guide, the minimum width of the soil envelope on each side of the buried structure should not be less than the widths specified in Table C12.6.6.2-1:

**Table C12.6.6.2-1—Minimum Width of Soil Envelope**

Diameter, $S$ (in.)	Minimum Envelope Width (ft)
<24	$S/12$
24–144	2.0
>144	5.0

### 12.6.6.3—Minimum Soil Cover

The cover of a well-compacted granular subbase, taken from the top of rigid pavement or the bottom of flexible pavement, shall not be less than that specified in Table 12.6.6.3-1, where:

$S$  = diameter of pipe (in.)

$B_c$  = outside diameter or width of the structure (ft)

$B'_c$  = out-to-out vertical rise of pipe (ft)

$ID$  = inside diameter (in.)

**Table 12.6.6.3-1—Minimum Soil Cover**

Type	Condition	Minimum Cover
Corrugated Metal Pipe	—	$S/8 \geq 12.0$ in.
Spiral Rib Metal Pipe	Steel Conduit	$S/4 \geq 12.0$ in.
	Aluminum Conduit where $S \leq 48.0$ in.	$S/2 \geq 12.0$ in.
	Aluminum Conduit where $S > 48.0$ in.	$S/2.75 \geq 24.0$ in.
	—	$S/8 \geq 12.0$ in.
Structural Plate Pipe Structures	—	Refer to Table 12.8.3.1.1-1
Long-Span Structural Plate Pipe Structures	—	1.4 ft as specified in Article 12.9.1
Reinforced Concrete Pipe	Unpaved areas and under flexible pavement	$B_c/8$ or $B'_c/8$ , whichever is greater, $\geq 12.0$ in.
	Compacted granular fill under rigid pavement	9.0 in.
Thermoplastic Pipe	—	$ID/8 \geq 12.0$ in.
Deep Corrugated Structural Plate Structures	—	See Article 12.8.9.4

If soil cover is not provided, the top of precast or cast-in-place reinforced concrete box structures shall be designed for direct application of vehicular loads.

Additional cover requirements during construction shall be taken as specified in Article 30.5.5 of the *AASHTO LRFD Bridge Construction Specifications*.

### 12.6.7—Minimum Spacing between Multiple Lines of Pipe

The spacing between multiple lines of pipe shall be sufficient to permit the proper placement and compaction of backfill below the haunch and between the structures.

Contract documents should require that backfilling be coordinated to minimize unbalanced loading between multiple, closely spaced structures. Backfill should be kept level over the series of structures when possible. The effects of significant roadway grades across a series of structures shall be investigated for the stability of flexible structures subjected to unbalanced loading.

### C12.6.7

As a guide, the minimum spacing between pipes should not be less than that shown in Table C12.6.7-1.

**Table C12.6.7-1—Minimum Pipe Spacing**

Type of Structure	Minimum Distance Between Pipes (ft)
Round Pipes Diameter, $D$ (ft)	
	<2.0
	2.0–6.0
Pipe Arches Span, $S$ (ft)	>6.0
	<3.0
	3.0–9.0
Arches Span, $S$ (ft)	9.0–16.0
	<3.0
	3.0–9.0
All Spans	3.0
	2.0

The minimum spacing can be reduced if a flowable backfill material, as specified in Article 12.4.1.3, is placed between the structures.

### 12.6.8—End Treatment

#### 12.6.8.1—General

Protection of end slopes shall be given special consideration where backwater conditions occur or where erosion or uplift could be expected. Traffic safety treatments, such as a structurally adequate grating that conforms to the embankment slope, extension of the culvert length beyond the point of hazard, or provision of guide rail, should be considered.

#### 12.6.8.2—Flexible Culverts Constructed on Skew

The end treatment of flexible culverts skewed to the roadway alignment and extending through embankment fill shall be warped to ensure symmetrical loading along either side of the pipe or the headwall shall be designed to support the full thrust force of the cut end.

#### C12.6.8.1

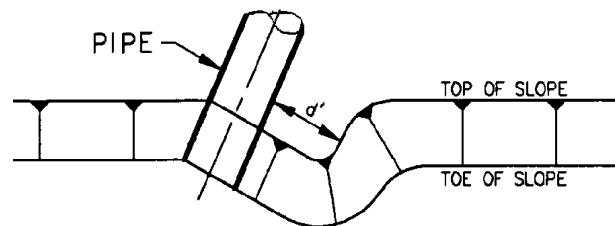

Culvert ends may represent a major traffic hazard.

When backwater conditions occur, pressure flow at the outlet end of culverts can result in uplift of pipe sections having inadequate cover and scour of erosive soils due to high water flow velocities. Measures to control these problems include anchoring the pipe end in a concrete headwall or burying it in riprap having sufficient mass to resist uplift forces as well as lining outlet areas with riprap or concrete to prevent scour.

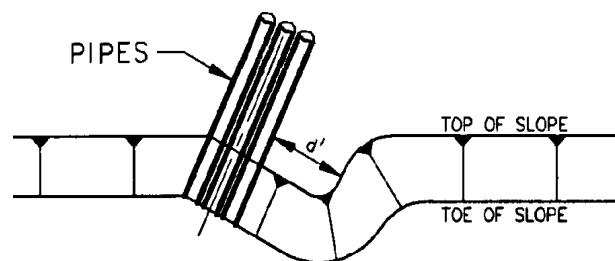

#### C12.6.8.2

For flexible structures, additional reinforcement of the end is recommended to secure the metal edges at inlet and outlet against hydraulic forces. Reinforcement methods include reinforced concrete or structural steel collars, tension tiebacks or anchors in soil, partial headwalls, and cut-off walls below invert elevation.

As a guide in Figure C12.6.8.2-1, limits are suggested for skews to embankments unless the embankment is warped. It also shows examples of warping an embankment cross-section to achieve a square-ended pipe for single and multiple flexible pipe installations where the minimum width of the warped embankment,  $d'$ , is taken as 1.50 times the sum of the rise of the culvert and the cover or three times the span of the culvert, whichever is less.

PROPER BALANCE FOR  
SINGLE STRUCTURE

PROPER BALANCE FOR  
MULTIPLE STRUCTURE

**Figure C12.6.8.2-1—End Treatment of Skewed Flexible Culvert**

### 12.6.9—Corrosive and Abrasive Conditions

The degradation of structural resistance due to corrosion and abrasion shall be considered.

If the design of a metal or thermoplastic culvert is controlled by flexibility factors during installation, the requirements for corrosion and/or abrasion protection may be reduced or eliminated, provided that it is demonstrated that the degraded culvert will provide adequate resistance to loads throughout the service life of the structure.

### C12.6.9

Several long-term tests of the field performance of buried structures have resulted in development of empirical guidelines for estimating the effects of corrosion and abrasion. A representative listing includes Bellair and Ewing (1984), Koepf and Ryan (1986), Hurd (1984), Meacham et al. (1982), Potter (1988), *NCHRP Synthesis No. 50* (1978), and Funahashi and Bushman (1991).

For highly abrasive conditions, a special design may be required. Protective coatings may be shop- or field-applied in accordance with AASHTO M 190, M 224, M 243, and M 245 ([ASTM A762](#)).

## 12.7—METAL PIPE, PIPE ARCH, AND ARCH STRUCTURES

### 12.7.1—General

The provisions herein shall apply to the design of buried corrugated and spiral rib metal pipe and structural plate pipe structures.

Corrugated metal pipe and pipe-arches may be of riveted, welded, or lockseam fabrication with annular or helical corrugations. Structural plate pipe, pipe-arches, and arches shall be bolted with annular corrugations only.

The rise-to-span ratio of structural plate arches shall not be less than 0.3.

The provisions of Article 12.8 shall apply to structures with a radius exceeding 13.0 ft.

### C12.7.1

These structures become part of a composite system comprised of the metal pipe section and the soil envelope, both of which contribute to the structural behavior of the system.

For information regarding the manufacture of structures and structural components referred to herein, AASHTO M 196 ([ASTM B745](#)) for aluminum, M 36 ([ASTM A760](#)) for steel corrugated metal pipe and pipe-arches, and M 167/M/M 167 ([ASTM A761/A761M](#)) for steel and M 219 ([ASTM B746](#)) for aluminum structural plate pipe may be consulted.

### 12.7.2—Safety against Structural Failure

Corrugated and spiral rib metal pipe and pipe arches and structural plate pipe shall be investigated at the strength limit state for:

- Wall area of pipe,
- Buckling strength, and
- Seam resistance for structures with longitudinal seams.

#### 12.7.2.1—Section Properties

Dimensions and properties of pipe cross-sections; minimum seam strength; mechanical and chemical requirements for aluminum corrugated and steel corrugated pipe and pipe-arch sections; and aluminum and steel corrugated structural plate pipe, pipe-arch, and arch sections, may be taken as given in Appendix A12.

#### 12.7.2.2—Thrust

The factored thrust,  $T_L$ , per unit length of wall shall be taken as:

$$T_L = P_L \left( \frac{S}{24} \right) \quad (12.7.2.2-1)$$

where:

$T_L$  = factored thrust per unit length (kip/ft)

$S$  = pipe span (in.)

$P_L$  = factored crown pressure (ksf)

### 12.7.2.3—Wall Resistance

The factored axial resistance,  $R_n$ , per unit length of wall, without consideration of buckling, shall be taken as:

$$R_n = \phi F_y A \quad (12.7.2.3-1)$$

where:

$A$  = wall area (in.<sup>2</sup>/ft)

$F_y$  = yield strength of metal (ksi)

$\phi$  = resistance factor as specified in Article 12.5.5

### 12.7.2.4—Resistance to Buckling

### C12.7.2.4

The wall area, calculated using Eq. 12.7.2.3-1, shall be investigated for buckling. If  $f_{cr} < F_y$ ,  $A$  shall be recalculated using  $f_{cr}$  in lieu of  $F_y$ .

The use of 0.22 for the soil stiffness is thought to be conservative for the types of backfill material allowed for pipe and arch structures. This lower bound on soil stiffness has a long history of use in previous editions of the Standard Specifications.

$$\text{If } S < \left(\frac{r}{k}\right) \sqrt{\frac{24E_m}{F_u}}, \text{ then } f_{cr} = F_u - \frac{\left(\frac{F_u k S}{r}\right)^2}{48E_m} \quad (12.7.2.4-1)$$

$$\text{If } S > \left(\frac{r}{k}\right) \sqrt{\frac{24E_m}{F_u}}, \text{ then } f_{cr} = \frac{12E_m}{\left(\frac{k S}{r}\right)^2} \quad (12.7.2.4-2)$$

where:

$S$  = diameter of pipe or span of plate structure (in.)

$E_m$  = modulus of elasticity of metal (ksi)

$F_u$  = tensile strength of metal (ksi)

$f_{cr}$  = critical buckling stress (ksi)

$r$  = radius of gyration of corrugation (in.)

$k$  = soil stiffness factor taken as 0.22

### 12.7.2.5—Seam Resistance

For pipe fabricated with longitudinal seams, the nominal resistance of the seam shall be sufficient to develop the factored thrust in the pipe wall,  $T_L$ .

### 12.7.2.6—Handling and Installation Requirements

Handling flexibility shall be indicated by a flexibility factor determined as:

$$FF = \frac{S^2}{E_m I} \quad (12.7.2.6-1)$$

Values of the flexibility factors for handling and installation shall not exceed the values for steel and aluminum pipe and plate pipe structures as specified in Article 12.5.6.

### 12.7.3—Smooth Lined Pipe

Corrugated metal pipe composed of a smooth liner and corrugated shell attached integrally at helical seams, spaced not more than 30.0 in. apart, may be designed on the same basis as a standard corrugated metal pipe having the same corrugations as the shell and a weight per ft not less than the sum of the weights per ft of liner and helically corrugated shell.

The pitch of corrugations shall not exceed 3.0 in., and the thickness of the shell shall not be less than 60 percent of the total thickness of the equivalent standard pipe.

### 12.7.4—Stiffening Elements for Structural Plate Structures

The stiffness and flexural resistance of structural plate structures may be increased by adding circumferential stiffening elements to the crown. Stiffening elements shall be symmetrical and shall span from a point below the quarter-point on one side of the structure, across the crown, and to the corresponding point on the opposite side of the structure.

### C12.7.2.6

Transverse stiffeners may be used to assist corrugated structural plate structures to meet flexibility factor requirements.

### 12.7.5—Construction and Installation

The contract documents shall require that construction and installation conform to Section 26, *AASHTO LRFD Bridge Construction Specifications*.

## 12.8—LONG-SPAN STRUCTURAL PLATE STRUCTURES

### 12.8.1—General

The provisions herein and in Article 12.7 shall apply to the structural design of buried long-span structural plate corrugated metal structures.

The following shapes, illustrated in Figure 12.8.1-1, shall be considered long-span structural plate structures:

### C12.7.4

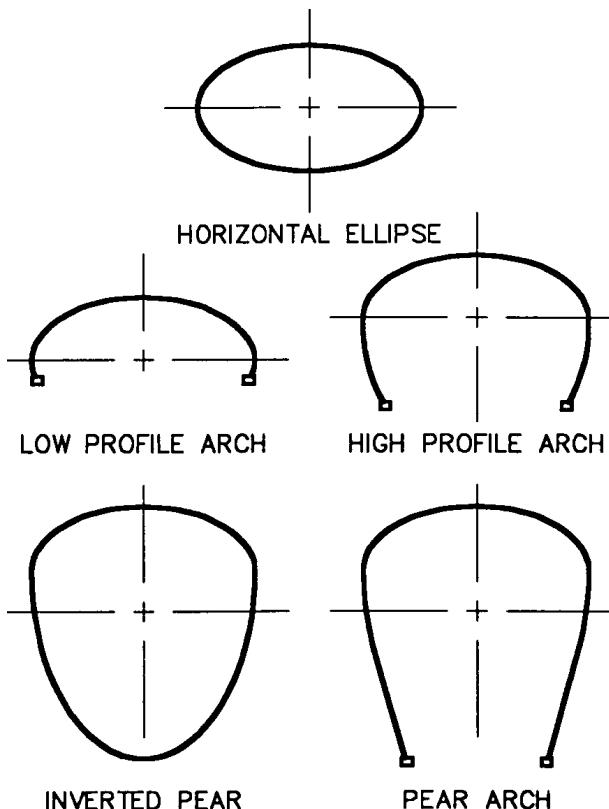

Acceptable stiffening elements are:

- Continuous longitudinal structural stiffeners connected to the corrugated plates at each side of the top arc: metal or reinforced concrete, either singly or in combination; and
- Reinforcing ribs formed from structural shapes, curved to conform to the curvature of the plates, fastened to the structure to ensure integral action with the corrugated plates, and spaced at such intervals as necessary.

### C12.8.1

These structures become part of a composite system comprised of the metal structure section and the soil envelope, both of which contribute to the behavior of the system.

- Structural plate pipe and arch shape structures that require the use of special features specified in Article 12.8.3.5, and
- Special shapes of any size having a radius of curvature greater than 13.0 ft in the crown or side plates. Metal box culverts are not considered long-span structures and are covered in Article 12.9.

**Figure 12.8.1-1—Long-Span Shapes**

### 12.8.2—Service Limit State

No service limit state criteria need be required.

### C12.8.2

Soil design and placement requirements for long-span structures are intended to limit structure deflections. The contract documents should require that construction procedures be monitored to ensure that severe deformations do not occur during backfill placement and compaction.

### 12.8.3—Safety against Structural Failure

With the exception of the requirements for buckling and flexibility, the provisions of Article 12.7 shall apply, except as described herein.

Dimensions and properties of structure cross-sections, minimum seam strength, mechanical and chemical requirements, and bolt properties for long-span structural plate sections shall be taken as specified in Appendix A12 or as described herein.

### C12.8.3

Most long-span culverts are designed for a larger load factor; however, the limit states of flexure and buckling are ignored for those structures. Considering these limit states reduces the uncertainty in the final design and permits use of a lower load factor. This is the same approach used for metal box culverts.

### 12.8.3.1—Section Properties

#### 12.8.3.1.1—Cross-Section

#### C12.8.3.1.1

The provisions of Article 12.7 shall apply, except as specified.

Structures not described herein shall be regarded as special designs.

Table A12-3 shall apply. Minimum requirements for section properties shall be taken as specified in Table 12.8.3.1.1-1. Covers that are less than that shown in Table 12.8.3.1-1 and that correspond to the minimum plate thickness for a given radius may be used if ribs are used to stiffen the plate. If ribs are used, the plate thickness may not be reduced below the minimum shown for that radius, and the moment of inertia of the rib and plate section shall not be less than that of the thicker unstiffened plate corresponding to the fill height. Use of soil cover less than the minimum values shown for a given radius shall require a special design.

Design not covered in Table 12.8.3.1.1-1 should not be permitted unless substantiated by documentation acceptable to the Owner.

Sharp radii generate high soil pressures. Avoid high ratios when significant heights of fill are involved.

**Table 12.8.3.1.1-1—Minimum Requirements for Long-Span Structures with Acceptable Special Features**

Top Radius (ft)	Top Arc Minimum Thickness (in.)				
	≤15.0	15.0–17.0	17.0–20.0	20.0–23.0	23.0–25.0
6" × 2" Corrugated Steel Plate—Top Arc Minimum Thickness (in.)	0.111	0.140	0.170	0.218	0.249
Geometric Limits					
The following geometric limits shall apply:					
<ul style="list-style-type: none"> <li>• Maximum plate radius—25.0 ft</li> <li>• Maximum central angle of top arc—80.0°</li> <li>• Minimum ratio, top arc radius to side arc radius—2</li> <li>• Maximum ratio, top arc radius to side arc radius—5</li> </ul>					
Minimum Cover (ft)					
Top Radius (ft)	≤ 15.0	15.0–17.0	17.0–20.0	20.0–23.0	23.0–25.0
Steel thickness without ribs (in.)					
0.111	2.5	—	—	—	—
0.140	2.5	3.0	—	—	—
0.170	2.5	3.0	3.0	—	—
0.188	2.5	3.0	3.0	—	—
0.218	2.0	2.5	2.5	3.0	—
0.249	2.0	2.0	2.5	3.0	4.0
0.280	2.0	2.0	2.5	3.0	4.0

#### 12.8.3.1.2—Shape Control

The requirements of Articles 12.7.2.4 and 12.7.2.6 shall not apply for the design of long-span structural plate structures.

#### 12.8.3.1.3—Mechanical and Chemical Requirements

Tables A12-3, A12-8, and A12-10 shall apply.

#### 12.8.3.2—Thrust

The factored thrust in the wall shall be determined by Eq. 12.7.2.2-1, except the value of  $S$  in the Equation shall be replaced by twice the value of the top arc radius,  $R_T$ .

#### 12.8.3.3—Wall Area

The provisions of Article 12.7.2.3 shall apply.

#### 12.8.3.4—Seam Strength

The provisions of Article 12.7.2.5 shall apply.

### 12.8.3.5—Acceptable Special Features

#### 12.8.3.5.1—Continuous Longitudinal Stiffeners

Continuous longitudinal stiffeners shall be connected to the corrugated plates at each side of the top arc. Stiffeners may be metal or reinforced concrete either singly or in combination.

#### 12.8.3.5.2—Reinforcing Ribs

Reinforcing ribs formed from structural shapes may be used to stiffen plate structures. Where used, they should be:

- Curved to conform to the curvature of the plates,
- Fastened to the structure as required to ensure integral action with the corrugated plates, and
- Spaced at such intervals as necessary to increase the moment of inertia of the section to that required for design.

### 12.8.4—Safety against Structural Failure— Foundation Design

#### 12.8.4.1—Settlement Limits

#### C12.8.4.1

A geotechnical survey of the site shall be made to determine that site conditions will satisfy the requirement that both the structure and the critical backfill zone on each side of the structure be properly supported. Design shall satisfy the requirements of Article 12.6.2.2, with the following factors to be considered when establishing settlement criteria:

- Once the structure has been backfilled over the crown, settlements of the supporting backfill relative to the structure must be limited to control dragdown forces. If the sidefill will settle more than the structure, a detailed analysis may be required.
- Settlements along the longitudinal centerline of arch structures must be limited to maintain slope and preclude footing cracks in arches.

Calculated differential settlements across the structure taken from springline-to-springline,  $\Delta$ , shall satisfy:

$$\Delta \leq \frac{0.01S^2}{R} \quad (12.8.4.1-1)$$

Once the top arc of the structure has been backfilled, dragdown forces may occur if the structure backfill settles into the foundation more than the structure. This results in the structure carrying more soil load than the overburden directly above it. If undertaken prior to erecting the structure, site improvements such as surcharging, foundation compacting, etc., often adequately correct these conditions.

Where the structure will settle uniformly with the adjacent soils, long-spans with full invert can be built on a camber to achieve a proper final grade.

For design, differential settlement between the footings taken across the structure is limited to avoid excessive eccentricity. The limit on any settlement-induced rotation of the structure maintains the top arc centerline within one percent of span, as shown in Figure C12.8.4.1-1.

where:

$S$  = span of structure between springlines of long-span structural plate structures (ft)

$R$  = rise of structure (ft)

More restrictive settlement limits may be required where needed to protect pavements or to limit longitudinal differential deflections.

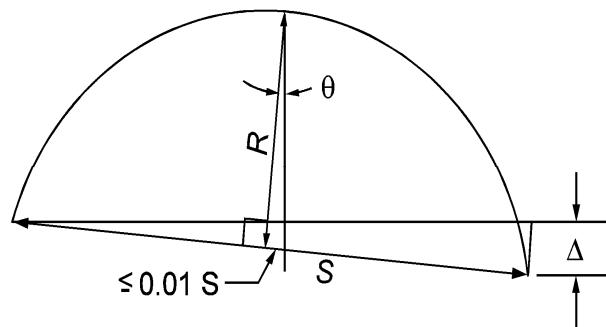

Figure C12.8.4.1-1—Differential Settlement

The rotation of the structure,  $\theta$ , may be determined as:

$$\theta = \tan^{-1} \left( \frac{\Delta}{S} \right) \quad (\text{C12.8.4.1-1})$$

#### 12.8.4.2—Footing Reactions in Arch Structures

Footing reactions may be taken as:

$$R_V = (V_{DL} + V_{LL}) \cos \Delta \quad (12.8.4.2-1)$$

$$R_H = (V_{DL} + V_{LL}) \sin \Delta \quad (12.8.4.2-2)$$

in which:

$$V_{DL} = [H_2(S) - A_T] \gamma_s / 2$$

$$V_{LL} = n(A_L) / (8 + 2 H_1)$$

$n$  = integer  $(2H_1/L_w + 2) \leq$  number of adjoining traffic lanes

where:

$R_V$  = vertical footing reaction component (kip/ft)

$R_H$  = horizontal footing reaction component (kip/ft)

$\Delta$  = return angle of the structure (degrees)

$A_L$  = axle load (kip), taken as 50 percent of all axle loads that can be placed on the structure at one time, i.e.:

#### C12.8.4.2

Footing reactions are calculated by simple statics to support the vertical loads. Soil load footing reactions ( $V_{DL}$ ) are taken as the weight of the fill and pavement above the springline of the structure. Where footings extend out beyond the springline and the foundation has not previously carried the design overburden, this additional soil load ( $E_v$ ) may need to be added to  $V_{DL}$  in an embankment installation.

Live loads that provide relatively limited pressure zones acting on the crown of the structure may be distributed to the footings as indicated in Figure C12.8.4.2-1.

- 32.0 kip for the design truck axle
- 50.0 kip for the design tandem axle pair
- 160.0 kip for E80 railroad loading

$A_T$  = area of the top portion of the structure above the springline ( $\text{ft}^2$ )

$H_1$  = height of cover above the footing to traffic surface (ft)

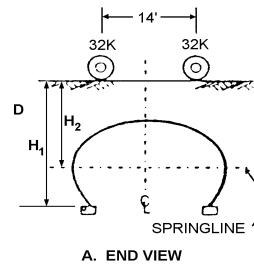

$H_2$  = height of cover from the springline of the structure to traffic surface (ft)

$L_w$  = lane width (ft)

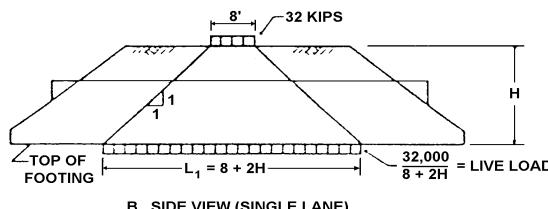

$\gamma_s$  = unit weight of soil (kcf)

$S$  = span (ft)

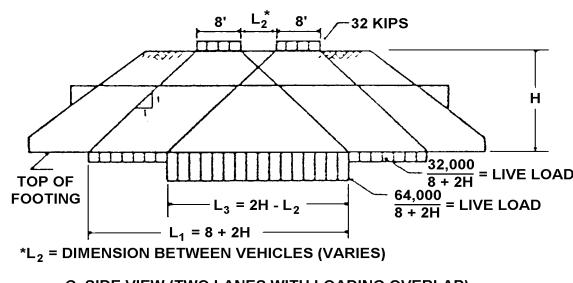

The distribution of live load through the fill shall be based on any accepted methods of analysis.

A. END VIEW

B. SIDE VIEW (SINGLE LANE)

C. SIDE VIEW (TWO LANES WITH LOADING OVERLAP)

Figure C12.8.4.2-1—Live-Load Footing Reaction Due to Axles of the Design Truck, per Footing

### 12.8.4.3—Footing Design

Reinforced concrete footings shall be designed in accordance with Article 10.6 and shall be proportioned to satisfy settlement requirements of Article 12.8.4.1.

### 12.8.5—Safety against Structural Failure—Soil Envelope Design

#### 12.8.5.1—General

Structural backfill material in the envelope around the structure shall satisfy the requirements of Article 12.4.1.3 for long-span structures. The width of the envelope on each side of the structure shall be proportioned to limit shape change during construction activities outside the envelope and to control deflections at the service limit state.

#### 12.8.5.2—Construction Requirements

The structural backfill envelope shall either extend to the trench wall and be compacted against it or extend a distance adequate to protect the shape of the structure from construction loads. The remaining trench width may be filled with suitable backfill material compacted

#### C12.8.5.1

Structure erection, backfill, and construction shall meet all the requirements of Section 26, *AASHTO LRFD Bridge Construction Specifications*. The performance of the structure depends upon the in-situ embankment or other fill materials beyond the structural backfill. Design must consider the performance of all materials within the zone affected by the structure.

#### C12.8.5.2

The purpose of this provision is to control shape change from construction activities outside the envelope in trench conditions.

to satisfy the requirements of Article 12.8.5.3. In embankment conditions, the minimum structural backfill width shall be taken as 6.0 ft. Where dissimilar materials not meeting geotechnical filter criteria are used adjacent to each other, a suitable geotextile shall be provided to avoid migration.

### 12.8.5.3—Service Requirements

The width of the envelope on each side of the structure shall be adequate to limit horizontal compression strain to one percent of the structure's span on each side of the structure.

Determination of the horizontal compressive strain shall be based on an evaluation of the width and quality of the structural backfill material selected as well as the in-situ embankment or other fill materials within the zone on each side of the structure taken to extend to a distance equal to the rise of the structure, plus its cover height as indicated in Figure 12.8.5.3-1.

Forces acting radially off the small radius corner arc of the structure at a distance,  $d_1$ , from the structure may be taken as:

$$P_1 = \frac{T}{R_c + d_1} \quad (12.8.5.3-1)$$

where:

$P_1$  = horizontal pressure from the structure at a distance,  $d_1$  (ksf)

$d_1$  = distance from the structure (ft)

$T$  = total dead load and live load thrust in the structure (Article 12.8.3.2) (kip/ft)

$R_c$  = corner radius of the structure (ft)

The required envelope width adjacent the pipe,  $d$ , may be taken as:

$$d = \frac{T}{P_{Brg}} - R_c \quad (12.8.5.3-2)$$

where:

$d$  = required envelope width adjacent to the structure (ft)

$P_{Brg}$  = allowable bearing pressure to limit compressive strain in the trench wall or embankment (ksf)

### C12.8.5.3

The purpose of this provision is to limit deflections under service loads. The limit on soil compression limits the theoretical design increase in span to two percent. This is a design limit, not a performance limit. Any span increase that occurs is principally due to the consolidation of the side support materials as the structure is loaded during backfilling. These are construction movements that attenuate when full cover is reached.

Eqs. 12.8.5.3-1 and 12.8.5.3-2 conservatively assume that the pressure from the structure acts radially outward from the corner arc without further dissipation. Figure C12.8.5.3-1 provides the geometric basis of these Equations.

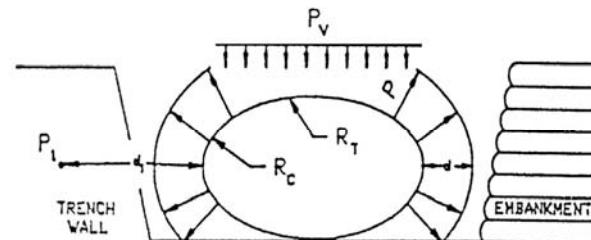

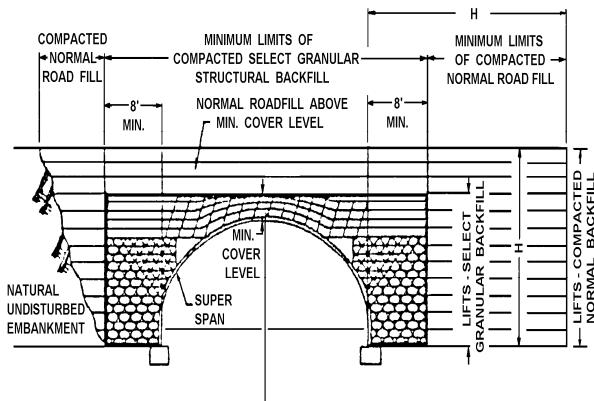

Figure C12.8.5.3-1—Radial Pressure Diagram

The structural backfill envelope shall be taken to continue above the crown to the lesser of:

- The minimum cover level specified for that structure,
- The bottom of the pavement or granular base course where a base course is present below the pavement, or
- The bottom of any relief slab or similar construction where one is present.

**Figure 12.8.5.3-1—Typical Structural Backfill Envelope and Zone of Structure Influence**

## 12.8.6—Safety against Structural Failure—End Treatment Design

### 12.8.6.1—General

End treatment selection and design shall be considered as an integral part of the structural design.

### 12.8.6.2—Standard Shell End Types

The standard end types for the corrugated plate shell shall be taken to be those shown in Figure 12.8.6.2-1.

### C12.8.6.1

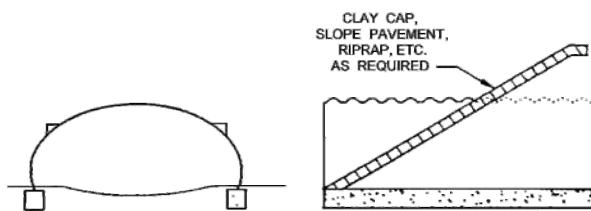

Proper end treatment design ensures proper support of the ends of the structure while providing protection from scour, hydraulic uplift, and loss of backfill due to erosion forces.

### C12.8.6.2

Standard end types refer to the way the structural plate structure's ends are cut to match the fill slope, stream banks, etc. While the type of end selected may have aesthetic or hydraulic considerations, the structural design must ensure adequate structural strength and protection from erosion. Hydraulic considerations may require wingwalls, etc.

Step bevel, full bevel, and skewed ends all involve cutting the plates within a ring. Each has its own structural considerations.

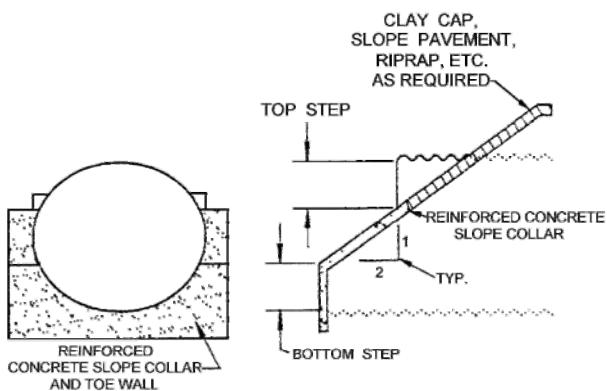

The square end is the simplest arrangement. No plates are cut and the barrel retains its integrity.

END VIEW

ELEVATION VIEW

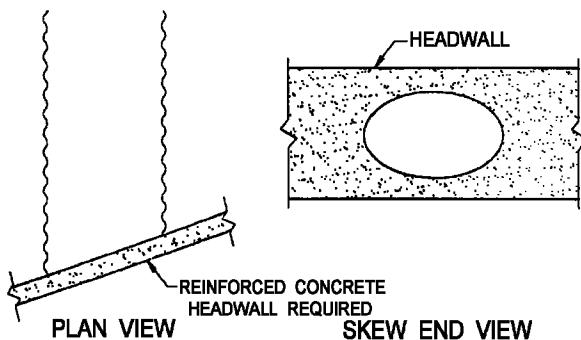

## (A) SQUARE END

END VIEW

ELEVATION VIEW

## (B) STEP BEVEL

(C) SKEW CUT END  
(REQUIRES FULL HEADWALL)**Figure 12.8.6.2-1—Standard Structure End Types**

The following considerations shall apply to step bevels:

- The rise of the top step shall be equal to or greater than the rise of the top arc, i.e., plates in the top arc are left uncut.

Step bevels cut the corner (and side on pear and high profile arch shapes) plates on a diagonal (bevel) to match the fill slope.

Step bevels are widely used. The plates in the large radius top arc are left uncut to support the sides of the structure near each end.

- For structures with inverts, the bottom step shall satisfy the requirements for a top step.
- For arches, the bottom step shall be a minimum of 6.0 in. high.
- The slope of the cut plates generally should be no flatter than 3:1.
- The upper edge of the cut plates shall be bolted to and supported by a structural concrete slope collar, slope pavement, or similar device.

Full bevel ends shall be used in special design only. Structures with full inverts shall have a bottom step conforming to the requirements for step bevel ends.

The bevel cut edge of all plates shall be supported by a suitable, rigid concrete slope collar.

Skew cut ends shall be fully connected to and supported by a headwall of reinforced concrete or other rigid construction. The headwall shall extend an adequate distance above the crown of the structure to be capable of reacting the ring compression thrust forces from the cut plates. In addition to normal active earth and live load pressures, the headwall shall be designed to react a component of the radial pressure exerted by the structure as specified in Article 12.8.5.

### 12.8.6.3—Balanced Support

Designs and details shall provide soil support that is relatively balanced from side-to-side, perpendicularly across the structure. In lieu of a special design, slopes running perpendicularly across the structure shall not exceed ten percent for cover heights of 10.0 ft or less and 15 percent for higher covers.

When a structure is skewed to an embankment, the fill shall be detailed to be warped to maintain balanced support and to provide an adequate width of backfill and embankment soil to support the ends.

Invert plates must be left uncut to avoid leaving the invert as triangular shaped elements, when viewed in plan, running upstream and downstream.

Diagonally cut corner and side plates become a retaining wall, supporting the fill slope beside them. They must be provided with suitable, rigid support at the top that acts as a top wale beam and be limited in length. These plates have limited longitudinal strength and inadequate bending strength or fixity to act as a cantilevered retaining wall.

When a full bevel cuts the top plates, additional support is necessary to backfill the structure. Typically, the top step is left in place and field cut only after a suitable rigid concrete slope collar has been poured and adequately cured.

Ring compressive thrust forces act circumferentially around the structure following the corrugations. At the skew cut ends of the plate, these forces act tangentially to the plate and must be resisted by a headwall. Additionally, because a skew cut structure is not perpendicular to the headwall, a portion of the radial pressure from the structure acts normal to the back of the headwall.

### C12.8.6.3

Flexible structures have relatively low bending strength. If the earth support is not balanced, the structure in effect becomes a retaining wall. An excessive imbalance causes shape distortion and ultimately failure.

When a structure is skewed to an embankment, two diagonally opposite areas at the ends of the structure are not adequately supported. This must be corrected by extending the embankment an adequate distance out beside the structure.

In lieu of a special design, details provided in Article C12.6.8.2 may be considered.

A properly warped embankment is characterized by equal elevation topographical lines crossing the structure perpendicularly and extending beyond it a suitable distance so that the volume of earth included in the warp provides a gravity retaining wall capable of supporting the radial pressures from the structure with adequate safety.

### 12.8.6.4—Hydraulic Protection

#### 12.8.6.4.1—General

In hydraulic applications, provisions shall be made to protect the structure, taken to include the shell, footings, structural backfill envelope, and other fill materials within the zone influenced by the structure.

***12.8.6.4.2—Backfill Protection***

Design or selection of backfill gradation shall include consideration of loss of backfill integrity due to piping. If materials prone to piping are used, the structure and ends of the backfill envelope shall be adequately sealed to control soil migration and/or infiltration.

***12.8.6.4.3—Cut-Off (Toe) Walls***

All hydraulic structures with full invert shall be designed and detailed with upstream and downstream cut-off walls. Invert plates shall be bolted to cut-off walls at a maximum 20.0-in. center-to-center spacing using 0.75-in. bolts.

The cut-off wall shall extend to an adequate depth to limit hydraulic percolation to control uplift forces as specified in Article 12.8.6.4.4 and scour as specified in Article 12.8.6.4.5.

***12.8.6.4.4—Hydraulic Uplift***

Hydraulic uplift shall be considered for hydraulic structures with full invert where the design flow level in the pipe can drop quickly. The design shall provide means to limit the resulting hydraulic gradients, with the water level higher in the backfill than in the pipe, so that the invert will not buckle and the structure will not float. Buckling may be evaluated as specified in Article 12.7.2.4, with the span of the structure taken as twice the invert radius.

***12.8.6.4.5—Scour***

Scour design shall satisfy the requirements of Article 12.6.5. Where erodible soils are encountered, conventional means of scour protection may be employed to satisfy these requirements.

Deep foundations such as piles or caissons should not be used unless a special design is provided to consider differential settlement and the inability of intermittent supports to retain the structural backfill if scour proceeds below the pile cap.

***12.8.7—Concrete Relieving Slabs***

Concrete relieving slabs may be used to reduce moments in long-span structures.

The length of the concrete relieving slab shall be at least 2.0 ft greater than the span of the structure. The relieving slab shall extend across the width subject to vehicular loading, and its depth shall be determined as specified in Article 12.9.4.6.

***C12.8.6.4.2***

Backfill piping and migration is always a major consideration in selecting its specific gradation. The ends of the backfill envelope may be sealed using one or a combination of a compacted clay cap, concrete slope pavements, grouted riprap, headwalls to the design storm elevation, and similar details.

***C12.8.6.4.4***

Structural plate structures are not watertight and allow for both infiltration and exfiltration through the structure's seams, bolt holes, and other discontinuities. Where uplift can be a concern, designs typically employ adequate cut-off walls and other means to seal off water flow into the structural backfill.

***C12.8.6.4.5***

Structures with full invert eliminate footing scour considerations when adequate cut-off walls are used. For arches, reinforced concrete invert pavements, riprap, grouted riprap, etc., can be employed to provide scour protection.

***C12.8.7***

Application of a typical concrete relieving slab is shown in Figure 12.9.4.6-1.

## 12.8.8—Construction and Installation

The construction documents shall require that construction and installation conform to Section 26 of the *AASHTO LRFD Bridge Construction Specifications*.

## 12.8.9—Deep Corrugated Structural Plate Structures

### 12.8.9.1—General

The provisions of this Section shall apply to the structural design of buried, deep corrugated structural plate. These structures are designed as long-span culverts but must also meet provisions for flexure and general buckling. These structures may be manufactured in multiple shapes. Flexibility criteria and special features are not applicable to deep corrugated structures. The rise to span limit of 0.3 in Article 12.7.1 does not apply.

### C12.8.9.1

The design of long-span metal structures in these Specifications is currently completed with empirical procedures that limit the shapes and plate thicknesses for the structures and require special features. If the provisions are met, then no design is required for flexure or buckling. NCHRP Report 473 recommended updating design provisions for long-span structures and included provisions to allow structures outside the current limits for long-span structures but included limit states for flexure and general buckling. Article 12.8.9 provides a design procedure for such structures.

### 12.8.9.2—Width of Structural Backfill

#### 12.8.9.2.1—Deep Corrugated Structures with Ratio of Crown Radius to Haunch Radius $\leq 5$

The structural backfill zone around deep corrugated structures with ratio of crown radius to haunch radius  $\leq 5$  shall extend to at least the minimum cover height above the crown. At the sides of the structure, the minimum extent of the structural backfill from the outside of the structure springline shall meet one of the following:

- Structure constructed in a trench in which the natural soil is at least as stiff as the engineered soil: 8.0 ft or
- Structure constructed in an embankment or in a trench in which the natural soil is less stiff than the engineered soil: one-third of the structure span but not less than 10.0 ft or more than 17.0 ft.

but not less than required by culvert-soil interaction analysis.

#### 12.8.9.2.2—Deep Corrugated Structures with Ratio of Crown Radius to Haunch Radius $> 5$

The structural backfill zone around deep corrugated structures with ratio of crown radius to haunch radius  $> 5$  shall extend to at least 3.5 ft beyond the widest part of the structure for spans up to 26.0 ft 3 in. For structures with spans greater than 26.0 ft 3 in., the extent of structural backfill shall meet one of the following:

- Structure constructed in a trench in which the natural soil is at least as stiff as the engineered soil: 7.0 ft or

- Structure constructed in an embankment or in a trench in which the natural soil is poorer than the engineered soil: one-fifth of the structure span but not less than 5.0 ft or more than 17.0 ft.

but not less than required by culvert-soil interaction analysis.

### **12.8.9.3—Safety against Structural Failure**

Deep corrugated structures shall be designed in accordance with the provisions of Articles 12.8.1 to 12.8.8 except for modified or additional provisions as follow in Article 12.8.9.

#### *12.8.9.3.1—Structural Plate Requirements*

Deep corrugated structural plate used to manufacture structures designed under this section shall meet the requirements of AASHTO M 167M/M 167.

Sections may be stiffened. If stiffening is provided by ribs, the ribs shall be bolted to the structural plate corrugation prior to backfilling using a bolt spacing of not more than 16 in.

#### *12.8.9.3.2—Structural Analysis*

Structures designed under the provisions of this Article shall be analyzed by accepted finite element analysis methods that consider both the strength and stiffness properties of the structural plate and the soil. The analysis shall produce thrust and moments for use in design. The analysis must consider all applicable combinations of construction, earth, live, and other applicable load conditions. Springline thrust used in design shall not be less than 1.3 times the thrust computed in accordance with Article 12.7.2.2.

#### **C12.8.9.3.2**

The computer program CANDE was developed by the FHWA specifically for the design of buried culverts and has the necessary soil and culvert material models to complete designs.

### **12.8.9.4—Minimum Depth of Fill**

For structures with deep corrugations, the minimum depth of cover ( $H_D$ ) shall be the smaller of 5.0 ft, or the current AASHTO limits for long-spans based on top radius and plate thickness. For deep corrugated structures with the ratio of crown radius to haunch radius  $> 5$ , minimum cover shall be 1.5 ft for spans  $\leq 25.0$  ft 5.0 in. and 2.0 ft for spans  $> 25.0$  ft 5.0 in.

Minimum cover may be reduced with the use of relieving slabs or other designed load spreading mechanisms.

### **12.8.9.5—Combined Thrust and Moment**

The combined effects of moment and thrust at all stages of construction shall meet the following requirement:

$$\left(\frac{T_f}{R_t}\right)^2 + \frac{M_u}{M_n} \leq 1.00 \quad (12.8.9.5-1)$$

#### **C12.8.9.5**

The equation for combined moment and thrust is taken from the provision for buried structures in the Canadian Highway Bridge Design Code CSA S6 06. The equation is more liberal than the AASHTO equations for combined moment and thrust (axial force) for steel structures in Article 12.8.9.6. However, the

where:

$T_f$  = factored thrust

$R_t$  = factored thrust resistance =  $\phi_h F_y A$

$M_u$  = factored applied moment

$M_n$  = factored moment resistance =  $\phi_h M_p$

$M_p$  = plastic moment capacity of section

provisions in Article 12.8.9.6 are based on strong axis bending of wide flange sections. Wide flange sections in weak axis bending are known to have higher relative capacity under combined moment and thrust than sections under strong axis bending (see Figure C12.8.9.5-1 from White and Clarke, 1997) and deep corrugated profiles are more closely represented by the weak axis bending model.

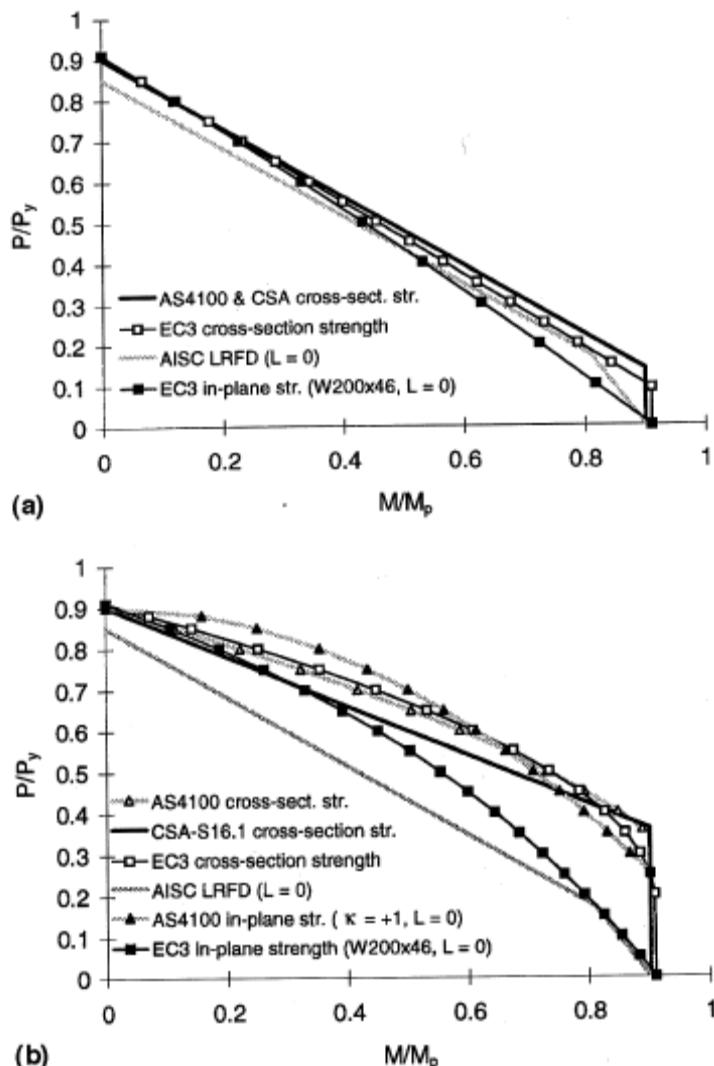

Figure C12.8.9.5-1—Strength Curves for Member of Zero Length:  
(a) Strong-Axis; (b) Weak-Axis from White and Clark (1997)

### 12.8.9.6—Global Buckling

The factored thrust in the culvert wall under the final installed condition shall not exceed the nominal resistance to general buckling capacity of the culvert, computed as:

$$R_b = 1.2 \phi_b C_n (E_p I_p)^{\frac{1}{3}} (\phi_s M_s K_b)^{\frac{2}{3}} R_h \quad (12.8.9.6-1)$$

### C12.8.9.6

The proposed buckling equations are taken from the recommendations of NCHRP Report 473, *Recommended Specifications for Large-Span Culverts*.

where:

$R_b$  = nominal axial force in culvert wall to cause general buckling

$\phi_b$  = resistance factor for general buckling

$C_n$  = scalar calibration factor to account for some nonlinear effects = 0.55

$E_p$  = modulus of elasticity of pipe wall material, (ksi)

$I_p$  = moment of inertia of stiffened culvert wall per unit length, (in.<sup>4</sup>)

$\phi_s$  = resistance factor for soil

$M_s$  = constrained modulus of embedment  
(Table 12.12.3.4-1)

$K_b$  =  $(1 - 2v) / (1 - v^2)$

$v$  = Poisson's ratio of soil

$R_h$  = correction factor for backfill geometry  
=  $11.4 / (11 + S/H)$

$S$  = culvert span

$H$  = depth of fill over top of culvert

### 12.8.9.7—Connections

The factored moment resistance of longitudinal connections shall be at least equal to the factored applied moment but not less than the greater of:

- 75 percent of the factored moment resistance of the member or
- The average of the factored applied moment and the factored moment resistance of the member.

Moment resistance of connections may be obtained from qualified tests or published standards.

## 12.9—STRUCTURAL PLATE BOX STRUCTURES

### 12.9.1—General

The design method specified herein shall be limited to depth of cover from 1.4 to 5.0 ft.

The provisions of this Article shall apply to the design of structural plate box structures, hereinafter called "metal box culverts." The provisions of Articles 12.7 and 12.8 shall not apply to metal box culvert designs, except as noted.

If rib stiffeners are used to increase the flexural resistance and moment capacity of the plate, the transverse stiffeners shall consist of structural steel or

### C12.8.9.7

The *AASHTO LRFD Bridge Construction Specifications* require longitudinal joints to be staggered to avoid a continuous line of bolts on a structure.

### C12.9.1

These Specifications are based on three types of data:

- Finite element soil-structure interaction analyses,
- Field loading tests on instrumented structures, and
- Extensive field experience.

These Specifications conform to the same standards as those structures completed since about 1980.

aluminum sections curved to fit the structural plates. Ribs shall be bolted to the plates to develop the plastic flexural resistance of the composite section. Spacing between ribs shall not exceed 2.0 ft on the crown and 4.5 ft on the haunch. Rib splices shall develop the plastic flexural resistance required at the location of the splice.

Structural plate box culverts are composite-reinforced rib plate structures of approximately rectangular shape. They are intended for shallow covers and low wide waterway openings. The shallow covers and extreme shapes of box culverts require special design procedures.

Metal box culverts differ greatly from conventional metal culvert shapes. Metal box culverts are relatively flat at the top and require a large flexural capacity due to extreme geometry and shallow depths of cover of 5.0 ft or less. Analyses over the range of sizes permitted under these Specifications indicate that flexural requirements govern the choice of section in all cases. The effects of thrust are negligible in comparison with those of flexure. This difference in behavior requires a different approach in design.

For information regarding the manufacture of structures and structural components referred to herein, see AASHTO M 167M/M 167 ([ASTM A761/A761M](#)) for steel and M 219 ([ASTM B746](#)) for aluminum.

## **12.9.2—Loading**

For live loads, the provisions of Article 3.6.1 shall apply.

Unit weights for soil backfill, other than 0.12 kcf, may be considered as specified in Article 12.9.4.2.

## **12.9.3—Service Limit State**

No service limit state criteria need be applied in the design of box culvert structures.

## **C12.9.2**

The earth loads for the design procedure described herein are based upon soil backfill having a standard unit weight,  $\gamma_s$ , of 0.12 kcf.

## **C12.9.3**

Soil design and placement requirements for box culvert structures can limit structure deflections satisfactorily. The contract documents should require that construction procedures be monitored to ensure that severe deformations do not occur during backfill placement and compaction, in which case no deflection limits should be imposed on the completed structure.

## **12.9.4—Safety against Structural Failure**

### **12.9.4.1—General**

The resistance of corrugated box culverts shall be determined at the strength limit state in accordance with Articles 12.5.3, 12.5.4, and 12.5.5 and the requirements specified herein.

Box culvert sections for which these Articles apply are defined in Figure 12.9.4.1-1 and Table 12.9.4.1-1. Table A12-10 shall apply.

### **C12.9.4.1**

Finite element analyses covering the range of metal box culvert shapes described in this Article have shown that flexural requirements govern the design in all cases. Effects of thrust are negligible when combined with flexure.

The structural requirements for metal box culverts are based on the results of finite element analyses and field measurements of in-service box culverts.

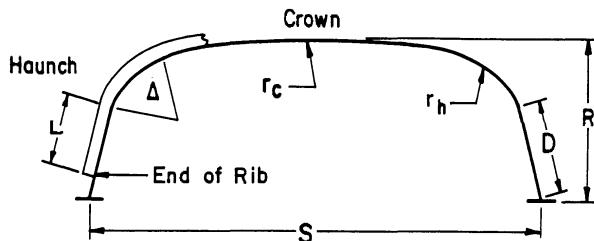

Figure 12.9.4.1-1—Geometry of Box Culverts

Table 12.9.4.1-1—Geometric Requirements for Box Culverts with Spans from 8 ft 9 in. to 25 ft 5 in.

Span, $S$ : 8 ft 9 in. to 25 ft 5 in.
Rise, $R$ : 2 ft 6 in. to 10 ft 6 in.
Radius of crown, $r_c \leq 24$ ft 9 1/2 in.
Radius of haunch, $r_h \geq 2$ ft 6 in.
Haunch radius included angle, $\Delta$ : 50° to 70°
Length of leg, $D$ : measured to the bottom of the plate, may vary from 4 3/4 to 71 in.
Minimum length of rib on leg, $L$ , least of 19.0 in., ( $D - 3.0$ ) in. or to within 3.0 in. of the top of a concrete footing

Table 12.9.4.1-2—Geometric Requirements for Box Culverts with Spans from 25 ft 6 in. to 36 ft 0 in.

Span, $S$ : 25 ft 6 in. to 36 ft 0 in.
Rise, $R$ : 5 ft 7 in. to 14 ft 0 in.
Radius of crown, $r_c \leq 26$ ft 4 in.
Radius of haunch, $r_h \geq 3$ ft 8 in.
Haunch radius included angle, $\Delta$ : 48° to 68°
Length of leg, $D$ : measured to the bottom of the plate, may vary from 4 3/4 to 71 in.
Minimum length of rib on leg, $L$ , least of 28.0 in., ( $D - 3.0$ ) in., or to within 3.0 in. of the top of a concrete footing

The flexural resistance of corrugated plate box structures shall be determined using the specified yield strength of the corrugated plate.

The flexural resistance of plate box structures with ribbed sections shall be determined using specified yield strength values for both rib and corrugated shell. Computed values may be used for design only after confirmation by representative flexural testing. Rib splices shall develop the plastic moment capacity required at the location of the splice.

#### 12.9.4.2—Moments Due to Factored Loads

Unfactored crown and haunch dead and live load moments,  $M_{dt}$  and  $M_{lt}$ , may be taken as:

For spans  $\leq 25$  ft 5 in.:

#### C12.9.4.2

The number of “wheels per notional axle group” determines the value of  $C_2$  in Table 12.9.4.2-1. The following guidelines are consistent with the development of Table 12.9.4.2-1:

$$M_{dl} = \gamma_s \left\{ S^3 [0.0053 - 0.00024(S-12)] + 0.053(H-1.4)S^2 \right\} \quad (12.9.4.2-1)$$

For spans from 25 ft 6 in. through 36 ft 0 in. with a geometry profile that meets  $r_c = 26$  ft,  $r_h = 3$  ft 8 7/8 in. and  $\Delta = 49.16$  degrees:

$$M_{dl} = \lambda_s \left\{ S^3 [0.00194 - 0.0002(S-26)(H-1.1)] \right\} \\ + (H-1.4) \left[ 0.053S^2 + 0.6(S-26)^2 \right] \quad (12.9.4.2-2)$$

$$M_{ll} = C_{ll} K_1 \frac{S}{K_2} \quad (12.9.4.2-3)$$

where:

$M_{dl}$  = sum of the nominal crown and haunch dead load moments (kip-ft/ft)

$M_{ll}$  = sum of the nominal crown and haunch live load moments (kip-ft/ft)

$S$  = box culvert span (ft)

$\gamma_s$  = soil unit weight (kcf)

$H$  = height of cover from the box culvert rise to top of pavement (ft)

$C_{ll}$  = adjusted live load  
=  $C_1 C_2 A_L$  (kip)

$A_L$  = sum of all axle loads in an axle group (kip)

$C_1$  = 1.0 for single axles and  $0.5 + S/50 \leq 1.0$  for tandem axles

$C_2$  = adjustment factor for number of wheels on a design axle as specified in Table 12.9.4.2-1

in which:

$$K_1 = \frac{0.08}{\left(\frac{H}{S}\right)^{0.2}}, \text{ for } 8 \leq S < 20 \quad (12.9.4.2-4)$$

$$K_1 = \frac{0.08 - 0.002(S-20)}{\left(\frac{H}{S}\right)^{0.2}}, \text{ for } 20 \leq S \leq 26 \quad (12.9.4.2-5)$$

$$K_2 = 0.54H^2 - 0.4H + 5.05, \text{ for } 1.4 \leq H < 3.0 \quad (12.9.4.2-6)$$

$$K_2 = 1.90H + 3, \text{ for } 3.0 \leq H \leq 5.0 \quad (12.9.4.2-7)$$

- Use “2” as the number of wheels when the design is based on an axle with two wheels, e.g., two 16.0-kip wheels on one 32.0-kip axle.
- Use “4” as the number of wheels where the design is based on either an axle with four wheels, e.g., two 8.0-kip wheels on each end of a 32.0-kip axle; or two axles with two wheels each, e.g., two 12.5-kip wheels on each of two tandem 25.0-kip axles.
- Use “8” as the number of wheels when the design is based on two axles, each with a pair of wheels at each end of each axle.

For spans from 25 ft 6 in. through 36 ft 0 in. with profiles that do not meet the requirements of Eq. 12.9.4.2-2, finite element modeling that employs soil structure interaction may be performed to obtain the nominal crown and haunch moments.

**Table 12.9.4.2-1—Adjustment Coefficient Values ( $C_2$ ) for Number of Wheels per Axle**

Wheels per Notional Axle Group	Cover Depth (ft)			
	1.4	2.0	3.0	5.0
2	1.18	1.21	1.24	1.02
4	1.00	1.00	1.00	1.00
8	0.63	0.70	0.82	0.93

Unless otherwise specified, the design truck specified in Article 3.6.1.2.2 should be assumed to have four wheels on an axle. The design tandem specified in Article 3.6.1.2.3 should be assumed to be an axle group consisting of two axles with four wheels on each axle.

The factored moments,  $M_{d\ell u}$  and  $M_{\ell\ell u}$  as referred to in Article 12.9.4.3, shall be determined as specified in Table 3.4.1-1, except that the live load factor used to compute  $M_{\ell\ell u}$  shall be 2.0. The factored reactions shall be determined by factoring the reactions specified in Article 12.9.4.5.

#### 12.9.4.3—Plastic Moment Resistance

The plastic moment resistance of the crown,  $M_{pc}$ , and the plastic moment resistance of the haunch,  $M_{ph}$ , shall not be less than the proportioned sum of adjusted dead and live load moments. The values of  $M_{pc}$  and  $M_{ph}$  shall be determined as follows:

$$M_{pc} \geq C_H P_c (M_{d\ell u} + M_{\ell\ell u}) \quad (12.9.4.3-1)$$

$$M_{ph} \geq C_H (1.0 - P_c) (M_{d\ell u} + R_h M_{\ell\ell u}) \quad (12.9.4.3-2)$$

where:

$C_H$  = crown soil cover factor specified in Article 12.9.4.4

$P_c$  = allowable range of the ratio of total moment carried by the crown as specified in Table 12.9.4.3-1

$R_h$  = acceptable values of the haunch moment reduction factor as specified in Table 12.9.4.3-2

$M_{d\ell u}$  = factored dead load moment as specified in Article 12.9.4.2 (kip-ft)

$M_{\ell\ell u}$  = factored live load moment as specified in Article 12.9.4.2 (kip-ft)

#### C12.9.4.3

Some discretion is allowed relative to the total flexural capacity assigned to the crown and haunches of box culverts.

The distribution of moment between the crown and haunch, described in Article C12.9.4.2, is accomplished in the design using the crown moment proportioning factor,  $P_c$ , which represents the proportion of the total moment that can be carried by the crown of the box culvert and that varies with the relative flexural capacities of the crown and haunch components.

The requirements given herein can be used to investigate products for compliance with these Specifications. Using the actual crown flexural capacity,  $M_{pc}$ , provided by the metal box structure under consideration and the loading requirements of the application, Eq. 12.9.4.3-1 can be solved for the factor  $P_c$ , which should fall within the allowable range of Table 12.9.4.3-1. Knowing  $P_c$ , Eq. 12.9.4.3-2 can be solved for  $M_{ph}$ , which should not exceed the actual haunch flexural resistance provided by the structure section. If Eq. 12.9.4.3-1 indicates a higher value of  $P_c$  than permitted by the allowable ranges in Table 12.9.4.3-1, the actual crown is over designed, which is acceptable. However, in this case, only the maximum value of  $P_c$ , allowed by Table 12.9.4.3-1, should be used to calculate the required  $M_{ph}$  from Eq. 12.9.4.3-2.

**Table 12.9.4.3-1—Crown Moment Proportioning Values,  $P_c$ , for Spans  $\leq 25$  ft 5 in.**

Span (ft)	Allowable Range of $P_c$
<10.0	0.55–0.70
10.0–15.0	0.50–0.70
15.0–20.0	0.45–0.70
20.0–25.4	0.45–0.60

**Table 12.9.4.3-2—Crown Moment Positioning Values,  $P_c$ , for Spans from 25 ft 6 in. to 36 ft 0 in.**

Depth of Fill (ft)	Allowable Range of $P_c$
1.4–2.5	0.55–0.65
2.5–4.0	0.45–0.55
4.0–5.0	0.35–0.55

**Table 12.9.4.3-3—Haunch Moment Reduction Values,  $R_H$ , for Spans  $\leq 25$  ft 5 in.**

	Cover Depth (ft)			
	1.4	2.0	3.0	4.0 to 5.0
$R_H$	0.66	0.74	0.87	1.00

For spans from 25 ft 6 in. to 36 ft 0 in.,  $R_H = 1.0$  for all cover depths.

#### 12.9.4.4—Crown Soil Cover Factor, $C_H$

For depths of soil cover greater than or equal to 3.5 ft, the crown soil cover factor,  $C_H$ , shall be taken as 1.0.

For crown cover depth between 1.4 and 3.5 ft, the crown soil cover factor shall be taken as:

$$C_H = 1.15 - \left( \frac{H - 1.4}{14} \right) \quad (12.9.4.4-1)$$

where:

$H$  = depth of cover over crown (ft)

#### 12.9.4.5—Footing Reactions

Reactions at the box culvert footing shall be determined as:

$$V = \gamma_s \left( \frac{HS}{2.0} + \frac{S^2}{40.0} \right) + \frac{A_L}{8 + 2(H + R)} \quad (12.9.4.5-1)$$

#### C12.9.4.4

The results of finite element analyses and field monitoring studies to evaluate the effects of load-induced deformations and in-plane deformed geometries indicate that the design moments should be increased where the cover is less than 3.5 ft.

Eq. 12.9.4.4-1 is discussed in Boulanger et al. (1989).

where:

$V$  = unfactored footing reaction (kip/ft)

$\gamma_s$  = unit weight of backfill (kcf)

$H$  = depth of cover over crown (ft)

$R$  = rise of culvert (ft)

$S$  = span (ft)

$A_L$  = total axle load (kip)

#### 12.9.4.6—Concrete Relieving Slabs

Relieving slabs may be used to reduce flexural moments in box culverts. Relieving slabs shall not be in contact with the crown as shown in Figure 12.9.4.6-1.

The length of the concrete relieving slab shall be at least 2.0 ft greater than the culvert span and sufficient to project 1.0 ft beyond the haunch on each side of the culvert. The relieving slab shall extend across the width subject to vehicular loading.

The depth of reinforced concrete relieving slabs shall be determined as:

$$t = t_b R_{AL} R_c R_f \quad (12.9.4.6-1)$$

where:

$t$  = minimum depth of slab (in.)

$t_b$  = basic slab depth as specified in Table 12.9.4.6-1 (in.)

$R_{AL}$  = axle load correction factor specified in Table 12.9.4.6-2

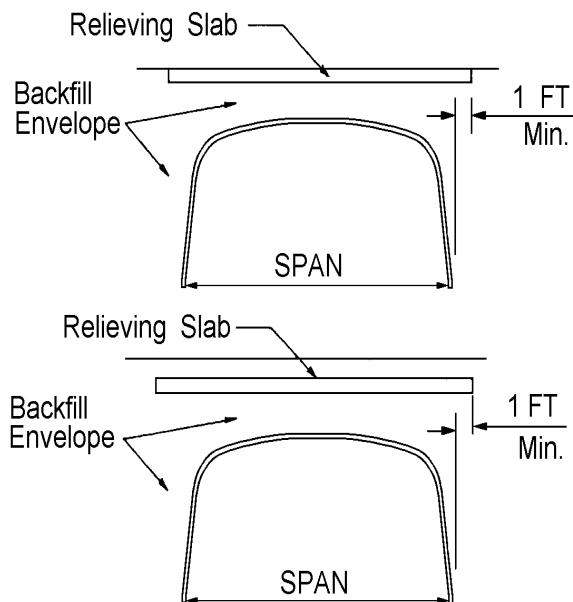

$R_c$  = concrete strength correction factor specified in Table 12.9.4.6-3

$R_f$  = factor taken as 1.2 for box structures having spans less than 26.0 ft

#### C12.9.4.6

The box culvert design procedure described herein does not directly incorporate consideration of concrete relieving slabs on the influence of concrete pavement. Therefore, the procedures described in Duncan et al. (1985) should be used instead. At this time, the beneficial effect of a relieving slab can only be determined by refined soil-structure interaction analyses. The provisions given herein are applicable only for box structures having spans under 26.0 ft. The purpose of avoiding contact between the relieving slab and the culvert is to avoid concentration of the load applied through the slab to the crown of the culvert. As little as 1.0- to 3.0-in. clearance is thought to be sufficient to distribute the load.

Where an Owner requires design for an axle other than the standard 32.0-kip axle, the factor  $R_{AL}$  may be used to adjust the depth of a concrete relieving slab as specified in Eq. 12.9.4.6-1.

**Figure 12.9.4.6-1—Metal Box Culverts with Concrete Relieving Slab**

**Table 12.9.4.6-1—Basic Slab Depth,  $t_b$  (in.) (Duncan et al., 1985)**

Unified Classification of Subgrade Beneath Slab	Relative Compaction—% of Standard AASHTO Maximum Dry Unit Weight		
	100	95	90
	Basic Slab Depth (in.)		
GW, GP, SW, SP, or SM	7.5	8.0	8.5
SM-SC or SC	8.0	8.5	9.0
ML or CL	8.5	9.0	9.5

4.5	1.05
5.0	1.01
5.5	0.97
6.0	0.94

## 12.9.5—Construction and Installation

The contract documents shall require that construction and installation conform to Section 26, “Metal Culverts,” *AASHTO LRFD Bridge Construction Specifications*.

## 12.10—REINFORCED CONCRETE PIPE

### 12.10.1—General

The provisions herein shall apply to the structural design of buried precast reinforced concrete pipes of circular, elliptical, and arch shapes.

The structural design of the types of pipes indicated above may proceed by either of two methods:

- The direct design method at the strength limit state as specified in Article 12.10.4.2, or
- The indirect design method at the service limit state as specified in Article 12.10.4.3.

### 12.10.2 Loading

#### 12.10.2.1 Standard Installations

The contract documents shall specify that the foundation bedding and backfill comply with the provisions of Article 27.5.2 of the *AASHTO LRFD Construction Specifications*.

Minimum compaction requirements and bedding thickness for standard embankment installations and standard trench installations shall be as specified in Tables 12.10.2.1-1 and 12.10.2.1-2, respectively.

### C12.10.1

These structures become part of a composite system comprised of the reinforced concrete buried section and the soil envelope.

Standard dimensions for these units are shown in AASHTO M 170 ([ASTM C76](#)), M 206/M/M 206 ([ASTM C506M](#) and [C506](#)), M 207/M/M 207 ([ASTM C507M](#) and [C507](#)), and M 242/M/M 242 ([ASTM C655M](#) and [C655](#)).

#### C12.10.2.1

The four standard installations replace the historic bedding classes. A comprehensive soil-structure interaction analysis and design program (SPIDA) was developed and used to perform soil-structure interaction analyses for the various soil and installation parameters encompassed in the provisions. The SPIDA studies used to develop the standard installations were conducted for positive projection embankment conditions to provide conservative results for other embankment and trench conditions. These studies also conservatively assume a hard foundation and bedding existing beneath the invert of the pipe, plus void and/or poorly compacted material in the haunch areas, 15 degrees to 40 degrees each side of the invert, resulting in a load concentration such that calculated moments, thrusts, and shears are increased.

**Table 12.10.2.1-1—Standard Embankment Installation Soils and Minimum Compaction Requirements**

Installation Type	Bedding Thickness	Haunch and Outer Bedding	Lower Side
Type 1	For soil foundation, use $B_c/2.0$ ft minimum, not less than 3.0 in. For rock foundation, use $B_c$ ft minimum, not less than 6.0 in.	95% SW	90% SW, 95% ML, or 100% CL
Type 2—Installations are available for horizontal elliptical, vertical elliptical, and arch pipe	For soil foundation, use $B_c/2.0$ ft minimum, not less than 3.0 in. For rock foundation, use $B_c$ ft minimum, not less than 6.0 in.	90% SW or 95% ML	85% SW, 90% ML, or 95% CL
Type 3—Installations are available for horizontal elliptical, vertical elliptical, and arch pipe	For soil foundation, use $B_c/2.0$ ft minimum, not less than 3.0 in. For rock foundation, use $B_c$ ft minimum, not less than 6.0 in.	85% SW, 90% ML, or 95% CL	85% SW, 90% ML, or 95% CL
Type 4	For soil foundation, no bedding required. For rock foundation, use $B_c/2.0$ ft minimum, not less than 6.0 in.	No compaction required, except if CL, use 85% CL	No compaction required, except if CL, use 85% CL

The following interpretations apply to Table 12.10.2.1-1:

- Compaction and soil symbols, i.e., “95 percent SW,” shall be taken to refer to SW soil material with a minimum standard proctor compaction of 95 percent. Equivalent modified proctor values shall be as given in Table 27.5.2.2-3 of the *AASHTO LRFD Bridge Construction Specifications*.
- Soil in the outer bedding, haunch, and lower side zones, except within  $B_c/3$  from the pipe springline, shall be compacted to at least the same compaction as the majority of soil in the overfill zone.
- The minimum width of a subtrench shall be  $1.33B_c$ , or wider if required for adequate space to attain the specified compaction in the haunch and bedding zones.
- For subtrenches with walls of natural soil, any portion of the lower side zone in the subtrench wall shall be at least as firm as an equivalent soil placed to the compaction requirements specified for the lower side zone and as firm as the majority of soil in the overfill zone. Otherwise, it shall be removed and replaced with soil compacted to the specified level.
- A subtrench is defined as a trench in the natural material under an embankment used to retain bedding material with its top below finished grade by more than ten percent of the depth of soil cover on the top of the culvert or pipe. For roadways, the top of a subtrench is at an elevation lower than 1.0 ft below the bottom of the pavement base material.

**Table 12.10.2.1-2—Standard Trench Installation Soils and Minimum Compaction Requirements**

Installation Type	Bedding Thickness	Haunch and Outer Bedding	Lower Side
Type 1	For soil foundation, use $B_c/2.0$ ft minimum, not less than 3.0 in. For rock foundation, use $B_c$ ft minimum, not less than 6.0 in.	95% SW	90% SW, 95% ML, or 100% CL, or natural soils of equal firmness
Type 2—Installations are available for horizontal elliptical, vertical elliptical, and arch pipe	For soil foundation, use $B_c/2.0$ ft minimum, not less than 3.0 in. For rock foundation, use $B_c$ ft minimum, not less than 6.0 in.	90% SW or 95% ML	85% SW, 90% ML, 95% CL, or natural soils of equal firmness
Type 3—Installations are available for horizontal elliptical, vertical elliptical, and arch pipe	For soil foundation, use $B_c/4.0$ ft minimum, not less than 3.0 in. For rock foundation, use $B_c$ ft minimum, not less than 6.0 in.	85% SW, 90% ML or 95% CL	85% SW, 90% ML, 95% CL, or natural soils of equal firmness
Type 4	For soil foundation, no bedding required. For rock foundation, use $B_c$ ft minimum, not less than 6.0 in.	No compaction required, except if CL, use 85% CL	85% SW, 90% ML, 95% CL, or natural soil of equal firmness

The following interpretations apply to Table 12.10.2.1-2:

- Compaction and soil symbols, i.e., “95 percent SW,” shall be taken to refer to SW soil material with minimum standard proctor compaction of 95 percent. Equivalent modified proctor values shall be as given in Table 27.5.2.2-3 of the *AASHTO LRFD Bridge Construction Specifications*.
- The trench top elevation shall be no lower than  $0.1H$  below finish grade; for roadways, its top shall be no lower than an elevation of 1.0 ft below the bottom of the pavement base material.
- Soil in bedding and haunch zones shall be compacted to at least the same compaction as specified for the majority of soil in the backfill zone.
- If required for adequate space to attain the specified compaction in the haunch and bedding zones the trench width shall be wider than that shown in Figures 27.5.2.2-1 and 27.5.2.2-2 of the *AASHTO LRFD Bridge Construction Specifications*.
- For trench walls that are within 10 degrees of vertical, the compaction or firmness of the soil in the trench walls and lower side zone need not be considered.
- For trench walls with greater than 10 degrees slopes that consist of embankment, the lower side shall be compacted to at least the same compaction as specified for the soil in the backfill zone.

The unfactored earth load,  $W_E$ , shall be determined as:

The product  $wB_cH$  is sometimes referred to as the prism load,  $PL$ , the weight of the column of earth over the outside diameter of the pipe.

$$W_E = F_e w B_c H \quad (12.10.2.1-1)$$

where:

$W_E$  = unfactored earth load (kip/ft)

$F_e$  = soil-structure interaction factor for the specified installation as defined herein

$B_c$  = out-to-out horizontal dimension of pipe (ft)

$H$  = height of fill over pipe (ft)

$w$  = unit weight of soil (pcf)

The unit weight of soil used to calculate earth load shall be the estimated unit weight for the soils specified for the pipe soil installation but shall not be taken to be less than 110 lb./ft<sup>3</sup>.

Standard installations for both embankments and trenches shall be designed for positive projection, embankment loading conditions where  $F_e$  shall be taken as the vertical arching factor, VAF, specified in Table 12.10.2.1-3 for each type of standard installation.

For standard installations, the earth pressure distribution shall be the Heger pressure distribution shown in Figure 12.10.2.1-1 and Table 12.10.2.1-3 for each type of standard installation.

The earth load for designing pipe using a standard installation is obtained by multiplying the weight of the column of earth above the outside diameter of the pipe by the soil-structure interaction factor,  $F_e$ , for the design installation type.  $F_e$  accounts for the transfer of some of the overburden soil above the regions at the sides of the pipe because the pipe is more rigid than the soil at the side of the pipe for pipe in embankment and wide trench installations. Because of the difficulty of controlling maximum trench width in the field with the widespread use of trench boxes or sloped walls for construction safety, the potential reduction in earth load for pipe in trenches of moderate to narrow width is not taken into account in the determination of earth load and earth pressure distribution on the pipe. Both trench and embankment installations are to be designed for embankment (positive projecting) loads and pressure distribution in direct design or bedding factors in indirect design.

The earth pressure distribution and lateral earth force for a unit vertical load is the Heger pressure distribution and horizontal arching factor, HAF. The normalized pressure distribution and HAF values were obtained for each standard installation type from the results of soil-structure interaction analyses using SPIDA, together with the minimum soil properties for the soil types and compaction levels specified for the installations.

When nonstandard installations are used, the earth load and pressure distribution should be determined by an appropriate soil-structure interaction analysis.

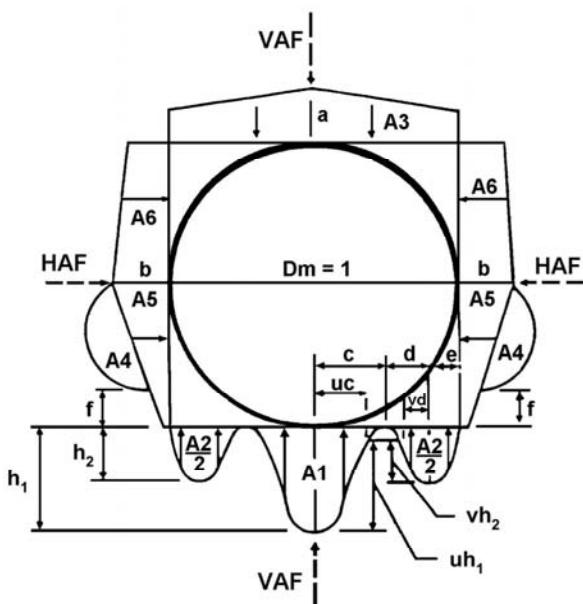

Figure 12.10.2.1-1—Heger Pressure Distribution and Arching Factors

**Table 12.10.2.1-3—Coefficients for Use with  
Figure 12.10.2.1-1**

	Installation Type			
	1	2	3	4
VAF	1.35	1.40	1.40	1.45
HAF	0.45	0.40	0.37	0.30
A1	0.62	0.85	1.05	1.45
A2	0.73	0.55	0.35	0.00
A3	1.35	1.40	1.40	1.45
A4	0.19	0.15	0.10	0.00
A5	0.08	0.08	0.10	0.11
A6	0.18	0.17	0.17	0.19
a	1.40	1.45	1.45	1.45
b	0.40	0.40	0.36	0.30
c	0.18	0.19	0.20	0.25
e	0.08	0.10	0.12	0.00
f	0.05	0.05	0.05	—
u	0.80	0.82	0.85	0.90
v	0.80	0.70	0.60	—

The following shall apply to Table 12.10.2.1-3:

- VAF and HAF are vertical and horizontal arching factors. These coefficients represent nondimensional total vertical and earth loads on the pipe, respectively. The actual total vertical and horizontal loads are  $(VAF) \times (PL)$  and  $(HAF) \times (PL)$ , respectively, where  $PL$  is the prism load.
- Coefficients A1 through A6 represent the integration of nondimensional vertical and horizontal components of soil pressure under the indicated portions of the component pressure diagrams, i.e., the area under the component pressure diagrams.
- The pressures are assumed to vary either parabolically or linearly, as shown in Figure 12.10.2.1-1, with the nondimensional magnitudes at governing points represented by  $h_1$ ,  $h_2$ ,  $uh_1$ ,  $vh_2$ ,  $a$ , and  $b$ .
- Nondimensional horizontal and vertical dimensions of component pressure regions are defined by  $c$ ,  $d$ ,  $e$ ,  $uc$ ,  $vd$ , and  $f$  coefficients,

where:

$$d = (0.5 - c - e) \quad (12.10.2.1-2)$$

$$h_1 = (1.5A1)/(c)(1+u) \quad (12.10.2.1-3)$$

$$h_2 = (1.5A2)/[(d)(1+v)+(2e)] \quad (12.10.2.1-4)$$

### 12.10.2.2 Pipe Fluid Weight

The unfactored weight of fluid,  $W_f$ , in the pipe shall be considered in design based on a fluid weight of 62.4 lb./ft<sup>3</sup>, unless otherwise specified. For standard installations, the fluid weight shall be supported by vertical earth pressure that is assumed to have the same distribution over the lower part of the pipe as given in Figure 12.10.2.1-1 for earth load.

### 12.10.2.3—Live Loads

Live loads shall be as specified in Article 3.6 and shall be distributed through the earth cover as specified in Article 3.6.1.2.6. For standard installations, the live load on the pipe shall be assumed to have a uniform vertical distribution across the top of the pipe and the same distribution across the bottom of the pipe as given in Figure 12.10.2.1-1.

### 12.10.3—Service Limit State

The width of cracks in the wall shall be investigated at the service limit state for moment and thrust. Generally, the crack width should not exceed 0.01 in.

### 12.10.4—Safety against Structural Failure

#### 12.10.4.1—General

The resistance of buried reinforced concrete pipe structures against structural failure shall be determined at the strength limit state for:

- Flexure,
- Thrust,
- Shear, and
- Radial tension.

The dimensions of pipe sections shall be determined using either the analytically-based direct design method or the empirically-based indirect design method.

When quadrant mats, stirrups, and/or elliptical cages are specified in the contract documents, the orientation of the pipe installation shall be specified, and the design shall account for the possibility of an angular misorientation of 10 degrees during the pipe installation.

#### C12.10.4.1

The direct design method uses a pressure distribution on the pipe from applied loads and bedding reactions based on a soil-structure interaction analysis or an elastic approximation. The indirect design method uses empirically-determined bedding factors that relate the total factored earth load to the concentrated loads and reactions applied in three-edge bearing tests.

### 12.10.4.2—Direct Design Method

#### 12.10.4.2.1—Loads and Pressure Distribution

The total vertical load acting on the pipe shall be determined as specified in Article 12.10.2.1.

The pressure distribution on the pipe from applied loads and bedding reaction shall be determined from either a soil-structure analysis or from a rational approximation, either of which shall permit the development of a pressure diagram, shown schematically in Figure 12.10.4.2.1-1, and the analysis of the pipe.

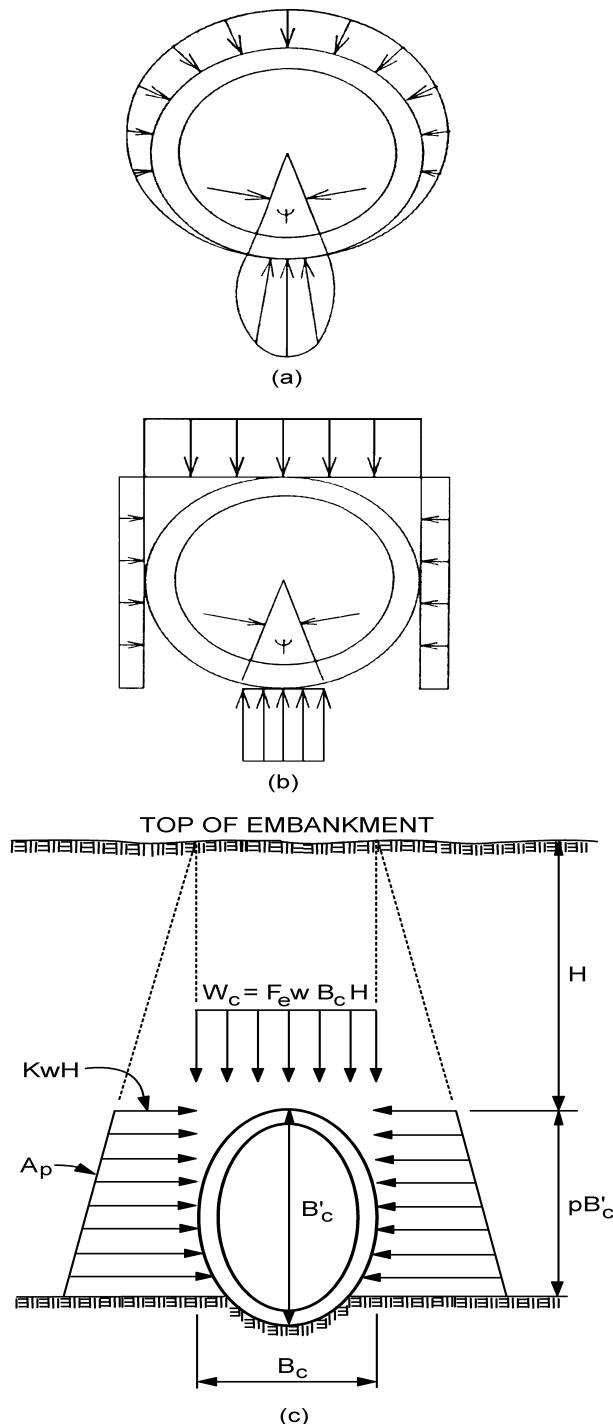

#### C12.10.4.2.1

The direct design method was accepted in 1993 by ASCE and is published in ASCE 93-15, *Standard Practice for Direct Design of Buried Precast Concrete Pipe Using Standard Installations* (SIDD). The design method was developed along with the research performed on the standard installations. However, the design equations are applied after the required bending moments, thrusts, and shear forces at all critical sections have been determined using any one of the acceptable pressure distributions. Therefore, the use of the design equations herein is not limited to the standard installations or any one assumed pressure distribution.

Direct design requires:

- The determination of earth loads and live load pressure distributions on the structure for the bedding and installation conditions selected by the Engineer;
- Analysis to determine thrust, moments, and shears; and
- Design to determine circumferential reinforcement.

The procedures for analysis and design are similar to those used for other reinforced concrete structures.

**Figure 12.10.4.2.1-1—Suggested Design Pressure Distribution around a Buried Concrete Pipe for Analysis by Direct Design**

**12.10.4.2.2 —Analysis for Force Effects with the Pipe Ring**

Force effects in the pipe shall be determined by an elastic analysis of the pipe ring under the assumed pressure distribution or a soil-structure analysis.

#### 12.10.4.2.3—Process and Material Factors

Process and material factors,  $F_{rp}$  for radial tension and  $F_{vp}$  for shear strength, for design of plant-made reinforced concrete pipe should be taken as 1.0. Higher values of these factors may be used if substantiated by sufficient testing in accordance with AASHTO M 242/M 242 ([ASTM C655M](#) and [C655](#)).

#### 12.10.4.2.4—Flexural Resistance at the Strength Limit State

##### 12.10.4.2.4a—Circumferential Reinforcement

##### C12.10.4.2.4a

Reinforcement for flexural resistance provided in a length,  $b$ , usually taken as 12.0 in. shall satisfy:

$$A_s \geq \frac{g\phi d - N_u - \sqrt{g\left[g(\phi d)^2 - N_u(2\phi d - h) - 2M_u\right]}}{f_y} \quad (12.10.4.2.4a-1)$$

in which:

$$g = 0.85bf'_c \quad (12.10.4.2.4a-2)$$

where:

$A_s$  = area of reinforcement per length of pipe,  $b$  (in.<sup>2</sup>/ft)

$f_y$  = specified yield strength of reinforcing (ksi)

$d$  = distance from compression face to centroid of tension reinforcement (in.)

$h$  = wall thickness of pipe (in.)

$M_u$  = moment due to factored loads (kip-in./ft)

$N_u$  = thrust due to factored load, taken to be positive for compression (kip/ft)

$\phi$  = resistance factor for flexure specified in Article 12.5.5

##### 12.10.4.2.4b—Minimum Reinforcement

The reinforcement,  $A_s$ , per ft of pipe shall not be less than:

- For inside face of pipe with two layers of reinforcement:

$$A_s \geq \frac{(S_i + h)^2}{1,000f_y} \geq 0.07 \quad (12.10.4.2.4b-1)$$

The required area of steel,  $A_s$ , as determined by Eq. 12.10.4.2.4a-1, should be distributed over a unit length of the pipe,  $b$ , which is typically taken as 12.0 in.

The factored actions should also be consistent with the selected unit width.

- For outside face of pipe with two layers of reinforcement:

$$A_s \geq 0.60 \frac{(S_i + h)^2}{1,000 f_y} \geq 0.07 \quad (12.10.4.2.4b-2)$$

- For elliptical reinforcement in circular pipe and for 33.0-in. diameter and smaller pipe with a single cage of reinforcement in the middle third of the pipe wall:

$$A_s \geq 2 \frac{(S_i + h)^2}{1,000 f_y} \geq 0.07 \quad (12.10.4.2.4b-3)$$

where:

$S_i$  = internal diameter or horizontal span of the pipe (in.)

$h$  = wall thickness of pipe (in.)

$f_y$  = yield strength of reinforcement (ksi)

*12.10.4.2.4c—Maximum Flexural Reinforcement without Stirrups*

The flexural reinforcement per ft of pipe without stirrups shall satisfy:

- For inside steel in radial tension:

$$A_{s\ max} \leq \frac{0.506 r_s F_{rp} \sqrt{f'_c(R_\phi)} F_n}{f_y} \quad (12.10.4.2.4c-1)$$

where:

$r_s$  = radius of the inside reinforcement (in.)

$f'_c$  = compressive strength of concrete (ksi)

$f_y$  = specified yield strength of reinforcement (ksi)

$R_\phi$  =  $(\phi_r/\phi_f)$ ; ratio of resistance factors for radial tension and moment specified in Article 12.5.5

$F_{rp}$  = 1.0 unless a higher value substantiated by test data and approved by the Engineer

in which:

- For  $12.0 \text{ in.} \leq S_i \leq 72.0 \text{ in.}$

$$F_n = 1 + 0.00833 (72 - S_i)$$

- For  $72.0 \text{ in.} < S_i \leq 144.0 \text{ in.}$ :

$$F_{rt} = \frac{(144 - S_i)^2}{26,000} + 0.80$$

- For  $S_i > 144.0 \text{ in.}$ :

$$F_{rt} = 0.80$$

- For reinforcing steel in compression:

$$A_{smax} \leq \frac{\left[ \left( \frac{55g'\phi d}{87 + f_y} \right) - 0.75N_u \right]}{f_y} \quad (12.10.4.2.4c-2)$$

in which:

$$g' = b f'_c [0.85 - 0.05(f'_c - 4.0)] \quad (12.10.4.2.4c-3)$$

$$0.85 b f'_c \geq g' \geq 0.65 b f'_c \quad (12.10.4.2.4c-4)$$

where:

$b$  = width of section taken as 12.0 in.

$\phi$  = resistance factor for flexure as specified in Article 5.5.4.2

#### *12.10.4.2.4d—Reinforcement for Crack Width Control*

The crack width factor,  $F_{cr}$ , may be determined as:

- If  $N_s$  is compressive, it is taken as positive and:

$$F_{cr} = \frac{B_1}{30\phi d A_s} \left[ \frac{M_s + N_s \left( d - \frac{h}{2} \right)}{ij} - 0.0316 C_1 b h^2 \sqrt{f'_c} \right] \quad (12.10.4.2.4d-1)$$

- If  $N_s$  is tensile, it is taken as negative and:

$$F_{cr} = \frac{B_1}{30dA_s\phi} \left( 1.1M_s - 0.6N_sd - 0.0316C_1bh^2\sqrt{f'_c} \right) \quad (12.10.4.2.4d-2)$$

in which:

$$j = 0.74 + 0.1 \frac{e}{d} \leq 0.9 \quad (12.10.4.2.4d-3)$$

The crack control coefficients,  $B_1$  and  $C_1$ , are dependent on the type of reinforcement.

Crack control is assumed to be 1.0 in. from the closest tension reinforcement, even if the cover over the reinforcement is greater than or less than 1.0 in. The crack control factor,  $F_{cr}$ , in Eq. 12.10.4.2.4d-1 indicates the probability that a crack of a specified maximum width will occur.

If the ratio of  $e/d$  is less than 1.15, crack control will not govern.

$$i = \frac{1}{\left(1 - \frac{jd}{e}\right)} \quad (12.10.4.2.4d-4)$$

$$e = \frac{M_s}{N_c} + d - \frac{h}{2} \quad (12.10.4.2.4d-5)$$

$$B_1 = \left( \frac{t_b S_\ell}{2n} \right)^{\frac{1}{3}} \quad (12.10.4.2.4d-6)$$

where:

$M_s$  = flexural moment at service limit state  
(kip-in./ft)

$N_s$  = axial thrust at service limit state (kip/ft)

*d* = distance from compression face to centroid of tension reinforcement (in.)

*h* = wall thickness (in.)

$f'_c$  = specified compressive strength of concrete (ksi)

$C_1$  = crack control coefficient for various types of reinforcement as specified in Table 12.10.4.2.4d-1

$A_s$  = area of steel (in.<sup>2</sup>/ft)

*b* = width of section taken as 12.0 in.

$t_b$  = clear cover over reinforcement (in.)

$S_r$  = spacing of circumferential reinforcement (in.)

$n = 1.0$  when tension reinforcement is a single layer

$n = 2.0$  when tension reinforcement is made of multiple layers

$\phi$  = resistance factor for flexure as specified in Article 12.5.5

Table 12.10.4.2.4d-1—Crack Control Coefficients

Type	Reinforcement	$C_1$
1	Smooth wire or plain bars	1.0
2	Welded smooth wire fabric with 8.0-in. maximum spacing of longitudinals, welded deformed wire fabric, or deformed wire	1.5
3	Deformed bars or any reinforcement with stirrups anchored thereto	1.9

For Type 2 reinforcement in Table 12.10.4.2.4d-1 having  $t_b^2 S_i/n > 3.0$ , the crack width factor,  $F_{cr}$ , shall also be investigated using coefficients  $B_1$  and  $C_1$  specified for Type 3 reinforcement, and the larger value for  $F_{cr}$  shall be used.

Higher values for  $C_1$  may be used if substantiated by test data and approved by the Engineer.

#### *12.10.4.2.4e—Minimum Concrete Cover*

The provisions of Article 5.12.3 shall apply to minimum concrete cover, except as follows:

- If the wall thickness is less than 2.5 in., the cover shall not be less than 0.75 in., and
- If the wall thickness is not less than 2.5 in., the cover shall not be less than 1.0 in.

#### *12.10.4.2.5—Shear Resistance without Stirrups*

Where  $F_{cr} = 1.0$ , the specified reinforcement is expected to produce an average maximum crack width of 0.01 in. For  $F_{cr} < 1.0$ , the probability of a 0.01-in. crack is reduced, and for  $F_{cr} > 1.0$ , it is increased.

#### *C12.10.4.2.5*

The section shall be investigated for shear at a critical section taken where  $M_{nu}/(V_u d) = 3.0$ . The factored shear resistance without radial stirrups,  $V_r$ , shall be taken as:

$$V_r = \phi V_n \quad (12.10.4.2.5-1)$$

in which:

$$V_n = 0.0316 b d F_{vp} \sqrt{f'_c} (1.1 + 63\rho) \left( \frac{F_d F_n}{F_c} \right) \quad (12.10.4.2.5-2)$$

$$\rho = \frac{A_s}{bd} \leq 0.02 \quad (12.10.4.2.5-3)$$

- For pipes with two cages or a single elliptical cage:

$$F_d = 0.8 + \frac{1.6}{d} \leq 1.3 \quad (12.10.4.2.5-4)$$

- For pipes not exceeding 36.0-in. diameter with a single circular cage:

$$F_d = 0.8 + \frac{1.6}{d} \leq 1.4 \quad (12.10.4.2.5-5)$$

For the purpose of this Article, a cage is considered to be a layer of reinforcement.

If  $N_u$  is compressive, it is taken as positive and:

$$F_n = 1 + \frac{N_u}{24h} \quad (12.10.4.2.5-6)$$

If  $N_u$  is tensile, it is taken as negative and:

$$F_n = 1 + \frac{N_u}{6h} \quad (12.10.4.2.5-7)$$

$$F_c = 1 \pm \frac{d}{2r} \quad (12.10.4.2.5-8)$$

$$M_{nu} = M_u - N_u \left[ \frac{(4h-d)}{8} \right] \quad (12.10.4.2.5-9)$$

The algebraic sign in Eq. 12.10.4.2.5-8 shall be taken as positive where tension is on the inside of the pipe and negative where tension is on the outside of the pipe.

where:

$$f'_{cmax} = 7.0 \text{ ksi}$$

$b$  = width of design section taken as 12.0 in.

$d$  = distance from compression face to centroid of tension reinforcement (in.)

$h$  = wall thickness (in.)

$\phi$  = resistance factor for shear as specified in Article 5.5.4.2

$r$  = radius to centerline of concrete pipe wall (in.)

$N_u$  = thrust due to factored loads (kip/ft)

$V_u$  = shear due to factored loads (kip/ft)

$F_{vp}$  = process and material factor specified in Article 12.10.4.2.3

If the factored shear resistance, as determined herein, is not adequate, radial stirrups shall be provided in accordance with Article 12.10.4.2.6.

#### 12.10.4.2.6—Shear Resistance with Radial Stirrups

Radial tension and shear stirrup reinforcement shall not be less than:

- For radial tension:

$$A_{vr} = \frac{1.1s_v(M_u - 0.45N_u\phi_r d)}{f_y r_s \phi_r d} \quad (12.10.4.2.6-1)$$

$$s_v \leq 0.75\phi_r d \quad (12.10.4.2.6-2)$$

- For shear:

$$A_{vs} = \frac{1.1s_v}{f_y \phi_v d} (V_u F_c - V_c) + A_{vr} \quad (12.10.4.2.6-3)$$

$$s_v \leq 0.75\phi_v d \quad (12.10.4.2.6-4)$$

in which:

$$V_c = \frac{4V_r}{\frac{M_{nu}}{V_u d} + 1} \leq 0.0633\phi_v b d \sqrt{f'_c} \quad (12.10.4.2.6-5)$$

where:

$M_u$  = flexural moment due to factored loads (kip-in./ft)

$M_{nu}$  = factored moment acting on cross-section width,  $b$ , as modified for effects of compressive or tensile thrust (kip-in./ft)

$N_u$  = thrust due to factored loads (kip/ft)

$V_u$  = shear due to factored loads (kip/ft)

$V_c$  = shear resistance of concrete section (kip/ft)

$d$  = distance from compression face to centroid of tension reinforcement (in.)

$f_y$  = specified yield strength for reinforcement; the value of  $f_y$  shall be taken as the lesser of the yield strength of the stirrup or its developed anchorage capacity (ksi)

$r_s$  = radius of inside reinforcement (in.)

$s_v$  = spacing of stirrups (in.)

$V_r$  = factored shear resistance of pipe section without radial stirrups per unit length of pipe (kip/ft)

$A_{vr}$  = stirrup reinforcement area to resist radial tension forces on cross-section width,  $b$ , in each line of stirrups at circumferential spacing,  $s_v$  ( $\text{in.}^2/\text{ft}$ )

$A_{vs}$  = required area of stirrups for shear reinforcement ( $\text{in.}^2/\text{ft}$ )

$f'_c$  = compressive strength of concrete (ksi)

$\phi_v$  = resistance factor for shear as specified in Article 12.5.5

$\phi_r$  = resistance factor for radial tension as specified in Article 12.5.5

$F_c$  = curvature factor as determined by Eq. 12.10.4.2.5-8

#### 12.10.4.2.7—Stirrup Reinforcement Anchorage

##### 12.10.4.2.7a—Radial Tension Stirrup Anchorage

When stirrups are used to resist radial tension, they shall be anchored around each circumferential of the inside cage to develop the resistance of the stirrup, and they shall also be anchored around the outside cage or embedded sufficiently in the compression side to develop the required resistance of the stirrup.

##### 12.10.4.2.7b—Shear Stirrup Anchorage

Except as specified herein, when stirrups are not required for radial tension but required for shear, their longitudinal spacing shall be such that they are anchored around each tension circumferential or every other tension circumferential. The spacing of such stirrups shall not exceed 6.0 in.

##### 12.10.4.2.7c—Stirrup Embedment

Stirrups intended to resist forces in the invert and crown regions shall be anchored sufficiently in the opposite side of the pipe wall to develop the required resistance of the stirrup.

#### 12.10.4.3—Indirect Design Method

##### 12.10.4.3.1—Bearing Resistance

Earth and live loads on the pipe shall be determined in accordance with Article 12.10.2 and compared to three-edge bearing strength D-load for the pipe. The service limit state shall apply using the criterion of acceptable crack width specified herein.

The D-load for a particular class and size of pipe shall be determined in accordance with AASHTO M 242/M 242 ([ASTM C655M](#) and [C655](#)).

The three-edge bearing resistance of the reinforced concrete pipe, corresponding to an experimentally observed 0.01-in. width crack, shall not be less than the design load determined for the pipe as installed, taken as:

$$D = \left( \frac{12}{S_i} \right) \left( \frac{W_E + W_F}{B_{FE}} + \frac{W_L}{B_{FLL}} \right) \quad (12.10.4.3.1-1)$$

##### C12.10.4.2.7a

Stirrup reinforcement anchorage development research by pipe manufacturers has demonstrated that the free ends of loop-type stirrups need only be anchored in the compression zone of the concrete cross-section to develop the full tensile strength of the stirrup wire. Stirrup loop lengths equivalent to 70 percent of the wall thickness may be considered to provide adequate anchorage.

##### C12.10.4.3.1

The indirect design method has been the most commonly utilized method of design for buried reinforced concrete pipe. It is based on observed successful past installations.

The required D-load at which the pipe develops its ultimate strength in a three-edge bearing test is the design D-load at a 0.01-in. crack multiplied by a strength factor specified in AASHTO M 170 or M 242/M 242 ([ASTM C76](#) or [C655M](#) and [C655](#)) for circular pipe, M 206/M/M 206 ([ASTM C506M](#) and [C506](#)) for arch pipe, and M 207/M/M 207 ([ASTM C507M](#) or [C507](#)) for elliptical pipe.

where:

- $B_{FE}$  = earth load bedding factor specified in Article 12.10.4.3.2a or Article 12.10.4.3.2b
- $B_{FLL}$  = live load bedding factor specified in Article 12.10.4.3.2c
- $S_i$  = internal diameter of pipe (in.)
- $W_E$  = total unfactored earth load specified in Article 12.10.2.1 (kip/ft)
- $W_F$  = total unfactored fluid load in the pipe as specified in Article 12.10.2.2 (kip/ft)
- $W_L$  = total unfactored live load on unit length pipe specified in Article 12.10.2.3 (kip/ft)

For Type 1 installations,  $D$  loads, as calculated above, shall be modified by multiplying by an installation factor of 1.10.

#### 12.10.4.3.2—Bedding Factor

The minimum compaction specified in Tables 12.10.2.1-1 and 12.10.2.1-2 shall be required by the contract document.

#### C12.10.4.3.2

The bedding factor is the ratio of the moment at service limit state to the moment applied in the three-edge bearing test. The standard supporting strength of buried pipe depends on the type of installation. The bedding factors given herein are based on the minimum levels of compaction indicated.

#### 12.10.4.3.2a—Earth Load Bedding Factor for Circular Pipe

Earth load bedding factors,  $B_{FE}$ , for circular pipe are presented in Table 12.10.4.3.2a-1.

For pipe diameters, other than those listed in Table 12.10.4.3.2a-1, embankment condition bedding factors,  $B_{FE}$ , may be determined by interpolation.

#### C12.10.4.3.2a

The bedding factors for circular pipe were developed using the bending moments produced by the Heger pressure distributions from Figure 12.10.2.1-1 for each of the standard embankment installations. The bedding factors for the embankment condition are conservative for each installation. This conservatism is based on assuming voids and poor compaction in the haunch areas and a hard bedding beneath the pipe in determining the moments, thrusts, and shears used to calculate the bedding factors. The modeling of the soil pressure distribution used to determine moments, thrusts, and shears is also conservative by 10–20 percent, compared with the actual SPIDA analysis.

**Table 12.10.4.3.2a-1—Bedding Factors for Circular Pipe**

Pipe Diameter, in.	Standard Installations			
	Type 1	Type 2	Type 3	Type 4
12	4.4	3.2	2.5	1.7
24	4.2	3.0	2.4	1.7
36	4.0	2.9	2.3	1.7
72	3.8	2.8	2.2	1.7
144	3.6	2.8	2.2	1.7

**12.10.4.3.2b—Earth Load Bedding Factor for Arch and Elliptical Pipe**

The bedding factor for installation of arch and elliptical pipe shall be taken as:

$$B_{FE} = \frac{C_A}{C_N - xq} \quad (12.10.4.3.2b-1)$$

where:

$C_A$  = constant corresponding to the shape of the pipe, as specified in Table 12.10.4.3.2b-1

$C_N$  = parameter that is a function of the distribution of the vertical load and vertical reaction, as specified in Table 12.10.4.3.2b-1

$x$  = parameter that is a function of the area of the vertical projection of the pipe over which lateral pressure is effective, as specified in Table 12.10.4.3.2b-1

$q$  = ratio of the total lateral pressure to the total vertical fill load specified herein

Design values for  $C_A$ ,  $C_N$ , and  $x$  are listed in Table 12.10.4.3.2b-1.

**Table 12.10.4.3.2b-1—Design Values of Parameters in Bedding Factor Equation**

Pipe Shape	$C_A$	Installation Type	$C_N$	Projection Ratio, $p$	$x$
Horizontal Elliptical and Arch	1.337	2	0.630	0.9 0.7	0.421 0.369
		3	0.763	0.5 0.3	0.268 0.148
	1.021	2	0.516	0.9 0.7	0.718 0.639
		3	0.615	0.5 0.3	0.457 0.238

The value of the parameter  $q$  is taken as:

- For arch and horizontal elliptical pipe:

$$q = 0.23 \frac{p}{F_e} \left( 1 + 0.35 p \frac{B_c}{H} \right) \quad (12.10.4.3.2b-2)$$

- For vertical elliptical pipe:

$$q = 0.48 \frac{p}{F_e} \left( 1 + 0.73 p \frac{B_c}{H} \right) \quad (12.10.4.3.2b-3)$$

where:

$p$  = projection ratio, ratio of the vertical distance between the outside top of the pipe, and the ground of bedding surface to the outside vertical height of the pipe

#### 12.10.4.3.2c—Live Load Bedding Factors

The bedding factors for live load,  $W_L$ , for both circular pipe and arch and for elliptical pipe are given in Table 12.10.4.3.2c-1. If  $B_{FE}$  is less than  $B_{FLL}$ , use  $B_{FE}$  instead of  $B_{FLL}$ , for the live load bedding factor. For pipe diameters not listed in Table 12.10.4.3.2c-1, the bedding factor may be determined by interpolation.

**Table 12.10.4.3.2c-1—Bedding Factors,  $B_{FLL}$ , for the Design Truck**

Fill Height, ft	Pipe Diameter, in.										
	12	24	36	48	60	72	84	96	108	120	144
0.5	2.2	1.7	1.4	1.3	1.3	1.1	1.1	1.1	1.1	1.1	1.1
1.0	2.2	2.2	1.7	1.5	1.4	1.3	1.3	1.3	1.1	1.1	1.1
1.5	2.2	2.2	2.1	1.8	1.5	1.4	1.4	1.3	1.3	1.3	1.1
2.0	2.2	2.2	2.2	2.0	1.8	1.5	1.5	1.4	1.4	1.3	1.3
2.5	2.2	2.2	2.2	2.2	2.0	1.8	1.7	1.5	1.4	1.4	1.3
3.0	2.2	2.2	2.2	2.2	2.2	2.2	1.8	1.7	1.5	1.5	1.4
3.5	2.2	2.2	2.2	2.2	2.2	2.2	1.9	1.8	1.7	1.5	1.4
4.0	2.2	2.2	2.2	2.2	2.2	2.2	2.1	1.9	1.8	1.7	1.5
4.5	2.2	2.2	2.2	2.2	2.2	2.2	2.2	2.0	1.9	1.8	1.7
5.0	2.2	2.2	2.2	2.2	2.2	2.2	2.2	2.2	2.0	1.9	1.8
5.5	2.2	2.2	2.2	2.2	2.2	2.2	2.2	2.2	2.2	2.0	1.9
6.0	2.2	2.2	2.2	2.2	2.2	2.2	2.2	2.2	2.2	2.1	2.0
6.5	2.2	2.2	2.2	2.2	2.2	2.2	2.2	2.2	2.2	2.2	2.2

#### 12.10.4.4—Development of Quadrant Mat Reinforcement

##### 12.10.4.4.1—Minimum Cage Reinforcement

In lieu of a detailed analysis, when quadrant mat reinforcement is used, the area of the main cage shall be no less than 25 percent of the area required at the point of maximum moment.

*12.10.4.4.2—Development Length of Welded Wire Fabric*

Unless modified herein, the provisions of Article 5.11.2.5 shall apply.

*12.10.4.4.3—Development of Quadrant Mat Reinforcement Consisting of Welded Plain Wire Fabric*

The embedment of the outermost longitudinals on each end of the circumferentials shall not be less than:

- The greater of 12 circumferential bar diameters or three-quarters of the wall thickness of the pipe beyond the point where the quadrant reinforcement is no longer required by the orientation angle, and
- A distance beyond the point of maximum flexural stress by the orientation angle plus the development length,  $\ell_d$ , where  $\ell_d$  is specified in Article 5.11.2.5.2.

The mat shall contain no less than two longitudinals at a distance 1.0 in. greater than that determined by the orientation angle from either side of the point requiring the maximum flexural reinforcement.

The point of embedment of the outermost longitudinals of the mat shall be at least a distance determined by the orientation angle past the point where the continuing reinforcement is no less than double the area required for flexure.

*12.10.4.4.4—Development of Quadrant Mat Reinforcement Consisting of Deformed Bars, Deformed Wire, or Deformed Wire Fabric*

When deformed bars, deformed wire, or deformed wire fabric is used, the circumferential bars in quadrant mat reinforcement shall satisfy the following requirements:

- Circumferentials shall extend past the point where they are no longer required by the orientation angle plus the greater of 12 wire or bar diameters or three-quarters of the wall thickness of the pipe,
- Circumferentials shall extend on either side of the point of maximum flexural stress not less than the orientation angle plus the development length,  $\ell_{hd}$ , as required by Article 5.11.2.5.1 and modified by the applicable modification factor or factors, and
- Circumferentials shall extend at least a distance determined by the orientation angle past the point where the continuing reinforcement is no less than double the area required for flexure.

### 12.10.5—Construction and Installation

The contract documents shall require that the construction and installation conform to Section 27, "Concrete Culverts," AASHTO LRFD Bridge Construction Specifications.

## 12.11—REINFORCED CONCRETE CAST-IN-PLACE AND PRECAST BOX CULVERTS AND REINFORCED CAST-IN-PLACE ARCHES

### 12.11.1—General

The provisions herein shall apply to the structural design of cast-in-place and precast reinforced concrete box culverts and cast-in-place reinforced concrete arches with the arch barrel monolithic with each footing.

Designs shall conform to applicable Articles of these Specifications, except as provided otherwise herein.

### C12.11.1

These structures become part of a composite system comprised of the box or arch culvert structure and the soil envelope.

Precast reinforced concrete box culverts may be manufactured using conventional structural concrete and forms, or they may be machine made with dry concrete and vibrating form pipe making methods.

Standard dimensions for precast reinforced concrete box culverts are shown in AASHTO M 259 ([ASTM C789](#)) and M 273 ([ASTM C850](#)).

### 12.11.2—Loads and Live Load Distribution

#### 12.11.2.1—General

Loads and load combinations specified in Table 3.4.1-1 shall apply. Live load shall be considered as specified in Article 3.6.1.3. Distribution of wheel loads and concentrated loads for culverts with less than 2.0 ft of fill shall be taken as specified in Article 4.6.2.10. For traffic traveling parallel to the span, box culverts shall be designed for a single loaded lane with the single lane multiple presence factor applied to the load. Requirements for bottom distribution reinforcement in top slabs of such culverts shall be as specified in Article 9.7.3.2 for mild steel reinforcement and Article 5.14.4.1 for prestressed reinforcement.

Distribution of wheel loads to culverts with 2.0 ft or more of cover shall be as specified in Article 3.6.1.2.6.

The dynamic load allowance for buried structures shall conform to Article 3.6.2.2.

#### C12.11.2.1

Research into live load distribution on box culverts (McGrath et al., 2004) has shown that design for a single loaded lane with a multiple presence factor of 1.2 on the live load and using the live load distribution widths in Article 4.6.2.10 will provide adequate design loading for multiple loaded lanes with multiple presence factors of 1.0 or less when the traffic direction is parallel to the span.

For cast-in-place box culverts, and for precast box culverts with top slabs having span to thickness ratios ( $s/t$ ) >18 or segment lengths <4.0 ft, edge beams shall be provided as specified in Article 4.6.2.1.4 as follows:

- At ends of culvert runs where wheel loads travel within 24.0 in. from the end of culvert,
- At expansion joints of cast-in-place culverts where wheel loads travel over or adjacent to the expansion joint.

### **12.11.2.2—Modification of Earth Loads for Soil-Structure Interaction**

#### *12.11.2.2.1—Embankment and Trench Conditions*

In lieu of a more refined analysis, the total unfactored earth load,  $W_E$ , acting on the culvert may be taken as:

- For embankment installations:

$$W_E = F_e \gamma_s B_c H \quad (12.11.2.2.1-1)$$

in which:

$$F_e = 1 + 0.20 \frac{H}{B_c} \quad (12.11.2.2.1-2)$$

- For trench installations:

$$W_E = F_t \gamma_s B_c H \quad (12.11.2.2.1-3)$$

in which:

$$F_t = \frac{C_d B_d^2}{H B_c} \leq F_e \quad (12.11.2.2.1-4)$$

where:

$W_E$  = total unfactored earth load (kip/ft)

$B_c$  = outside width of culvert as specified in Figures 12.11.2.2.1-1 or 12.11.2.2.1-2, as appropriate (ft)

$H$  = depth of backfill as specified in Figures 12.11.2.2.1-1 or 12.11.2.2.1-2 (ft)

$F_e$  = soil-structure interaction factor for embankment installation specified herein

$F_t$  = soil-structure interaction factor for trench installations specified herein

$\gamma_s$  = unit weight of backfill (kcf)

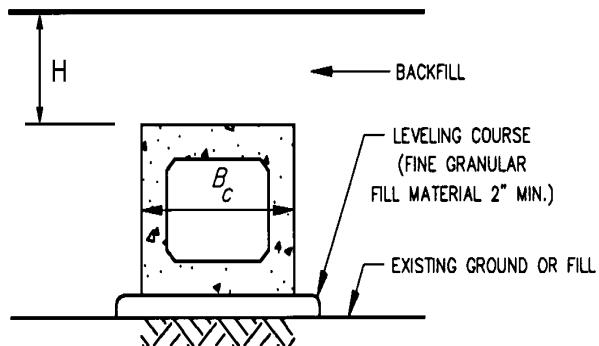

$B_d$  = horizontal width of trench as specified in Figure 12.11.2.2.1-2 (ft)

$C_d$  = a coefficient specified in Figure 12.11.2.2.1-3

The edge beam provisions are only applicable for culverts with less than 2.0 ft of fill. Precast box culverts with span to thickness ratios ( $s/t$ ) ≤18 have been shown to have significantly more strength than would be predicted by Article 5.8.3 (Abolmaali and Garg, 2007). While the distribution of the load when it is applied to the edge of these structures would not be as large as would be predicted by Article 4.6.2.10, the residual strength in the structure more than compensates for the liberal load distribution.

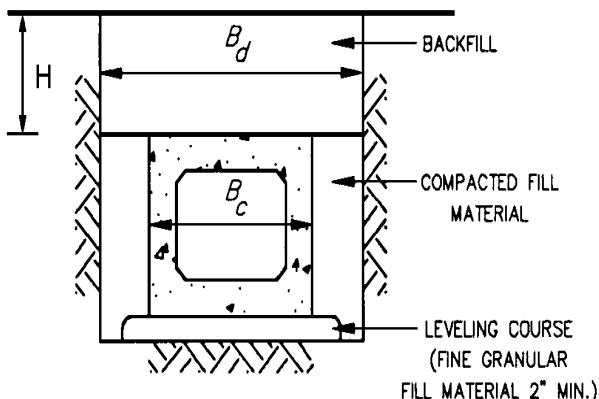

$F_e$  shall not exceed 1.15 for installations with compacted fill along the sides of the box section, or 1.40 for installations with uncompacted fill along the sides of the box section.

For wide trench installations where the trench width exceeds the horizontal dimension of the culvert across the trench by more than 1.0 ft,  $F_t$  shall not exceed the value specified for an embankment installation.

### EMBANKMENT CONDITION

**Figure 12.11.2.2.1-1—Embankment Condition—Precast Concrete Box Sections**

### TRENCH CONDITION

**Figure 12.11.2.2.1-2—Trench Condition—Precast Concrete Box Sections**

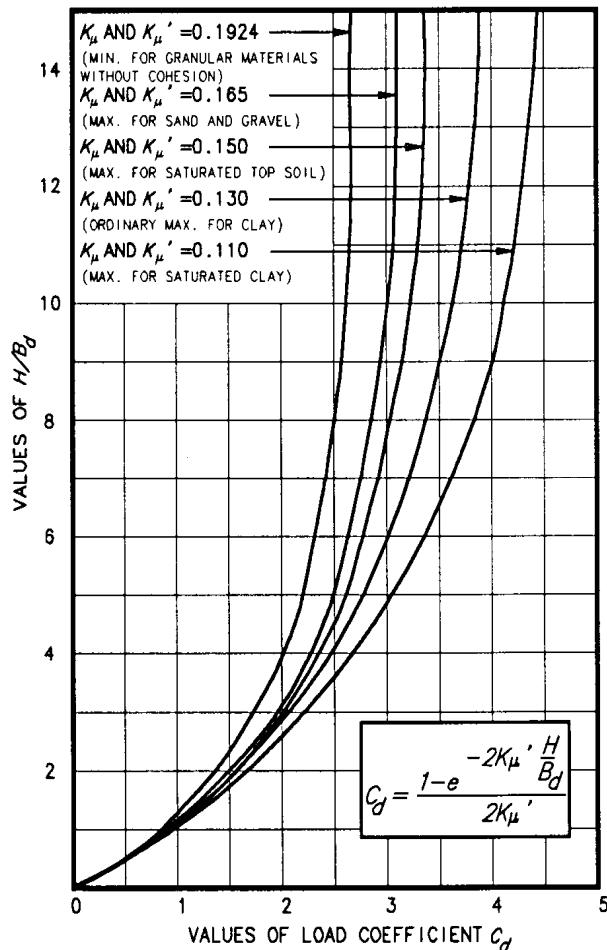

Figure 12.11.2.2.1-3—Coefficient  $C_d$  for Trench Installations

#### 12.11.2.2.2—Other Installations

Methods of installation other than embankment or trench may be used to reduce the loads on the culvert, including partial positive projection, 0.0 projection, negative projection, induced trench, and jacked installations. The loads for such installations may be determined by accepted methods based on tests, soil-structure interaction analyses, or previous experience.

#### 12.11.2.3—Distribution of Concentrated Loads to Bottom Slab of Box Culvert

The width of the top slab strip used for distribution of concentrated wheel loads, specified in Article 12.11.2, shall also be used for the determination of moments, shears, and thrusts in the side walls and the bottom slab.

#### C12.11.2.3

Restricting the live load distribution width for the bottom slab to the same width used for the top slab provides designs suitable for multiple loaded lanes, even though analysis is only completed for a single loaded lane (as discussed in Article C12.11.2.1).

While typical designs assume a uniform pressure distribution across the bottom slab, a refined analysis that considers the actual soil stiffness under box sections will result in pressure distributions that reduce bottom slab shear and moment forces (McGrath et al., 2004).

Such an analysis requires knowledge of in-situ soil properties to select the appropriate stiffness for the supporting soil. A refined analysis taking this into account may be beneficial when analyzing existing culverts.

#### **12.11.2.4—Distribution of Concentrated Loads in Skewed Box Culverts**

Wheel distribution specified in Article 12.11.2.3 need not be corrected for skew effects.

#### **12.11.3—Service Limit State**

The provisions of Article 5.7.3.4 shall apply to crack width control in reinforced concrete cast-in-place and precast box culverts and reinforced cast-in-place arches.

#### **C12.11.3**

Buried box culverts are subject to high compressive thrust forces compared to most flexural members and this thrust can result in a substantial reduction in the stresses at the service limit state that is often ignored in design. The following Equations, derived from ACI SP-3 can be used to consider the effect of thrust on stresses at the service limit state:

$$f_s = \frac{M_s + N_s \left( d - \frac{h}{2} \right)}{(A_s j i d)} \quad (\text{C12.11.3-1})$$

in which:

$$e = M_s / N_s + d - h / 2$$

$$i = 1 / (1 - jd / e)$$

$$j = 0.74 + 0.1(e/d) \leq 0.9$$

where:

$M_s$  = flexural moment at service limit state (kip-in./ft)

$N_s$  = axial thrust at service limit state (kip/ft)

$d$  = distance from compression face to centroid of tension reinforcement (in.)

$h$  = wall thickness (in.)

$A_s$  = area of reinforcement per unit length (in.<sup>2</sup>/ft)

$f_s$  = reinforcement stress under service load condition (ksi)

$e/d$  min = 1.15 (dim.)

## 12.11.4—Safety against Structural Failure

### 12.11.4.1—General

All sections shall be designed for the applicable factored loads specified in Table 3.4.1-1 at the strength limit state, except as modified herein. Shear in culverts shall be investigated in conformance with Article 5.14.5.3.

### 12.11.4.2—Design Moment for Box Culverts

Where monolithic haunches inclined at 45 degrees are specified, negative reinforcement in walls and slabs may be proportioned based on the flexural moment at the intersection of the haunch and uniform depth member. Otherwise, the provisions of Section 5 shall apply.

### 12.11.4.3—Minimum Reinforcement

#### 12.11.4.3.1—Cast-in-Place Structures

Reinforcement shall not be less than that specified in Article 5.7.3.3.2 at all cross-sections subject to flexural tension, including the inside face of walls. Shrinkage and temperature reinforcement shall be provided near the inside surfaces of walls and slabs in accordance with Article 5.10.8.

#### 12.11.4.3.2—Precast Box Structures

At all cross-sections subjected to flexural tension, the ratio of primary flexural reinforcement in the direction of the span to gross concrete area shall be not less than 0.002. Such minimum reinforcement shall be provided at the inside faces of walls and in each direction at the top of slabs of box sections having less than 2.0 ft of cover.

The provisions of Article 5.10.8 shall not apply to precast concrete box sections fabricated in lengths not exceeding 16.0 ft. Where the fabricated length exceeds 16.0 ft, the minimum longitudinal reinforcement for shrinkage and temperature should be in conformance with Article 5.10.8.

### 12.11.4.4—Minimum Cover for Precast Box Structures

The provisions of Article 5.12.3 shall apply unless modified herein for precast box structures.

If the height of the fill is <2.0 ft, the minimum cover in the top slab shall be 2.0 in. for all types of reinforcement.

Where welded wire fabric is used, the minimum cover shall be the greater of three times the diameter of the wire or 1.0 in.

.....

### 12.11.5—Construction and Installation

The contract documents shall require that construction and installation conform to Section 27, "Concrete Culverts," AASHTO LRFD Bridge Construction Specifications.

## 12.12—THERMOPLASTIC PIPES

### 12.12.1—General

The provisions herein shall apply to the structural design of buried thermoplastic pipe with solid, corrugated, or profile wall, manufactured of PE or PVC.

### C12.12.1

These structures become part of a composite system comprised of the plastic pipe and the soil envelope.

The following specifications are applicable:

For PE:

Solid Wall—[ASTM F714](#),

Corrugated—AASHTO M 294,

Profile—[ASTM F894](#).

For PVC:

Solid Wall—AASHTO M 278,

Profile—AASHTO M 304.

### 12.12.2—Service Limit States

The allowable maximum localized distortion of installed plastic pipe shall be limited based on the service requirements and overall stability of the installation. The extreme fiber tensile strain shall not exceed the allowable long-term strain in Table 12.12.3.3-1. The net tension strain shall be the numerical difference between the bending tensile strain and ring compression strain.

### C12.12.2

The allowable long-term strains should not be reached in pipes designed and constructed in accordance with this Specification. Deflections resulting from conditions imposed during pipe installation should also be considered in design.

### 12.12.3—Safety against Structural Failure

#### 12.12.3.1—General

Buried plastic pipe structures shall be investigated at the strength limit states for thrust, buckling, and combined strain.

#### C12.12.3.1

Total compressive strain in an element can result in local buckling and total tensile strain can result in cracking.

#### 12.12.3.2—Section Properties

Section properties for PE corrugated pipes, PE ribbed pipes, and PVC ribbed pipes may be taken as listed in Appendix A12, Tables A12-11 through A12-13, as appropriate.

### 12.12.3.3—Chemical and Mechanical Requirements

Mechanical properties for design shall be as specified in Table 12.12.3.3-1.

Except for buckling, the choice of either initial or 50-yr mechanical property requirements, as appropriate for a specific application, shall be determined by the Engineer. Investigation of buckling shall be based on the 50-yr value for modulus of elasticity.

The cell class for AASHTO M 294 corrugated PE Pipe specified in Table 12.12.3.3-1 shall be taken as 335400C with additional environmental stress crack resistance evaluation according to SP-NCTL test as per recommendations in (Husan and McGrath, 1999).

### C12.12.3.3

The PE and PVC materials described herein have stress/strain relationships that are nonlinear and time-dependent. The 50-yr design tensile strength requirements are derived from hydrostatic design models and indicate a minimum 50-yr life expectancy under continuous application of that stress. The 50-yr moduli of elasticity do not indicate a softening of the pipe material but the time-dependent relation between stress and strain. For each short-term increment of deflection, whenever it occurs, the response will reflect the initial modulus. Both short- and long-term properties are shown. Except for buckling, the Engineer should determine which is appropriate for the specific application. “Initial” and “long-term” relate to conditions of loading, not age of the installation. Response to live loads will reflect the initial modulus, regardless of the age of the installation.

**Table 12.12.3.3-1—Mechanical Properties of Thermoplastic Pipes**

Type of Pipe	Minimum Cell Class	Allowable Long-Term Strain %	Initial		50-yr	
			$F_u$ min (ksi)	$E$ min (ksi)	$F_u$ min (ksi)	$E$ min (ksi)
Solid Wall PE Pipe— <a href="#">ASTM F714</a>	<a href="#">ASTM D3350</a> , 335434C	5.0	3.0	110.0	1.44	22.0
Corrugated PE Pipe—AASHTO M 294	<a href="#">ASTM D3350</a> , 435400C	5.0	3.0	110.0	0.90	22.0
Profile PE Pipe— <a href="#">ASTM F894</a>	<a href="#">ASTM D3350</a> , 334433C	5.0	3.0	80.0	1.12	20.0
	<a href="#">ASTM D3350</a> , 335434C	5.0	3.0	110.0	1.44	22.0
Solid Wall PVC Pipe—AASHTO M 278, <a href="#">ASTM F679</a>	<a href="#">ASTM D1784</a> , 12454C	5.0	7.0	400.0	3.70	140.0
	<a href="#">ASTM D1784</a> , 12364C	3.5	6.0	440.0	2.60	158.4
Profile PVC Pipe—AASHTO M 304	<a href="#">ASTM D1784</a> , 12454C	5.0	7.0	400.0	3.70	140.0
	<a href="#">ASTM D1784</a> , 12364C	3.5	6.0	440.0	2.60	158.4

### 12.12.3.4—Thrust

### C12.12.3.4

The factored thrust per unit length of wall of buried plastic pipe structures shall be taken as:

$$T_L = P_F \left( \frac{D_o}{2} \right) \quad (12.12.3.4-1)$$

where:

$T_L$  = factored thrust per unit length (kip/ft)

$D_o$  = outside diameter of pipe (ft)

$P_F$  = factored vertical crown pressure (ksf)

For which, the factored vertical crown pressure,  $P_F$ , shall be taken as:

$$P_F = \eta_{EV} (\gamma_{EV} VAF P_{sp} + 1.3\gamma_{WA} P_w) + \eta_{LL} \gamma_{LL} C_L P_L \quad (12.12.3.4-2)$$

in which:

$$VAF = 0.76 - 0.71 \left( \frac{S_H - 1.17}{S_H + 2.92} \right) \quad (12.12.3.4-3)$$

$$S_H = \frac{\phi_s M_s R}{EA} \quad (12.12.3.4-4)$$

$$P_w = \gamma_w H_s \quad (12.12.3.4-5)$$

where:

$P_F$  = factored vertical crown pressure (ksf)

$\eta_{EV}$  = load modifier, specified in Article 1.3.2, as they apply to vertical earth loads on culverts

$\gamma_{EV}$  = load factor for vertical pressure from dead load of earth fill, as specified in Article 3.4.1

$\gamma_{WA}$  = load factor for hydrostatic pressure, as specified in Article 3.4.1

$VAF$  = vertical arching factor

$P_{sp}$  = geostatic earth pressure ( $EV$ ) as specified in Section 3. Does not include hydrostatic pressure (ksf)

$P_w$  = hydrostatic water pressure (ksf)

$H_s$  = depth of water table above springline of pipe (ft)

$\gamma_w$  = unit weight of water (kcf)

$\eta_{LL}$  = load modifier, as specified in Article 1.3.2, as they apply to live loads on culverts

$\gamma_{LL}$  = load factor for live load, as specified in Article 3.4.1

In Eq. 12.12.3.4-2, a factor of 1.3 is applied to water load to account for uncertainty of the level of the groundwater. The Engineer may vary this factor based on knowledge of actual site conditions.

For  $\eta$  factors, refer to Article 12.5.4 regarding assumptions about redundancy for earth loads and live loads.

Figure C3.11.3-1 shows the effect of groundwater on the earth pressure.  $P_{sp}$  does not include the hydrostatic pressure.  $P_{sp}$  is the pressure due to the soil above and below the water table directly above the pipe. See Table 3.5.1-1 for common unit weights.

The use of the vertical arching factor is based on the behavior demonstrated by Burns and Richard (1964), that pipe with high hoop stiffness ratios (ratio of soil stiffness to pipe hoop stiffness) carry substantially less load than the weight of the prism of soil directly over the pipe. This behavior was demonstrated experimentally by Hashash and Selig (1990) and analytically by Moore (1995). McGrath (1999) developed the simplified form of the equation presented in Eq. 12.12.3.4-3.

If evaluating the short-term loading conditions, then use the initial modulus of elasticity to compute  $S_H$ . Similarly, if evaluating the long-term loading conditions, then use the 50-yr modulus of elasticity to compute  $S_H$ .

The initial modulus should be used when checking short-term thrust demands. The long-term modulus should be used when checking long-term thrust demands.

$P_L$	= pressure due to live load ( $LL$ ) and dynamic load allowance ( $IM$ ) impact loads (ksf)
$C_L$	= live load distribution coefficient $L_W / D_o < 1$
$L_W$	= horizontal live load distribution width in the circumferential direction, at the elevation of the crown (ft)
$S_H$	= hoop stiffness factor
$\phi_s$	= resistance factor for soil stiffness, $\phi_s = 0.9$
$M_s$	= constrained soil modulus specified in Table 12.12.3.4-1 (ksi)
$R$	= radius to centroid of culvert wall (in.)
$E$	= initial or long-term modulus of elasticity as specified in Table 12.12.3.3-1 (ksi)
$A$	= wall area (in. <sup>2</sup> /in.)

In the absence of site-specific data, the secant constrained soil modulus,  $M_s$ , may be selected from Table 12.12.3.4-1 based on the backfill type and density, and the geostatic earth pressure,  $P_{sp}$ . Linear interpolation between soil stress levels may be used for the determination of  $M_s$ .

For culverts under depths of fill up to 10.0 ft, the soil type and density selected from Table 12.12.3.4-1 should be representative of the conditions for a width of one-half diameter each side of the culvert, but never less than 18.0 in. each side of the culvert.

For culverts in embankment or wide trench installations under depths of fill greater than 10.0 ft, the soil type and density selected from Table 12.12.3.4-1 should be representative of the conditions for a width of one diameter each side of the culvert.

If the structural backfill material is compacted or uncompacted crushed stone then  $M_s$  values for Sn-100 and Sn-85, respectively, may be used.

Suggested practice is to design for a standard Proctor backfill density five percent less than specified by the contract documents.

For culverts in trench installations under depths of fill greater than 10.0 ft, evaluation of the values of  $M_s$  for in-situ soil for a width one diameter on either side of the pipe is not necessary, provided the in-situ soil has adequate vertical and lateral stiffness. Stable trench walls, during the excavation process, are generally predictive of adequate vertical and lateral stiffness for this application.

Installation in narrow trenches reduces the vertical load, provided vertical stiffness of the soil is adequate to carry the load that is distributed around the pipe due to arching, as represented by the vertical arching factor (VAF) in the design method and adequate space is preserved at the side of the pipe to place and compact backfill. The minimum trench widths provided in the *LRFD Bridge Construction Specifications* are set to provide adequate space. Narrow trenches yield a desirable level of conservatism, since the transfer of the load to in-situ trench wall is not considered in flexible pipe design.

If the structural backfill does not extend for one diameter on each side of culverts under 10 or more ft of fill, or one-half diameter, but not less than 18.0 in. each side of culverts under depths of fill up to 10.0 ft, then the value of  $M_s$  used may be a composite value representative of the structural backfill and the material at the sides of the structural backfill (see AWWA, 1996).

The secant constrained modulus may also be determined experimentally using the stress-strain curve resulting from a uniaxial strain test on a sample of soil compacted to the field specified density. The constrained modulus is the slope of the secant from the origin of the curve to a point on the curve corresponding to the geostatic earth pressure,  $P_{sp}$ .

Note that the units for wall area are in.<sup>2</sup>/in. in this Article. In other Articles, wall area is usually specified in in.<sup>2</sup>/ft.

**Table 12.12.3.4-1— $M_s$  Based on Soil Type and Compaction Condition**

$P_{sp}$ Stress level (ksf)	Sn-100 (ksi)	Sn-95 (ksi)	Sn-90 (ksi)	Sn-85 (ksi)
0.15	2.350	2.000	1.275	0.470
0.75	3.450	2.600	1.500	0.520
1.50	4.200	3.000	1.625	0.570

9.00	0.895	0.525	0.345	

1. The soil types are defined by a two-letter designation that indicates general soil classification, Sn for sands and gravels, Si for silts and Cl for clays. Specific soil groups that fall into these categories, based on [ASTM D2487](#) and AASHTO M 145, are listed in Table 12.12.3.4-2.
2. The numerical suffix to the soil type indicates the compaction level of the soil as a percentage of maximum dry density determined in accordance with AASHTO T 99.

**Table 12.12.3.4-2—Equivalent ASTM and AASHTO Soil Classifications**

Basic Soil Type (1)	ASTM D2487	AASHTO M 145
Sn (Gravelly sand, SW)	SW, SP (2) GW, GP sands and gravels with 12% or less fines	A1, A3 (2)
Si (Sandy silt, ML)	GM, SM, ML also GC and SC with less than 20% passing a No. 200 sieve	A-2-4, A-2-5, A4
Cl (Silty clay, CL)	CL, MH, GC, SC also GC and SC with more than 20% passing a No. 200 sieve	A-2-6, A-2-7, A5, A6

1. The soil classification listed in parentheses is the type that was tested to develop the constrained soil modulus values in Table 12.12.3.4-1. The correlations to other soil types are approximate.
2. Uniformly graded materials with an average particle size smaller than a No. 40 sieve shall not be used as backfill for thermoplastic culverts unless specifically allowed in the contract documents and special precautions are taken to control moisture content and monitor compaction levels.

### 12.12.3.5—Wall Resistance

#### 12.12.3.5.1—General

#### C12.12.3.5.1

The factored tensile resistance of the wall to thrust,  $R_r$ , shall be taken as:

$$R_r = \phi A F_u \quad (12.12.3.5.1-1)$$

where:

$R_r$  = factored tensile resistance to thrust (kip/ft)

$\phi$  = resistance factor specified in Article 12.5.5

$A$  = wall area ( $\text{in.}^2/\text{ft}$ )

$F_u$  = tensile strength as specified in Table 12.12.3.3-1 (ksi)

The factored compressive resistance of the wall to thrust,  $R_r$ , shall be taken as:

$$R_r = \phi A_{\text{eff}} F_u \quad (12.12.3.5.1-2)$$

where:

$R_r$  = factored compressive resistance to thrust (kip/ft)

$A_{\text{eff}}$  = effective wall area ( $\text{in.}^2/\text{ft}$ )

The limits on combined strain specified in Article 12.12.3.5.4 shall also apply.

If the evaluation for local buckling capacity in Article 12.12.3.5.3 results in a reduced total effective area, then the reduced effective area shall be used in evaluating the factored resistance.

The local buckling evaluation reduces the capacity of pipe wall sections with high ratios of width to thickness.

#### 12.12.3.5.2—Buckling

The pipe wall shall be investigated for buckling. If  $f_{cr} < F_u$ , the value of  $R_r$  shall be recalculated using  $f_{cr}$  in lieu of  $F_u$ .

$$f_{cr} = 9.24 \frac{R}{A_{\text{eff}}} \sqrt{B' R_w \phi_s M_s \left( \frac{EI}{0.149 R^3} \right)} \quad (12.12.3.5.2-1)$$

in which:

$$B' = \frac{1}{1 + 4e^{-0.065h}} \quad (12.12.3.5.2-2)$$

$$R_w = 1 - 0.33 \frac{h_w}{h} \quad (12.12.3.5.2-3)$$

where:

$f_{cr}$  = critical buckling stress (ksi)

$R$  = radius to centroid of culvert wall (in.)

$A_{eff}$  = effective wall area ( $\text{in.}^2/\text{ft}$ )

$B'$  = nonuniform stress distribution factor

$h$  = height of ground surface above pipe (ft)

$R_w$  = water buoyancy factor

$h_w$  = height of water surface above pipe (ft)

$\phi_s$  = resistance factor for soil stiffness,  $\phi_s = 0.9$

$M_s$  = constrained soil modulus, Table 12.12.3.4-1 (ksi)

$E$  = long-term modulus of elasticity as specified in Table 12.12.3.3-1 (ksi)

$I$  = moment of inertia ( $\text{in.}^4/\text{in.}$ )

### *12.12.3.5.3—Resistance to Local Buckling of Pipe Wall*

#### *12.12.3.5.3a—General*

Elements of profile wall pipe shall be designed to resist local buckling in accordance with the following provisions.

#### *12.12.3.5.3b—Idealized Wall Profile*

For the determination of buckling resistance, profile wall pipe shall be idealized as straight elements. Each element shall be assigned a width based on the clear distance between the adjoining elements and a thickness based on the thickness at the center of the element. See Figure 12.12.3.5.3b-1 for the idealization of a typical corrugated profile.

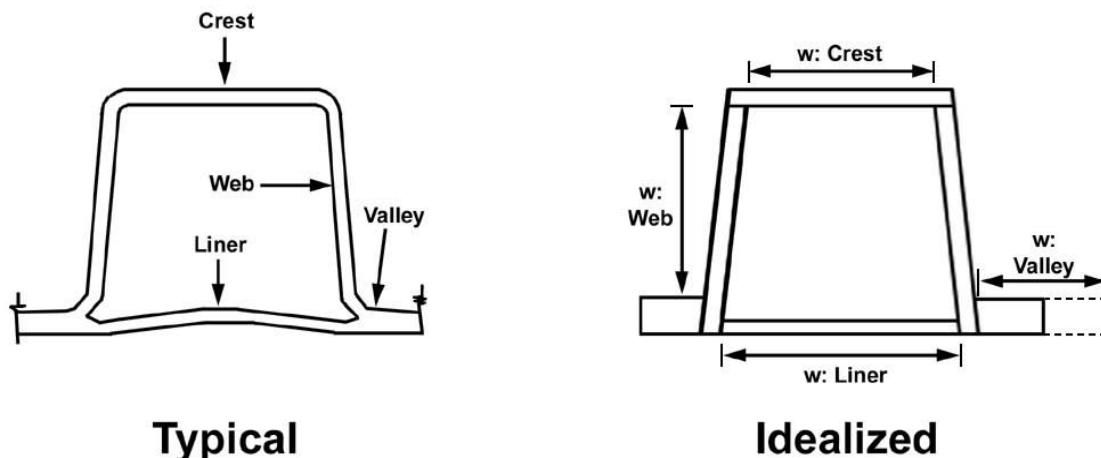

Figure 12.12.3.5.3b-1—Typical and Idealized Cross-Section of Profile Wall Pipe

*12.12.3.5.3c—Slenderness and Effective Width*

The effective width of each element for buckling shall be determined as:

$$b = \rho w \quad (12.12.3.5.3c-1)$$

in which:

$$\rho = \frac{\left(1 - \frac{0.22}{\lambda}\right)}{\lambda} \leq 1 \quad (12.12.3.5.3c-2)$$

$$\lambda = \left(\frac{w}{t}\right) \sqrt{\frac{\varepsilon}{k}} > 0.673 \quad (12.12.3.5.3c-3)$$

in which:

$$\varepsilon = \frac{T_L}{(AE_{50})} \quad (12.12.3.5.3c-4)$$

where:

$A$  = wall area specified in Article 12.12.3.5.1  
(in.<sup>2</sup>/ft)

$b$  = element effective width (in.)

$\varepsilon$  = strain in element (in./in.)

$\rho$  = effective width factor

$w$  = total clear width of element between supporting elements (in.)

$\lambda$  = slenderness factor

*C12.12.3.5.3c*

The resistance to local buckling is based on the effective width concept used by the cold formed steel industry (AISI, 1997). This theory assumes that even though buckling is initiated in the center of a plate element, the element still has substantial post-buckling strength at the edges where the element is supported. This concept is demonstrated in Figure C12.12.3.5.3c-1.

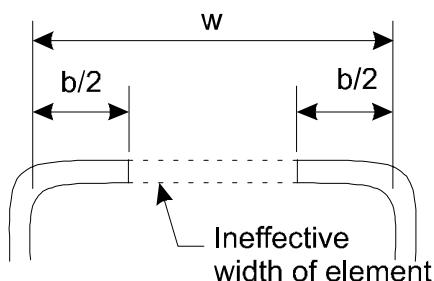

Figure C12.12.3.5.3c-1—Effective Width Concept

$t$  = thickness of element (in.)

$k$  = edge support coefficient

$E_{50}$  = 50-yr modulus of elasticity (ksi)

$T_L$  = factored thrust per unit length (kip/ft)

The edge support coefficient,  $k$ , may be taken as 4.0 for elements with both edges supported, and 0.43 for free standing elements such as ribs.

The total effective area,  $A_{eff}$ , shall be determined as the summation of the effective area for each element of the idealized wall profile taken as:

$$A_{eff} = \frac{A_g - \sum(1 - \rho_i)w_i t_i}{\omega} \quad (12.12.3.5.3c-5)$$

where:

$A_{eff}$  = effective area of pipe wall, the lesser of the gross area or the reduced area computed based on local buckling (in.<sup>2</sup>/ft)

$\omega$  = spacing of corrugation (ft)

$A_g$  = gross wall area within a length of one period (in.<sup>2</sup>)

#### 12.12.3.5.4—Combined Strain

##### 12.12.3.5.4a—General

The total factored compressive strain in a pipe wall due to thrust and bending shall not exceed the limiting combined compressive strain,  $\varepsilon_{cu}$ , determined as:

$$\varepsilon_{cu} = \varepsilon_{bu} + \frac{T_L}{A_{eff} E_{50}} \times \frac{\gamma_B}{\gamma_p} \leq \frac{1.5 F_u}{E_{50}} \quad (12.12.3.5.4a-1)$$

in which:

$$\varepsilon_{bu(max)} = \frac{1.5 F_u}{E_{50}} - \frac{T_L}{A_{eff} E_{50}} \times \frac{\gamma_B}{\gamma_p} \quad (12.12.3.5.4a-2)$$

where:

$F_u$  = tensile strength specified in Article 12.12.3.5.1

$\varepsilon_{bu(max)}$  = factored limiting combined compressive strain taken as  $\gamma_B \varepsilon_c$  (in./in.)

$\gamma_B$  = 1.5, modified load factor applied to combined strain

##### C12.12.3.5.4a

The criteria for combined compressive strain is based on limiting local buckling. A higher strain limit is allowed for combined strain because the web elements, which are subjected primarily to bending, are less likely to buckle and increase the stability of elements near the crest and valley.

The strain limit for combined compression strain is 50 percent higher than that for hoop compression alone because the web elements, which experience low strains due to bending, are not likely to buckle, thus increasing the stability of elements near the crest and valley. While this behavior would be more accurately modeled as an increase in the  $k$  factor of Eq. 12.12.3.5.3c-3, the increase in the limiting strain is considered adequate for this simplified design method.

For thrust capacity, the section is limited by consideration of hoop compression capacity alone. The check of combined compression strain, hoop plus bending, is used to limit the allowable pipe deflection.

Elements subjected primarily to bending (such as a web element in Figure 12.12.3.5.3b-1 when the pipe is deflected) are not highly stressed near the centroid, where buckling initiates, and theoretical  $k$  factors for

$\gamma_p$  = maximum load factor for permanent load resulting from Vertical Earth Pressure ( $E_V$ ) for the case of flexible buried structures other than metal box culverts, specified in Table 3.4.1-2

Total factored tension strain in the pipe wall due to thrust and bending shall not exceed the limiting combined tension strain,  $\varepsilon_{tu}$ , determined as:

$$\varepsilon_{tu} = \varepsilon_{bu} - \frac{T_L}{A_{eff} E_{50}} \times \frac{\gamma_B}{\gamma_p} \leq \varepsilon_{tt} \quad (12.12.3.5.4a-3)$$

where:

$\varepsilon_b$  = unfactored bending strain (in./in.)

$\varepsilon_{bu}$  = factored bending strain =  $\gamma_B \varepsilon_b$  (in./in.)

$\varepsilon_{tt}$  = factored long-term tension strain =  $\gamma_B \varepsilon_t$  (in./in.)

$\varepsilon_t$  = allowable tension strain as specified in Table 12.12.3.3-1 (in./in.)

#### 12.12.3.5.4b—Bending Strain

In the absence of a more detailed analysis, the bending strain may be computed based on an empirical relationship between strain and deflection taken as:

$$\varepsilon_{bu} = \gamma_B D_f \left( \frac{c}{R} \right) \left( \frac{\Delta}{D} \right) \quad (12.12.3.5.4b-1)$$

in which:

$$\Delta = 0.05 D - \frac{T_L D}{A_{eff} E_{50} \gamma_p} \quad (12.12.3.5.4b-2)$$

where:

$\varepsilon_{bu}$  = factored bending strain (in./in.)

$D_f$  = shape factor specified in Table 12.12.3.5.4b-1

$R$  = radius to centroid of pipe wall profile (in.)

$c$  = distance from neutral axis to extreme fiber (in.)

$\Delta$  = deflection of pipe, reduction of vertical diameter due to bending (in.)

$D$  = diameter to centroid of pipe wall (in.)

plates in bending are greater than 20. To simplify the analysis for combined bending and thrust, elements, such as the web whose centroid is within  $c/3$  of the centroid of the entire profile wall, may be analyzed only for the effect of hoop compression strains. That is, increases in strain due to bending may be ignored.

#### C12.12.3.5.4b

The empirical shape factor is used in the design of fiberglass pipe and is presented in AWWA Manual of Practice M45 Fiberglass Pipe Design (1996). It demonstrates that bending strains are highest in low stiffness pipe backfilled in soils that require substantial compactive effort (silts and clays), and is lowest in high stiffness pipe backfilled in soils that require little compactive effort (sands and gravels).

Table 12.12.3.5.4b-1 does not cover all possible backfills and density levels. Designers should interpolate or extrapolate the Table as necessary for specific projects.

More detailed analyses must consider the likelihood of inconsistent soil support to the pipe in the haunch zone, and of local deformations during placement and compaction of backfill.

Bending strains typically cannot be accurately predicted during design due to variations in backfill materials and compactive effort used during installation. Installation deflection limits are specified in the construction specifications to assure that design parameters are not exceeded.

The deflection design limit is five percent reduction of the vertical diameter as specified in the construction specification. The pipe must be designed to permit this deflection, unless extraordinary measures are specified in contract documents to minimize compactive effort and to control deflections.

**Table 12.12.3.5.4b-1—Shape Factors,  $D_f$ , based on Pipe Stiffness, Backfill and Compaction Level**

Pipe Stiffness $(F/\Delta_y, \text{ ksi})$ $= EI / 0.149 R^3$	Pipe Zone Embedment Material and Compaction Level			
	Gravel (1)		Sand (2)	
	Dumped to Slight (3)	Moderate to High (4)	Dumped to Slight (3)	Moderate to High (4)
0.009	5.5	7.0	6.0	8.0
0.018	4.5	5.5	5.0	6.5
0.036	3.8	4.5	4.0	5.5
0.072	3.3	3.8	3.5	4.5

1. GW, GP, GW-GC, GW-GM, GP-GC and GP-GM per [ASTM D2487](#) (includes crushed rock)
2. SW, SP, SM, SC, GM and GC or mixtures per [ASTM D2487](#)
3. <85% of maximum dry density per AASHTO T 99, < 40% relative density ([ASTM D4253](#) and [D4254](#))
4. ≥85% of maximum dry density per AASHTO T 99, ≥ 40% relative density ([ASTM D4253](#) and [D4254](#))

### 12.12.3.6—Handling and Installation Requirements

The flexibility factor,  $FF$ , in in./kip shall be taken as:

$$FF = \frac{S^2}{EI} \quad (12.12.3.6-1)$$

where:

$I$  = moment of inertia (in.<sup>4</sup>/in.)

$E$  = initial modulus of elasticity (ksi)

$S$  = diameter of pipe (in.)

The flexibility factor,  $FF$ , shall be limited as specified in Article 12.5.6.3.

## 12.13—STEEL TUNNEL LINER PLATE

### 12.13.1—General

The provisions of this Article shall apply to the structural design of steel tunnel liner plates. Construction shall conform to Section 25, "Steel and Concrete Tunnel Liners," *AASHTO LRFD Bridge Construction Specifications*.

The tunnel liner plate may be two-flange, fully corrugated with lapped longitudinal seams or four-flange, partially corrugated with flanged longitudinal seams. Both types shall be bolted together to form annular rings.

### C12.13.1

The supporting capacity of a nonrigid tunnel lining, such as a steel liner plate, results from its ability to deflect under load, so that side restraint developed by the lateral resistance of the soil constrains further deflection. Thus, deflection tends to equalize radial pressures and to load the tunnel liner as a compression ring.

## 12.13.2—Loading

The provisions for earth loads given in Article 3.11.5 shall not apply to tunnels.

## C12.13.2

The earth load to be carried by the tunnel liner is a function of the type of soil. In granular soil with little or no cohesion, the load is a function of the angle of internal friction of the soil and the diameter of the tunnel. In cohesive soils such as clays, the load to be carried by the tunnel liner is dependent on the shearing strength of the soil above the roof of the tunnel.

### 12.13.2.1—Earth Loads

The provisions of Article 12.4.1 shall apply. When more refined methods of soil analysis are not employed, the earth pressure may be taken as:

$$W_E = C_{dt} \gamma_s S \quad (12.13.2.1-1)$$

where:

$C_{dt}$  = load coefficient for tunnel installation specified in Figure 12.13.2.1-1

$\gamma_s$  = total unit weight of soil (kcf)

$W_E$  = earth pressure at the crown (ksf)

$S$  = tunnel diameter or span (ft)

### C12.13.2.1

Eq. 12.13.2.1-1 is a form of the Marston formula. It proportions the amount of total overburden pressure acting on the tunnel based on the internal friction angle of the soil to be tunneled.

In the absence of adequate borings and soil tests, use  $\phi_f = 0$  when calculating  $W_E$ .

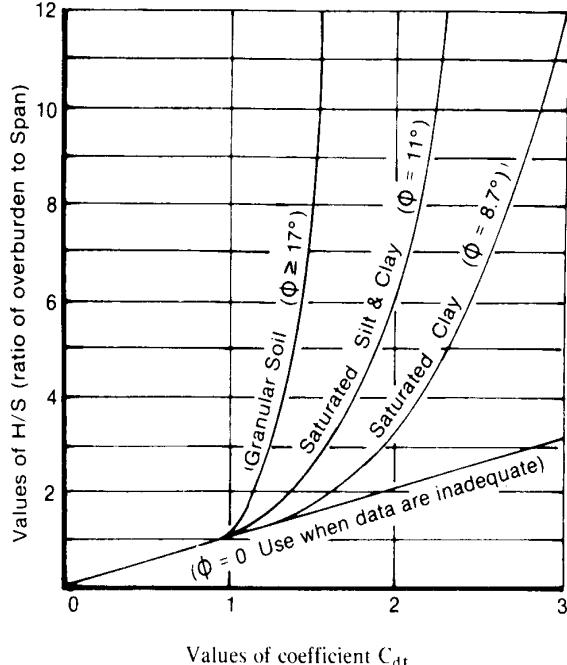

Figure 12.13.2.1-1—Diagram for Coefficient  $C_{dt}$  for Tunnel in Soil

in which:

$H$  = height of soil over top of tunnel (ft)

### **12.13.2.2—Live Loads**

The provisions of Article 12.6.1 shall apply.

### **12.13.2.3—Grouting Pressure**

If the grouting pressure is greater than the computed design load, the design load,  $W_T$ , on the tunnel liner shall be the grouting pressure.

### **12.13.3—Safety against Structural Failure**

#### **12.13.3.1—Section Properties**

Steel tunnel liner plate shall meet the minimum requirements of Table 12.13.3.1-1 for cross-sectional properties, Table 12.13.3.1-2 for seam strength, and Table 12.13.3.1-3 for mechanical properties.

#### **12.13.3.2—Wall Area**

The requirements of Articles 12.7.2.2 and 12.7.2.3 shall apply using effective area from Table 12.13.3.1-1.

#### **12.13.3.3—Buckling**

The requirements of Article 12.7.2.4 shall apply, except that the soil stiffness factor,  $k$ , may vary from 0.22 to 0.44 depending upon the quality and extent of the backfilling material used.

#### **C12.13.3.3**

Wall buckling is a function of the stiffness,  $k$ , of the surrounding soil bearing on the plates. Where portland cement grouting or quality backfilling (meeting the requirements of Section 25, "Steel and Concrete Tunnel Liners," *AASHTO LRFD Bridge Construction Specifications*) material fill the void outside the plates,  $k = 0.22$  is applicable. For other soils or in-situ backfilling material,  $k = 0.44$  is suggested. Where tunneled soils slough or voids are left in the backfilling, additional consideration as to the value of  $k$  may be required.

#### **12.13.3.4—Seam Strength**

The requirements of Article 12.7.2.5 shall apply.

#### **12.13.3.5—Construction Stiffness**

Construction stiffness shall be indicated by a construction stiffness factor as:

$$C_s = \frac{EI}{S^2} \quad (12.13.3.5-1)$$

where:

$S$  = diameter or span (in.)

$E$  = modulus of elasticity (ksi)

$I$  = moment of inertia ( $\text{in.}^4/\text{in.}$ )

The value of  $C_s$  from Eq. 12.13.3.5-1 shall not be less than the values for steel tunnel liner plate as given in Article 12.5.6.4.

#### **C12.13.3.5**

The liner plate ring should have sufficient rigidity to resist the unbalanced loads of normal construction from grouting, local slough-ins, and miscellaneous concentrated loads.

The minimum construction stiffness required for these loads,  $C_s$ , can be expressed for convenience by the formula below. It must be recognized, however, that the limiting values given here are only recommended minimums. Actual job conditions may require greater effective stiffness. Final determination of this factor should be based on intimate knowledge of the project and on practical experience.

The construction stiffness,  $C_s$ , given by Eq. 12.13.3.5-1, considers the moment of inertia of an individual plate.

0.375	0.625	—	—	0.625	A307	119

All nuts shall conform to [ASTM A307](#), Grade A or better.

Circumferential seam bolts shall conform to [ASTM A307](#) or better for all plate thicknesses.

**Table 12.13.3.1-3—Mechanical Properties—Steel Tunnel Liner Plate (Plate before Cold Forming)**

Minimum Tensile Strength	42.0 ksi
Minimum Yield Strength	28.0 ksi
Elongation, 2.0 in.	30%
Modulus of Elasticity	29,000 ksi

**12.14—PRECAST REINFORCED CONCRETE THREE-SIDED STRUCTURES****12.14.1—General**

The provisions herein shall apply to the design of precast reinforced concrete three-sided structures supported on a concrete footing foundation.

**C12.14.1**

Units may be manufactured using conventional structural concrete and forms (formed) or machine made using dry concrete and vibrating forms.

**12.14.2—Materials****12.14.2.1—Concrete**

Concrete shall conform to Article 5.4.2, except that evaluation of  $f'_c$  may also be based on cores.

**12.14.2.2—Reinforcement**

Reinforcement shall meet the requirements of Article 5.4.3, except that for welded wire fabric a yield strength of 65,000 psi may be used. For wire fabric, the spacing of longitudinal wires shall be a maximum of 8.0 in. Circumferential welded wire fabric spacing shall not be greater than 4.0 in. or less than 2.0 in. Prestressing, if used, shall be in accordance with Article 5.9.

**12.14.3—Concrete Cover for Reinforcement**

The minimum concrete cover for reinforcement in precast three-sided structures reinforced with welded wire fabric shall be taken as three times the wire diameter, but not less than 1.0 in., except for the reinforcement in the top of the top slab of structures covered by less than 2.0 ft of fill, in which case the minimum cover shall be taken as 2.0 in.

**12.14.4—Geometric Properties**

Except as noted herein, the shape of the precast three-sided structures may vary in span, rise, wall thickness, haunch dimensions, and curvature. Specific geometric properties shall be specified by the manufacturer. Wall thicknesses shall be a minimum of 8.0 in. for spans under 24.0 ft and 10.0 in. for 24.0 ft and larger spans.

**12.14.5—Design****12.14.5.1—General**

Designs shall conform to applicable sections of these Specifications, except as provided otherwise herein. Analysis shall be based on a pinned connection at the footing and shall take into account anticipated footing movement.

### **12.14.5.2—Distribution of Concentrated Load Effects in Top Slab and Sides**

Distribution of wheel loads and concentrated loads for the top slab and sides of three-sided structures shall be taken as specified in Article 12.11.2.1.

### **12.14.5.3—Distribution of Concentrated Loads in Skewed Culverts**

Wheel loads on skewed culverts shall be distributed using the same provisions as given for culverts with main reinforcement parallel to traffic. For culvert elements with skews greater than 15 degrees, the effect of the skew shall be considered in analysis.

### **12.14.5.4—Shear Transfer in Transverse Joints between Culvert Sections**

The provisions of Article 4.6.2.10.4 shall apply.

In addition, except as provided herein, a means of shear transfer between adjacent units shall be provided in the top slab of structures having flat tops under less than 2.0 ft of fill and subjected to vehicular live loads. Shear transfer between adjacent units may be considered adequate where the thickness of the top slab is equal to or greater than:

- For prestressed slabs:  
 $S/28$  (12.14.5.4-1)
- For non-prestressed slabs:  
 $(S + 10)/30$  (12.14.5.4-2)

where:

$S$  = clear span (ft) measured parallel to the joint with the adjacent section

### **C12.14.5.4**

Flat top structures with less than 2.0 ft of fill and with top slabs that are thinner than specified in this Article may experience differential deflection of adjacent units which can cause pavement cracking if a means of shear transfer is not utilized.

The specified minimum slab thickness and span to slab thickness ratios reflect years of experience in the design and construction of flat top three-sided structures and are influenced by Table 9.5(a) of ACI 318-08 and Table 8.9.2 of the *AASHTO Standard Specifications for Highway Bridges*, 17th Edition. Past performance of flat top three-sided structures designed in accordance with these provisions provides additional support for this exception.

For skewed sections, design is based on the span measured parallel to the joint with the adjacent section. This is a longer span than measured perpendicular to the end walls. However, designing for a longer span provides additional reinforcement to address the non-uniform stresses introduced by the skewed geometry which are not explicitly considered for modest skew angles.

Arch-top structures, because of their geometry and interaction with the surrounding soil, do not exhibit significant differential deflections that could cause pavement cracking for structures with less than 2.0 ft of fill. Thus, the requirements of this Article do not apply to arch-top structures.

The minimum thickness provision of this Section pertains only to addressing the need for shear transfer between adjacent three-sided sections. All other provisions of this Specification must be met.

### **12.14.5.5—Span Length**

When monolithic haunches inclined at 45 degrees are taken into account, negative reinforcement in walls and slabs may be proportioned on the basis of bending moment at the intersection of the haunch and uniform depth member.

**12.14.5.6—Resistance Factors**

The provisions of Articles 5.5.4.2 and 1.3.1 shall apply as appropriate.

**12.14.5.7—Crack Control**

The provisions of Article 5.7.3.4 for buried structures shall apply.

**12.14.5.8—Minimum Reinforcement**

The provisions of Article 5.10.8 shall not be taken to apply to precast three-sided structures.

The primary flexural reinforcement in the direction of the span shall provide a ratio of reinforcement area to gross concrete area at least equal to 0.002. Such minimum reinforcement shall be provided at all cross-sections subject to flexural tension, at the inside face of walls, and in each direction at the top of slabs of three-sided sections with less than 2.0 ft of fill.

**12.14.5.9—Deflection Control at the Service Limit State**

The deflection limits for concrete structures specified in Article 2.5.2.6.2 shall be taken as mandatory and pedestrian usage as limited to urban areas.

**12.14.5.10—Footing Design**

Design shall include consideration of differential horizontal and vertical movements and footing rotations. Footing design shall conform to the applicable Articles in Sections 5 and 10.

**12.14.5.11—Structural Backfill**

Specification of backfill requirements shall be consistent with the design assumptions used. The contract documents should require that a minimum backfill compaction of 90 percent Standard Proctor Density be achieved to prevent roadway settlement adjacent to the structure. A higher backfill compaction density may be required on structures utilizing a soil-structure interaction system.

**12.14.5.12—Scour Protection and Waterway Considerations**

The provisions of Article 2.6 shall apply as appropriate.

## SECTION 13

# RAILINGS

### 13.1—SCOPE

This Section applies to railings for new bridges and for rehabilitated bridges to the extent that railing replacement is determined to be appropriate.

This Section provides six bridge railing test levels and their associated crash test requirements. Guidance for determining the level to meet the warrants for the more common types of bridge sites and guidance for structural and geometric design of railings are provided.

A process for the design of crash test specimens to determine their crashworthiness is described in Appendix A. This methodology is based on an application of the yield line theory. For use beyond the design of test specimens with expected failure modes similar to those shown in Figures CA13.3.1-1 and CA13.3.1-2, a rigorous yield line solution or a finite element solution should be developed. The procedures of Appendix A are not applicable to traffic railings mounted on rigid structures, such as retaining walls or spread footings, when the cracking pattern is expected to extend to the supporting components.

### 13.2—DEFINITIONS

*Agency*—A responsible business or service authorized to act on behalf of others, i.e., a governmental department, consulting engineering firm, or owner of the facility or feature.

*Barrier Curb*—A platform or block used to separate a raised pedestrian and/or bicycle sidewalk above the roadway level; see Figure 13.7.1.1-1.

*Bicycle Railing*—A railing or fencing system, as illustrated in Figure 13.9.3-1, that provides a physical guide for bicyclists crossing bridges to minimize the likelihood of a bicyclist falling over the system.

*Bridge Approach Railing*—A roadside guardrail system preceding the structure and attached to the bridge rail system that is intended to prevent a vehicle from impacting the end of the bridge railing or parapet.

*Combination Railing*—A bicycle or pedestrian railing system, as illustrated in Figures 13.8.2-1 and 13.9.3-1, added to a crashworthy bridge vehicular railing or barrier system.

*Concrete Barrier*—A railing system of reinforced concrete having a traffic face that usually but not always adopts some form of a safety shape.

*Concrete Parapet*—A railing system of reinforced concrete, usually considered an adequately reinforced concrete wall.

*Crash Testing of Bridge Railings*—Conducting a series of full-scale impact tests of a bridge railing in accordance with the recommended guidelines in NCHRP Report 350 in order to evaluate the railing's strength and safety performance.

*Crashworthy*—A system that has been successfully crash-tested to a currently acceptable crash test matrix and test level or one that can be geometrically and structurally evaluated as equal to a crash-tested system.

*Design Force*—An equivalent static force that represents the dynamic force imparted to a railing system by a specified vehicle impacting a railing at a designated speed and angle.

### C13.1

All bridge traffic barrier systems will be referred to as railings herein.

The bridge railing performance need not be identical over the whole highway network. New railing designs should match site needs leading to a multiple test level concept, as described in NCHRP Report 350.

Previously crash tested railing should retain its test level approval and should not have to be tested to meet NCHRP Report 350 updating.

With the finite resources available to bridge owners, it is not reasonable to expect all existing rails to be updated any more than to expect every existing building to be immediately updated with the passing of a new building code. Many existing bridge rails have proven functional and need only be replaced when removed for bridge widenings.

*Encroachment*—An intrusion into prescribed, restrictive, or limited areas of a highway system, such as crossing a traffic lane or impacting a barrier system. Also, the occupancy of highway right-of-way by nonhighway structures or objects of any kind or character.

*End Zone*—The area adjacent to any open joint in a concrete railing system that requires added reinforcement.

*Expressway*—A controlled access arterial highway that may or may not be divided or have grade separations at intersections.

*Face of the Curb*—The vertical or sloping surface on the roadway side of the curb.

*Freeway*—A controlled access divided arterial highway with grade separations at intersections.

*Longitudinal Loads*—Horizontal design forces that are applied parallel to the railing or barrier system and that result from friction on the transverse loads.

*Multiple Use Railing*—Railing that may be used either with or without a raised sidewalk.

*Owner*—An authority or governmental department representing investors and/or taxpayers that is responsible for all the safety design features and functions of a bridge.

*Pedestrian Railing*—A railing or fencing system, as illustrated in Figure 13.8.2-1, providing a physical guidance for pedestrians across a bridge so as to minimize the likelihood of a pedestrian falling over the system.

*Post*—A vertical or sloping support member of a rail system that anchors a railing element to the deck.

*Rail Element*—Any component that makes up a railing system. It usually pertains to a longitudinal member of the railing.

*Severity*—A characterization of the degree of an event. It is usually associated with characterizing accidents as fatal, injury, or property damage only so that a dollar value can be assessed for economic study. It may also pertain to indexing the intensity of an accident so that a railing system can be assessed as a preventive or safety measure.

*Speeds—Low/High*—Vehicle velocities in mph. Low speeds are usually associated with city or rural travel where speeds are well posted and are under 45 mph. High speeds are usually associated with expressways or freeways where posted speeds are 45 mph or more.

*Traffic Railing*—Synonymous with vehicular railing; used as a bridge or structure-mounted railing, rather than a guardrail or median barrier as in other publications.

*Transverse Loads*—Horizontal design forces that are applied perpendicular to a railing or barrier system.

*Vehicle Rollover*—A term used to describe an accident in which a vehicle rotates at least 90° about its longitudinal axis after contacting a railing. This term is used if the vehicle rolls over as a result of contacting a barrier and not another vehicle.

*Warrants*—A document that provides guidance to the Designer in evaluating the potential safety and operational benefits of traffic control devices or features. Warrants are not absolute requirements; rather, they are a means of conveying concern over a potential traffic hazard.

### 13.3—NOTATION

$A_f$	= area of post compression flange (in. <sup>2</sup> ) (A13.4.3.2)
$B$	= out-to-out wheel spacing on an axle (ft); distance between centroids of tensile and compressive stress resultants in post (in.) (A13.2) (A13.4.3.2)
$b$	= length of deck resisting post strength or shear load = $h + W_b$ (A13.4.3.2)
$C$	= vertical post capacity or compression flange resistance of post in bending (kip-ft) (CA13.4.3.2)
$d_b$	= distance from the outer edge of the base plate to the innermost row of bolts (in.) (A13.4.3.1)
$E$	= distance from edge of slab to centroid of compressive stress resultant in post (in.) (A13.4.3.2)

$F_L$	= longitudinal friction force along rail = 0.33 $F_t$ (kips) (A13.2)
$F_t$	= transverse vehicle impact force distributed over a length $L_t$ at a height $H_e$ above bridge deck (kips) (A13.2)
$F_v$	= vertical force of vehicle laying on top of rail (kips) (A13.2)
$f'_c$	= 28-day compressive strength of concrete (ksi) (A13.4.3.2)
$G$	= height of vehicle center of gravity above bridge deck (in.) (A13.2)
$H$	= height of wall (ft) (A13.3.1)
$H_R$	= height of rail (ft) (13.4)
$H_w$	= height of wall (ft) (13.4)
$h$	= depth of slab (in.) (A13.4.3.2)
$L$	= post spacing of single span (ft) (A13.3.2)
$L_c$	= critical length of wall failure (ft) (A13.3.1)
$L_L$	= longitudinal length of distribution of friction force $F_L$ , $L_L = L_t$ (ft) (A13.2)
$L_t$	= longitudinal length of distribution of impact force $F_t$ along the railing located a height of the $H_e$ above the deck (ft) (A13.2)
$L_v$	= longitudinal distribution of vertical force $F_v$ on top of railing (ft) (A13.2)
$\ell$	= length of vehicle impact load on railing or barrier taken as $L_b$ , $L_v$ , or $L_L$ , as appropriate (ft) (A13.3.1)
$M_b$	= ultimate moment capacity of beam at top of wall (kip-ft) (A13.3.1)
$M_c$	= ultimate flexural resistance of wall about horizontal axis (kip-ft/ft) (A13.3.1)
$M_d$	= deck overhang moment (kip-ft/ft) (A13.4.3.1)
$M_p$	= plastic or yield line resistance of rail (kip-ft) (A13.3.2)
$M_{post}$	= plastic moment resistance of a single post (kip-ft) (A13.3.2)
$M_w$	= ultimate flexural resistance of wall about vertical axis (kip-ft) (A13.3.1)
$P_p$	= shear force on a single post which corresponds to $M_{post}$ and is located $\bar{Y}$ above the deck (kips) (A13.3.2)
$R$	= total ultimate resistance, i.e., nominal resistance, of the railing (kips) (A13.3.2)
$R_R$	= ultimate capacity of rail over one span (kips) (A13.3.3)
$R'_R$	= ultimate transverse resistance of rail over two spans (kips) (A13.3.3)
$R_w$	= total transverse resistance of the railing (kips); ultimate capacity of wall as specified in Article A13.3.1 (kips) (A13.3.1) (A13.3.3)
$R'_w$	= capacity of wall, reduced to resist post load (kips) (A13.3.3)
$\bar{R}$	= sum of horizontal components of rail strengths (kips) (A13.2)
$T$	= tensile force per unit of deck length (kip/ft) (A13.4.2)
$V_c$	= nominal shear resistance provided by tensile stresses in the concrete (kips) (A13.4.3.2)
$V_n$	= nominal shear resistance of the section considered (kips) (A13.4.3.2)
$V_r$	= factored shear resistance (kips) (A13.4.3.2)
$V_u$	= factored shear force at section (kips) (A13.4.3.2)
$W$	= weight of vehicle corresponding to the required test level, from Table 13.7.2-1 (kips) (13.7.2)
$W_b$	= width of base plate or distribution block (ft); width of base plate (in.) (A13.4.3.1) (A13.4.3.2)
$X$	= length of overhang from face of support to exterior girder or web (ft) (A13.4.3.1)
$\bar{Y}$	= height of $\bar{R}$ above bridge deck (in.) (A13.2)
$\beta_c$	= ratio of the long side to the short side of the concentrated load or reaction area (A13.4.3.2)
$\phi$	= resistance factor = 1.0 (A13.4.3.2)

**13.4—GENERAL****C13.4**

The Owner shall develop the warrants for the bridge site. A bridge railing should be chosen to satisfy the concerns of the warrants as completely as possible and practical.

Railings shall be provided along the edges of structures for protection of traffic and pedestrians. Other applications may be warranted on bridge-length culverts.

Additional guidance applicable to bridge-length culverts may be found in the AASHTO *Roadside Design Guide*.

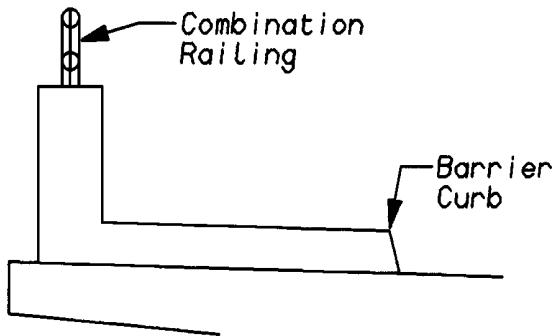

A pedestrian walkway may be separated from an adjacent roadway by a barrier curb, traffic railing, or combination railing, as indicated in Figure 13.4-1. On high-speed urban expressways where a pedestrian walkway is provided, the walkway area shall be separated from the adjacent roadway by a traffic railing or combination railing.

The following guidelines indicate the application of various types of rails:

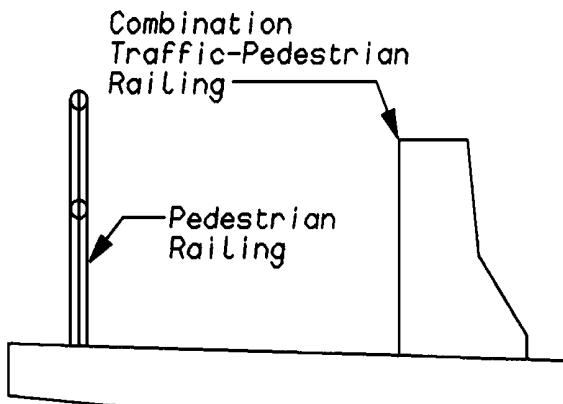

- Traffic railing is used when a bridge is for the exclusive use of highway traffic;
- A combination barrier in conjunction with a raised curb and sidewalk is used only on low-speed highways;
- On high-speed highways, the pedestrian or bicycle path should have both an outboard pedestrian or bicycle railing and an inboard combination railing; and
- Separate pedestrian bridges should be considered where the amount of pedestrian traffic or other risk factors so indicate.

For the purpose of this Article, low speed may be taken as speeds not exceeding 45 mph. High speed may be taken as speeds in excess of 45 mph.

The walkway faces of combination railings separating walkways from adjacent roadways serve as pedestrian or bicycle railings. When the height of such railings above the walkway surface is less than the minimum height required for pedestrian or bicycle railings, as appropriate, the Designer may consider providing additional components, such as metal rails, on top of the combination railing. The additional components need to be designed for the appropriate pedestrian or bicycle railing design forces.

*Low Speed Application*

*High Speed Application*

Figure 13.4-1—Pedestrian Walkway

New bridge railings and the attachment to the deck overhang shall satisfy crash testing requirements to confirm that they meet the structural and geometric requirements of a specified railing test level using the test criteria specified in Article 13.7.2.

Warning devices for pedestrians are beyond the scope of these Specifications, but they should be considered.

Procedures for testing railing are given in *NCHRP Report 350: Recommended Procedures for the Safety Performance Evaluation of Highway Features*.

**13.5—MATERIALS****C13.5**

The requirements of Sections 5, 6, 7, and 8 shall apply to the materials employed in a railing system, unless otherwise modified herein.

Factors to be considered in choosing the material for use in any railing system include ultimate strength, durability, ductility, maintenance, ease of replacement, and long-term behavior.

**13.6—LIMIT STATES AND RESISTANCE FACTORS****13.6.1—Strength Limit State**

The strength limit states shall apply using the applicable load combinations in Table 3.4.1-1 and the loads specified herein. The resistance factors for post and railing components shall be as specified in Articles 5.5.4, 6.5.4, 7.5.4, and 8.5.2.

Design loads for pedestrian railings shall be as specified in Article 13.8.2. Design loads for bicycle railings shall be as specified in Article 13.9.3. Pedestrian or bicycle loadings shall be applied to combination railings as specified in Article 13.10.3. Deck overhangs shall be designed for applicable strength load combinations specified in Table 3.4.1-1.

**13.6.2—Extreme Event Limit State**

The forces to be transmitted from the bridge railing to the bridge deck may be determined from an ultimate strength analysis of the railing system using the loads given in Appendix A. Those forces shall be considered to be the factored loads at the extreme event limit state.

**13.7—TRAFFIC RAILING****13.7.1—Railing System****13.7.1.1—General****C13.7.1.1**

The primary purpose of traffic railings shall be to contain and redirect vehicles using the structure. All new vehicle traffic barrier systems, traffic railings, and combination railings shall be shown to be structurally and geometrically crashworthy.

Variations in traffic volume, speed, vehicle mix, roadway alignment, activities and conditions beneath a structure, and other factors combine to produce a vast variation in traffic railing performance requirements.

Consideration should be given to:

- Protection of the occupants of a vehicle in collision with the railing,
- Protection of other vehicles near the collision,
- Protection of persons and property on roadways and other areas underneath the structure,
- Possible future rail upgrading,
- Railing cost-effectiveness, and

- Appearance and freedom of view from passing vehicles.

A combination railing, conforming to the dimensions given in Figures 13.8.2-1 and 13.9.3-1, and crash tested with a sidewalk may be considered acceptable for use with sidewalks having widths 3.5 ft or greater and curb heights up to the height used in the crash test installation.

A railing designed for multiple use shall be shown to be crashworthy with or without the sidewalk. Use of the combination vehicle-pedestrian rail shown in Figure 13.7.1.1-1 shall be restricted to roads designated for 45 mph or less and need be tested to Test Level 1 or 2.

Because of more recent tests on sidewalks, an 8.0-in. maximum height for sidewalk curbs has generally been accepted.

AASHTO's *A Policy on Geometric Design of Highways and Streets* recommends that a barrier curb be used only for speeds of 45 mph or less. For speeds of 50 mph or greater, pedestrians should be protected by a separation traffic barrier.

A railing intended for use only on a sidewalk need not be tested without the sidewalk.

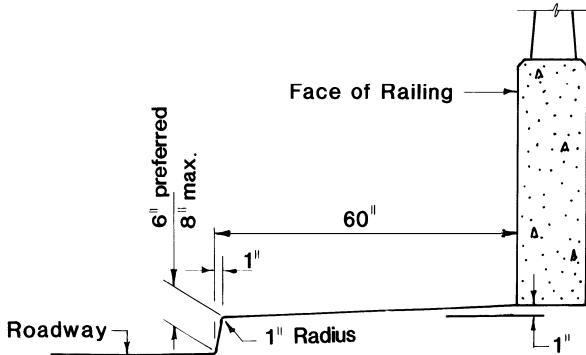

Figure 13.7.1.1-1—Typical Raised Sidewalk

### 13.7.1.2—Approach Railings

An approach guardrail system should be provided at the beginning of all bridge railings in high-speed rural areas.

A bridge approach railing system should include a transition from the guardrail system to the rigid bridge railing system that is capable of providing lateral resistance to an errant vehicle. The approach guardrail system shall have a crashworthy end terminal at its nosing.

### C13.7.1.2

In urban areas or where city streets and/or sidewalks prevent installation of approach guardrail transitions or crashworthy terminals, consideration should be given to:

- Extending the bridge rail or guard rail in a manner that prevents encroachment of a vehicle onto any highway system below the bridge,
- Providing a barrier curb,
- Restricting speed,
- Adding signing of intersections, and
- Providing recovery areas.

A bridge end drainage facility should be an integral part of the barrier transition design.

### 13.7.1.3—End Treatment

In high-speed rural areas, the approach end of a parapet or railing shall have a crashworthy configuration or be shielded by a crashworthy traffic barrier.

### C13.7.1.3

If the approach railing is connected to a side of road railing system, it can be continuous with the bridge approach system, and only a transition from a flexible to a rigid railing system is required.

### 13.7.2—Test Level Selection Criteria

One of the following test levels should be specified:

- TL-1—Test Level One—taken to be generally acceptable for work zones with low posted speeds and very low volume, low speed local streets;
- TL-2—Test Level Two—taken to be generally acceptable for work zones and most local and collector roads with favorable site conditions as well as where a small number of heavy vehicles is expected and posted speeds are reduced;
- TL-3—Test Level Three—taken to be generally acceptable for a wide range of high-speed arterial highways with very low mixtures of heavy vehicles and with favorable site conditions;
- TL-4—Test Level Four—taken to be generally acceptable for the majority of applications on high speed highways, freeways, expressways, and Interstate highways with a mixture of trucks and heavy vehicles;
- TL-5—Test Level Five—taken to be generally acceptable for the same applications as TL-4 and where large trucks make up a significant portion of the average daily traffic or when unfavorable site conditions justify a higher level of rail resistance; and
- TL-6—Test Level Six—taken to be generally acceptable for applications where tanker-type trucks or similar high center of gravity vehicles are anticipated, particularly along with unfavorable site conditions.

It shall be the responsibility of the user agency to determine which of the test levels is most appropriate for the bridge site.

The testing criteria for the chosen test level shall correspond to vehicle weights and speeds and angles of impact outlined in Table 13.7.2-1.

### C13.7.2

The six test levels mentioned herein are intended to correspond with the six test levels contained in NCHRP Report 350, “Recommended Procedures for the Safety Performance Evaluation of Highway Features.” AASHTO’s *A Policy on Geometric Design of Highways and Streets* (2004) and its *Roadside Design Guide* (2002) are referred to as aides in the bridge railing selection process.

The individual tests are designed to evaluate one or more of the principal performance factors of the bridge railing, which include structural adequacy, occupant risk, and postimpact behavior of the test vehicle. In general, the lower test levels are applicable for evaluating and selecting bridge railings to be used on segments of lower service level roadways and certain types of work zones. The higher test levels are applicable for evaluating and selecting bridge railings to be used on higher service level roadways or at locations that demand a special, high-performance bridge railing. In this regard, TL-4 railings are expected to satisfy the majority of interstate design requirements.

TL-5 provides for a van-type tractor-trailer that will satisfy design requirements where TL-4 railings are deemed to be inadequate due to the high number of this type of vehicle anticipated, or due to unfavorable site conditions where rollover or penetration beyond the railing could result in severe consequences.

TL-6 provides for a tanker-type truck that will satisfy design requirements where this type vehicle with a higher center of gravity has shown a history of rollover or penetration, or unfavorable site conditions may indicate the need for this level of rail resistance.

Unfavorable site conditions include but are not limited to reduced radius of curvature, steep downgrades on curvature, variable cross slopes, and adverse weather conditions.

Agencies should develop objective guidelines for use of bridge railings. These guidelines should take into account factors such as traffic conditions, traffic volume and mix, cost and in-service performance, and life-cycle cost of existing railings.

These criteria, including other vehicle characteristics and tolerances, are described in detail in the NCHRP Report 350.

**Table 13.7.2-1—Bridge Railing Test Levels and Crash Test Criteria**

Vehicle Characteristics	Small Automobiles		Pickup Truck	Single-Unit Van Truck	Van-Type Tractor-Trailer		Tractor-Tanker Trailer
<i>W</i> (kips)	1.55	1.8	4.5	18.0	50.0	80.0	80.0
<i>B</i> (ft)	5.5	5.5	6.5	7.5	8.0	8.0	8.0
<i>G</i> (in.)	22	22	27	49	64	73	81
Crash angle, $\theta$	20°	20°	25°	15°	15°	15°	15°
Test Level	Test Speeds (mph)						
TL-1	30	30	30	N/A	N/A	N/A	N/A
TL-2	45	45	45	N/A	N/A	N/A	N/A
TL-3	60	60	60	N/A	N/A	N/A	N/A
TL-4	60	60	60	50	N/A	N/A	N/A
TL-5	60	60	60	N/A	N/A	50	N/A
TL-6	60	60	60	N/A	N/A	N/A	50

### 13.7.3—Railing Design

#### 13.7.3.1—General

A traffic railing should normally provide a smooth continuous face of rail on the traffic side. Steel posts with rail elements should be set back from the face of rail. Structural continuity in the rail members and anchorages of ends should be considered.

A railing system and its connection to the deck shall be approved only after they have been shown through crash testing to be satisfactory for the desired test level.

##### *13.7.3.1.1—Application of Previously Tested Systems*

A crashworthy railing system may be used without further analysis and/or testing, provided that the proposed installation does not have features that are absent in the tested configuration and that might detract from the performance of the tested railing system.

##### *13.7.3.1.2—New Systems*

New railing systems may be used, provided that acceptable performance is demonstrated through full-scale crash tests.

The crash test specimen for a railing system may be designed to resist the applied loads in accordance with Appendix A of this Section or NCHRP Report 350 with its revisions.

Provision shall be made to transfer loads from the railing system to the deck. Railing loads may be taken from Appendix A of this Section.

#### C13.7.3.1

Protrusions or depressions at rail openings may be acceptable, provided that their thickness, depth, or geometry does not prevent the railing from meeting the crash test evaluation criteria.

Test specimens should include a representative length of the overhang to account for the effect of deck flexibility on the distance over which the railing engages the deck.

##### *C13.7.3.1.1*

When a minor detail is changed on or an improvement is made to a railing system that has already been tested and approved, engineering judgment and analysis should be used when determining the need for additional crash testing.

##### *C13.7.3.1.2*

Unless a lesser thickness can be proven satisfactory during the crash testing procedure, the minimum edge thickness for concrete deck overhangs shall be taken as:

- For concrete deck overhangs supporting a deck-mounted post system: 8.0 in.
- For a side-mounted post system: 12.0 in.
- For concrete deck overhangs supporting concrete parapets or barriers: 8.0 in.

### **13.7.3.2—Height of Traffic Parapet or Railing**

Traffic railings shall be at least 27.0 in. for TL-3, 32.0 in. for TL-4, 42.0 in. for TL-5, and 90.0 in. in height for TL-6.

The bottom 3.0-in. lip of the safety shape shall not be increased for future overlay considerations.

The minimum height for a concrete parapet with a vertical face shall be 27.0 in. The height of other combined concrete and metal rails shall not be less than 27.0 in. and shall be determined to be satisfactory through crash testing for the desired test level.

The minimum height of the pedestrian or bicycle railing should be measured above the surface of the sidewalk or bikeway.

The minimum geometric requirements for combination railings beyond those required to meet crash test requirements shall be taken as specified in Articles 13.8, 13.9, and 13.10.

## **13.8—PEDESTRIAN RAILING**

### **13.8.1—Geometry**

The minimum height of a pedestrian railing shall be 42.0 in. measured from the top of the walkway.

A pedestrian rail may be composed of horizontal and/or vertical elements. The clear opening between elements shall be such that a 6.0 in. diameter sphere shall not pass through.

When both horizontal and vertical elements are used, the 6.0 in. clear opening shall apply to the lower 27.0 in. of the railing, and the spacing in the upper portion shall be such that a 8.0-in. diameter sphere shall not pass through. A safety toe rail or curb should be provided. Rails should project beyond the face of posts and/or pickets as shown in Figure A13.1.1-2.

The rail spacing requirements given above should not apply to chain link or metal fabric fence support rails and posts. Mesh size in chain link or metal fabric fence should have openings no larger than 2.0 in.

Preliminary design for bridge decks should comply with Article A13.1.2. A determination of the adequacy of deck reinforcement for the distribution of post anchorage loads to the deck should be made during the rail testing program. If the rail testing program satisfactorily models the bridge deck, damage to the deck edge can be assessed at this time.

In adequately designed bridge deck overhangs, the major crash-related damage presently occurs in short sections of slab areas where the barrier is hit.

### **C13.7.3.2**

These heights have been determined as satisfactory through crash tests and experience.

For future deck overlays, an encroachment of 2.0 in., leaving a 1.0-in. lip, has been satisfactorily tested for safety shapes.

### **C13.8.1**

The size of openings should be capable of retaining an average size beverage container.

### 13.8.2—Design Live Loads

The design live load for pedestrian railings shall be taken as  $w = 0.050 \text{ klf}$ , both transversely and vertically, acting simultaneously. In addition, each longitudinal element will be designed for a concentrated load of 0.20 kips, which shall act simultaneously with the above loads at any point and in any direction at the top of the longitudinal element.

The posts of pedestrian railings shall be designed for a concentrated design live load applied transversely at the center of gravity of the upper longitudinal element or, for railings with a total height greater than 5.0 ft, at a point 5.0 ft above the top surface of the sidewalk. The value of the concentrated design live load for posts,  $P_{LL}$ , in kips, shall be taken as:

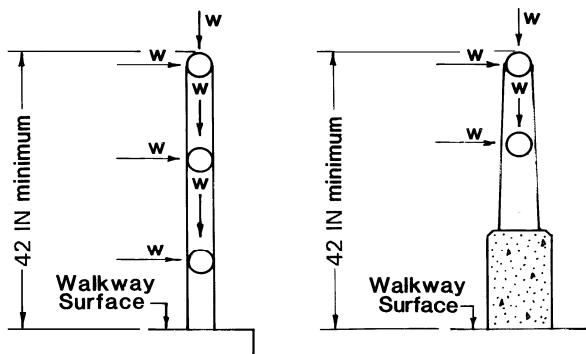

$$P_{LL} = 0.20 + 0.050L \quad (13.8.2-1)$$

where:

$L$  = post spacing (ft)

The design load for chain link or metal fabric fence shall be 0.015 ksf acting normal to the entire surface.

The application of loads shall be as indicated in Figure 13.8.2-1, in which the shapes of rail members are illustrative only. Any material or combination of materials specified in Article 13.5 may be used.

**Figure 13.8.2-1—Pedestrian Railing Loads—To be used on the outer edge of a sidewalk when highway traffic is separated from pedestrian traffic by a traffic railing. Railing shape illustrative only.**

### 13.9—BICYCLE RAILINGS

#### 13.9.1—General

Bicycle railings shall be used on bridges specifically designed to carry bicycle traffic and on bridges where specific protection of bicyclists is deemed necessary.

### C13.8.2

These live loads apply to the railing. The pedestrian live load, specified in Article 3.6.1.6, applies to the sidewalk.

### 13.9.2—Geometry

The height of a bicycle railing shall not be less than 42.0 in., measured from the top of the riding surface.

The height of the upper and lower zones of a bicycle railing shall be at least 27.0 in. The upper and lower zones shall have rail spacing satisfying the respective provisions of Article 13.8.1.

If deemed necessary, rubrails attached to the rail or fence to prevent snagging should be deep enough to protect a wide range of bicycle handlebar heights.

If screening, fencing, or a solid face is utilized, the number of rails may be reduced.

### 13.9.3—Design Live Loads

If the rail height exceeds 54.0 in. above the riding surface, design loads shall be determined by the Designer. The design loads for the lower 54.0 in. of the bicycle railing shall not be less than those specified in Article 13.8.2, except that for railings with total height greater than 54.0 in., the design live load for posts shall be applied at a point 54.0 in. above the riding surface.

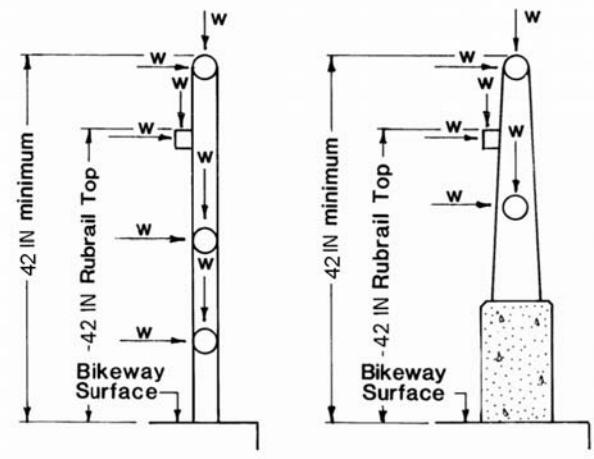

The application of loads shall be as indicated in Figure 13.9.3-1. Any material or combination of materials specified in Article 13.5 may be used.

### C13.9.2

Railings, fences or barriers on either side of a shared use path on a structure, or along bicycle lane, shared use path or signed shared roadway located on a highway bridge should be a minimum of 42.0 in. high. The 42.0-in. minimum height is in accordance with the *AASHTO Guide for the Development of Bicycle Facilities*, Third Edition (1999).

On such a bridge or bridge approach where high-speed high-angle impact with a railing, fence or barrier are more likely to occur (such as short radius curves with restricted sight distance or at the end of a long descending grade) or in locations with site-specific safety concerns, a railing, fence or barrier height above the minimum should be considered.

The need for rubrails attached to a rail or fence is controversial among many bicyclists.

**Figure 13.9.3-1—Bicycle Railing Loads—To be used on the outer edge of a bikeway when highway traffic is separated from bicycle traffic by a traffic railing. Railing shape illustrative only.**

## 13.10—COMBINATION RAILINGS

### 13.10.1—General

The combination railing shall conform to the requirements of either the pedestrian or bicycle railings, as specified in Articles 13.8 and 13.9, whichever is applicable. The traffic railing portion of the combination railing shall conform to Article 13.7.

### 13.10.2—Geometry

The geometric provisions of Articles 13.7, 13.8, and 13.9 shall apply to their respective portions of a combination railing.

### 13.10.3—Design Live Loads

Design loads, specified in Articles 13.8 and 13.9, shall not be applied simultaneously with the vehicular impact loads.

## 13.11—CURBS AND SIDEWALKS

### 13.11.1—General

Horizontal measurements of roadway width shall be taken from the bottom of the face of the curb. A sidewalk curb located on the highway traffic side of a bridge railing shall be considered an integral part of the railing and shall be subject to the crash test requirements specified in Article 13.7.

### 13.11.2—Sidewalks

When curb and gutter sections with sidewalks are used on roadway approaches, the curb height for raised sidewalks on the bridge should be no more than 8.0 in. If a barrier curb is required, the curb height should not be less than 6.0 in. If the height of the curb on the bridge differs from that off the bridge, it should be uniformly transitioned over a distance greater than or equal to 20 times the change in height.

### C13.11.2

Raised sidewalks on bridges are not usually provided where the approach roadway is not curbed for pedestrians or the structure is not planned for pedestrian occupancy.

For recommendations on sidewalk width, see Figure 13.7.1.1-1 and AASHTO's *A Policy on Geometric Design of Highways and Streets*.

During stage construction, the same transition considerations will be given to the provision of ramps from the bridge sidewalk to the approach surface.

### 13.11.3—End Treatment of Separation Railing

The end treatment of any traffic railing or barrier shall meet the requirements specified in Articles 13.7.1.2 and 13.7.1.3.

## APPENDIX A13—RAILINGS

### A13.1—GEOMETRY AND ANCHORAGES

#### A13.1.1—Separation of Rail Elements

For traffic railings, the criteria for maximum clear opening below the bottom rail,  $c_b$ , the setback distance,  $S$ , and maximum opening between rails,  $c$ , shall be based on the following criteria:

- The rail contact widths for typical railings may be taken as illustrated in Figure A13.1.1-1;
- The total width of the rail(s) in contact with the vehicle,  $\Sigma A$ , shall not be less than 25 percent of the height of the railing;
- For post railings, the vertical clear opening,  $c$ , and the post setback,  $S$ , shall be within or below the shaded area shown in Figure A13.1.1-2; and
- For post railings, the combination of  $(\Sigma A/H)$  and the post setback,  $S$  shall be within or above the shaded area shown in Figure A13.1.1-3.

#### CA13.1.1

The post setback shown from face of rail for various post shapes is based upon a limited amount of crash test data. The potential for wheel snagging involved with a given design should be evaluated as part of the crash test program.

The post setback,  $S$ , shown for various shape posts in Figure A13.1.1-2, recognizes the tendency for various shape posts to snag wheels. The implication of the various definitions of setback,  $S$ , is that all other factors being equal, the space between a rail and the face of a rectangular post will be greater than the distance between a rail and the face of a circular post.

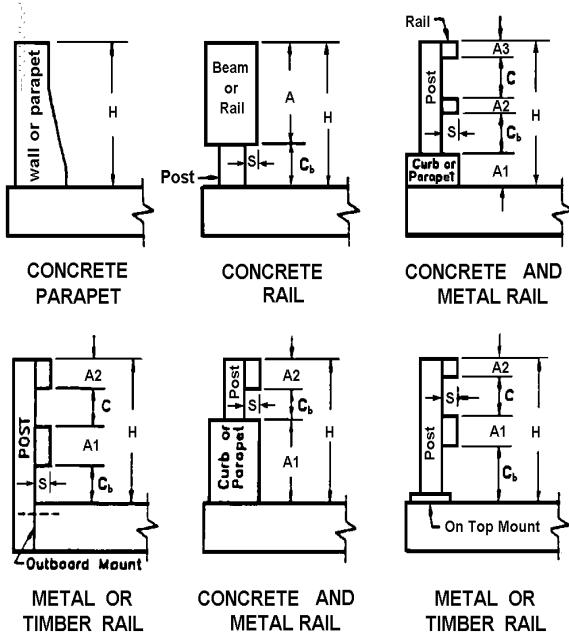

Figure A13.1.1-1—Typical Traffic Railings

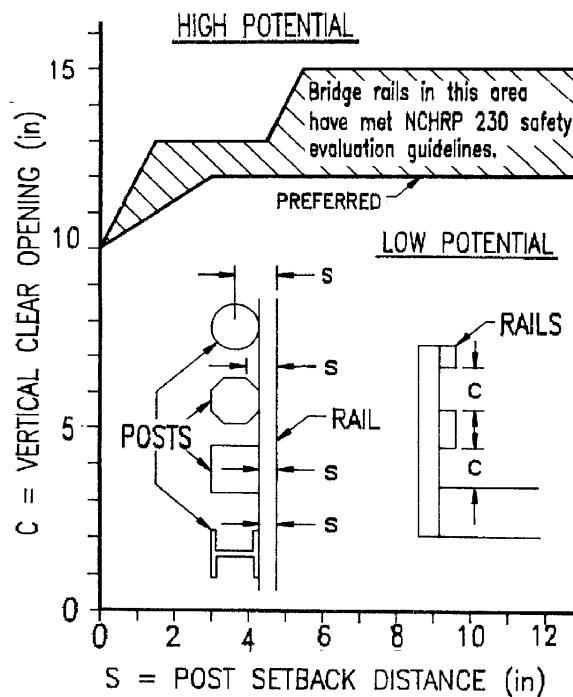

Figure A13.1.1-2—Potential for Wheel, Bumper, or Hood Impact with Post

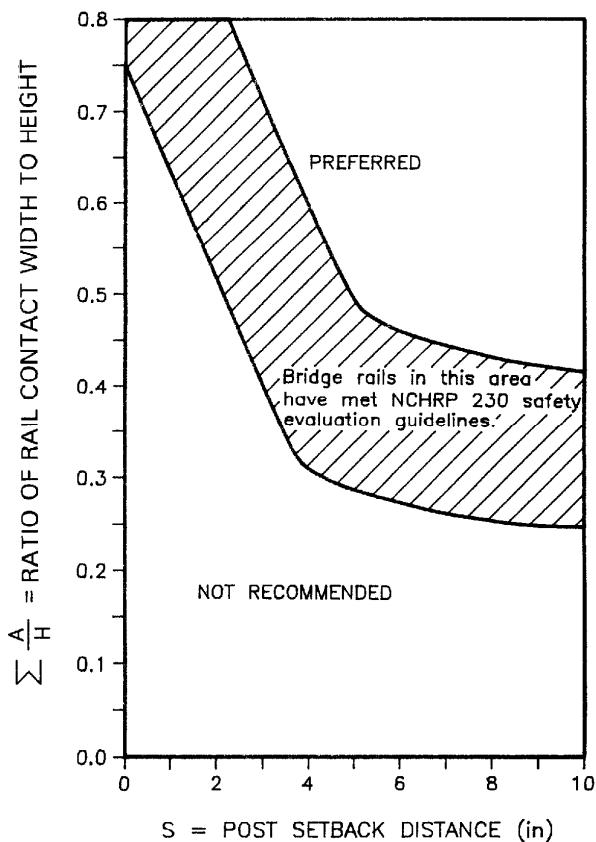

Figure A13.1.1-3—Post Setback Criteria

The maximum clear vertical opening between succeeding rails or posts shall be as specified in Articles 13.8, 13.9, and 13.10.

### A13.1.2—Anchorage

The yield strength of anchor bolts for steel railing shall be fully developed by bond, hooks, attachment to embedded plates, or any combination thereof.

Reinforcing steel for concrete barriers shall have embedment length sufficient to develop the yield strength.

### CA13.1.2

Noncorrosive bonding agents for anchor dowels may be cement grout, epoxy, or a magnesium phosphate compound. Sulfur or expansive-type grouts should not be used.

Some bonding agents on the market have corrosive characteristics; these should be avoided.

Development length for reinforcing bars is specified in Section 5.

### A13.2—TRAFFIC RAILING DESIGN FORCES

Unless modified herein, the extreme event limit state and the corresponding load combinations in Table 3.4.1-1 shall apply.

Railing design forces and geometric criteria to be used in developing test specimens for a crash test program should be taken as specified in Table A13.2-1 and illustrated in Figure A13.2-1. The transverse and longitudinal loads given in Table A13.2-1 need not be applied in conjunction with vertical loads.

The effective height of the vehicle rollover force is taken as:

$$H_e = G - \frac{12WB}{2F_t} \quad (\text{A13.2-1})$$

where:

$G$  = height of vehicle center of gravity above bridge deck, as specified in Table 13.7.2-1 (in.)

$W$  = weight of vehicle corresponding to the required test level, as specified in Table 13.7.2-1 (kips)

$B$  = out-to-out wheel spacing on an axle, as specified in Table 13.7.2-1 (ft)

$F_t$  = transverse force corresponding to the required test level, as specified in Table A13.2-1 (kips)

Railings shall be proportioned such that:

$$\bar{R} \geq F_t \quad (\text{A13.2-2})$$

$$\bar{Y} \geq \frac{H_e}{12} \quad (\text{A13.2-3})$$

in which:

$$\bar{R} = \sum R_i \quad (\text{A13.2-4})$$

$$\bar{Y} = \frac{\sum(R_i Y_i)}{\bar{R}} \quad (\text{A13.2-5})$$

### CA13.2

Nomenclature for Eqs. A13.2-1 and A13.2-2 is illustrated in Figure CA13.2-1.

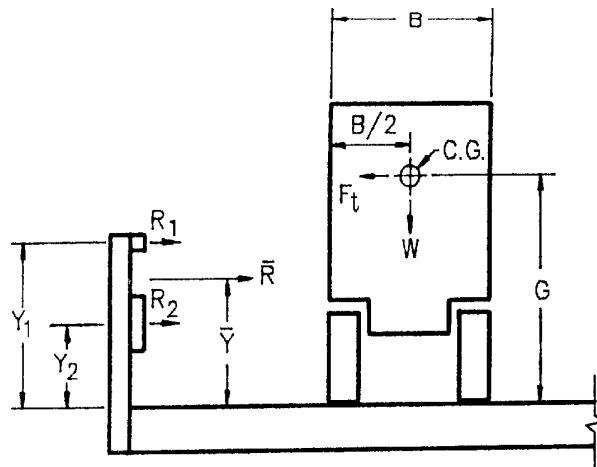

Figure CA13.2-1—Traffic Railing

If the total resistance,  $\bar{R}$ , of a post-and-beam railing system with multiple rail elements is significantly greater than the applied load,  $F_t$ , then the resistance,  $R_i$ , for the lower rail element(s) used in calculations may be reduced.

The reduced value of  $\bar{R}$  will result in an increase in the computed value of  $\bar{Y}$ . The reduced notional total rail resistance and its effective height must satisfy Eqs. A13.2-2 and A13.2-3.

where:

$R_i$  = resistance of the rail (kips)

$Y_i$  = distance from bridge deck to the  $i$ th rail (ft)

All forces shall be applied to the longitudinal rail elements. The distribution of longitudinal loads to posts shall be consistent with the continuity of rail elements. Distribution of transverse loads shall be consistent with the assumed failure mechanism of the railing system.

Eq. A13.2-1 has been found to give reasonable predictions of effective railing height requirements to prevent rollover.

If the design load located at  $H_e$  falls between rail elements, it should be distributed proportionally to rail elements above and below such that  $Y \geq H_e$ .

As an example of the significance of the data in Table A13.2-1, the length of 4.0 ft for  $L_t$  and  $L_L$  is the length of significant contact between the vehicle and railing that has been observed in films of crash tests. The length of 3.5 ft for TL-4 is the rear-axle tire diameter of the truck. The length of 8.0 ft for TL-5 and TL-6 is the length of the tractor rear tandem axles: two 3.5-ft diameter tires, plus 1.0 ft between them.

$F_v$ , the weight of the vehicle lying on top of the bridge rail, is distributed over the length of the vehicle in contact with the rail,  $L_v$ .

For concrete railings, Eq. A13.2-1 results in a theoretically-required height,  $H$ , of 34.0 in. for Test Level TL-4. However, a height of 32.0 in., shown in Table A13.2-1, was considered to be acceptable because many railings of that height have been built and appear to be performing acceptably.

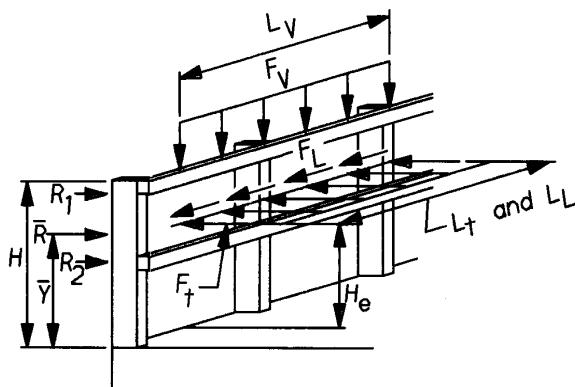

The minimum height,  $H$ , listed for TL-1, TL-2, and TL-3 is based on the minimum railings height used in the past. The minimum effective height,  $H_e$ , for TL-1 is an estimate based on the limited information available for this test level.

The minimum height,  $H$ , of 42.0 in., shown in Table A13.2-1, for TL-5 is based on the height used for successfully crash-tested concrete barrier engaging only the tires of the truck. For post and beam metal bridge railings, it may be prudent to increase the height by 12.0 in. so as to engage the bed of the truck.

The minimum height,  $H$ , shown in Table A13.2-1, for TL-6 is the height required to engage the side of the tank as determined by crash test.

Table A13.2-1—Design Forces for Traffic Railings

Design Forces and Designations	Railing Test Levels					
	TL-1	TL-2	TL-3	TL-4	TL-5	TL-6
$F_t$ Transverse (kips)	13.5	27.0	54.0	54.0	124.0	175.0
$F_L$ Longitudinal (kips)	4.5	9.0	18.0	18.0	41.0	58.0
$F_v$ Vertical (kips) Down	4.5	4.5	4.5	18.0	80.0	80.0
$L_t$ and $L_L$ (ft)	4.0	4.0	4.0	3.5	8.0	8.0
$L_v$ (ft)	18.0	18.0	18.0	18.0	40.0	40.0
$H_e$ (min) (in.)	18.0	20.0	24.0	32.0	42.0	56.0
Minimum $H$ Height of Rail (in.)	27.0	27.0	27.0	32.0	42.0	90.0

**Figure A13.2-1—Metal Bridge Railing Design Forces, Vertical Location, and Horizontal Distribution Length**

### A13.3—DESIGN PROCEDURE FOR RAILING TEST SPECIMENS

#### A13.3.1—Concrete Railings

Yield line analysis and strength design for reinforced concrete and prestressed concrete barriers or parapets may be used.

The nominal railing resistance to transverse load,  $R_w$ , may be determined using a yield line approach as:

- For impacts within a wall segment:

$$R_w = \left( \frac{2}{2L_c - L_t} \right) \left( 8M_b + 8M_w + \frac{M_c L_c^2}{H} \right) \quad (\text{A13.3.1-1})$$

The critical wall length over which the yield line mechanism occurs,  $L_c$ , shall be taken as:

$$L_c = \frac{L_t}{2} + \sqrt{\left( \frac{L_t}{2} \right)^2 + \frac{8H(M_b + M_w)}{M_c}} \quad (\text{A13.3.1-2})$$

- For impacts at end of wall or at joint:

$$R_w = \left( \frac{2}{2L_c - L_t} \right) \left( M_b + M_w + \frac{M_c L_c^2}{H} \right) \quad (\text{A13.3.1-3})$$

$$L_c = \frac{L_t}{2} + \sqrt{\left( \frac{L_t}{2} \right)^2 + H \left( \frac{M_b + M_w}{M_c} \right)} \quad (\text{A13.3.1-4})$$

where:

$F_t$  = transverse force specified in Table A13.2-1 assumed to be acting at top of a concrete wall (kips)

Figure A13.2-1 shows the design forces from Table A13.2-1 applied to a beam and post railing. This is for illustrative purposes only. The forces and distribution lengths shown apply to any type of railing.

#### CA13.3.1

The yield line analysis shown in Figures CA13.3.1-1 and CA13.3.1-2 includes only the ultimate flexural capacity of the concrete component. Stirrups or ties should be provided to resist the shear and/or diagonal tension forces.

The ultimate flexural resistance,  $M_s$ , of the bridge deck or slab should be determined in recognition that the deck is also resisting a tensile force, caused by the component of the impact forces,  $F_t$ .

In this analysis it is assumed that the yield line failure pattern occurs within the parapet only and does not extend into the deck. This means that the deck must have sufficient resistance to force the yield line failure pattern to remain within the parapet. If the failure pattern extends into the deck, the equations for resistance of the parapet are not valid.

The analysis is also based on the assumption that sufficient longitudinal length of parapet exists to result in the yield line failure pattern shown. For short lengths of parapet, a single yield line may form along the juncture of the parapet and deck. Such a failure pattern is permissible, and the resistance of the parapet should be computed using an appropriate analysis.

This analysis is based on the assumption that the negative and positive wall resisting moments are equal and that the negative and positive beam resisting moments are equal.

The measurement of system resistance of a concrete railing is  $R_w$ , which is compared to the loads in Table A13.2-1 to determine structural adequacy. The flexure resistances,  $M_b$ ,  $M_w$ , and  $M_c$ , are related to the system resistance  $R_w$  through the yield line analysis embodied in Eqs. A13.3.1-1 and A13.3.1-2. In the terminology of these Specifications,  $R_w$  is the “nominal resistance” because it is compared to the “nominal load” given in Table A13.2-1.

Where the width of the concrete railing varies along the height,  $M_c$  used in Eqs. A13.3.1-1 through A13.3.1-4 for wall resistance should be taken as the average of its value along the height of the railing.

$H$  = height of wall (ft)

$L_c$  = critical length of yield line failure pattern (ft)

$L_t$  = longitudinal length of distribution of impact force  $F_t$  (ft)

$R_w$  = total transverse resistance of the railing (kips)

$M_b$  = additional flexural resistance of beam in addition to  $M_w$ , if any, at top of wall (kip-ft)

$M_c$  = flexural resistance of cantilevered walls about an axis parallel to the longitudinal axis of the bridge (kip-ft/ft)

$M_w$  = flexural resistance of the wall about its vertical axis (kip-ft)

For use in the above equations,  $M_c$  and  $M_w$  should not vary significantly over the height of the wall. For other cases, a rigorous yield line analysis should be used.

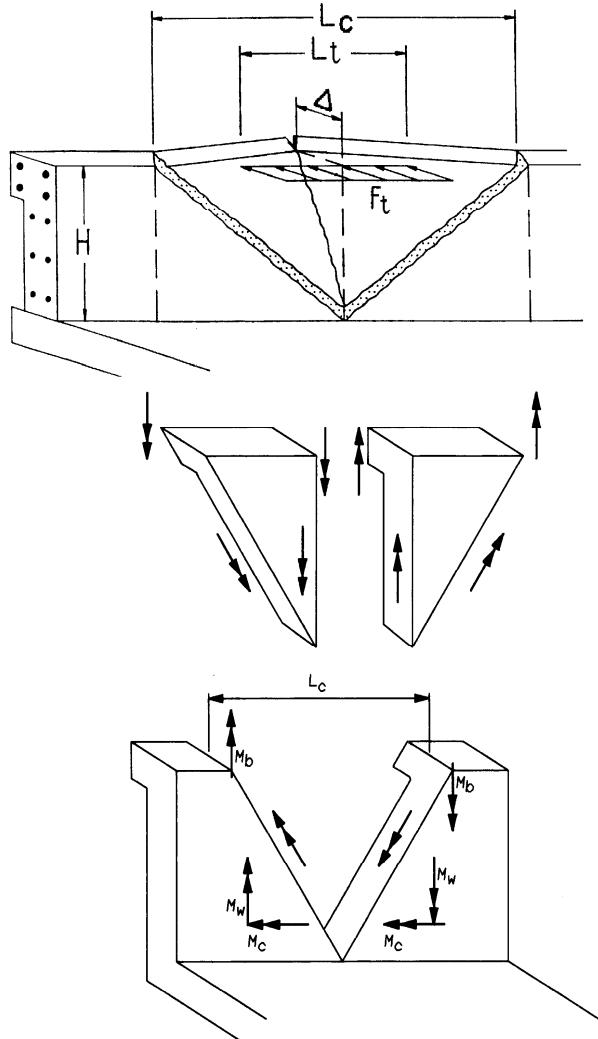

Figure CA13.3.1-1—Yield Line Analysis of Concrete Parapet Walls for Impact within Wall Segment

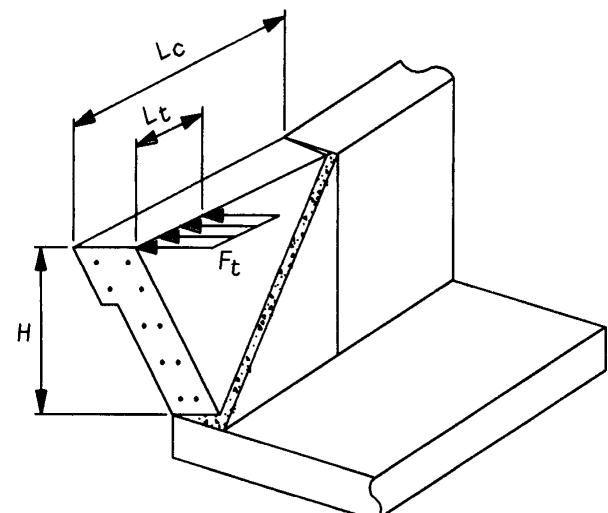

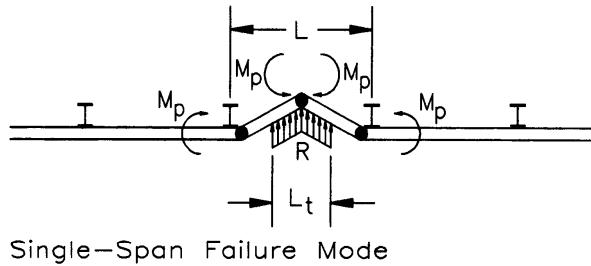

Figure CA13.3.1-2—Yield Line Analysis of Concrete Parapet Walls for Impact near End of Wall Segment

### A13.3.2—Post-and-Beam Railings

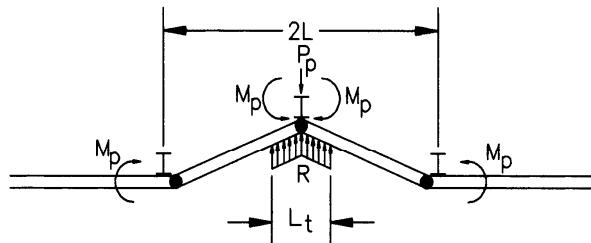

Inelastic analysis shall be used for design of post-and-beam railings under failure conditions. The critical rail nominal resistance,  $R$ , when the failure does not involve the end post of a segment, shall be taken as the least value determined from Eqs. A13.3.2-1 and A13.3.2-2 for various numbers of railing spans,  $N$ .

### CA13.3.2

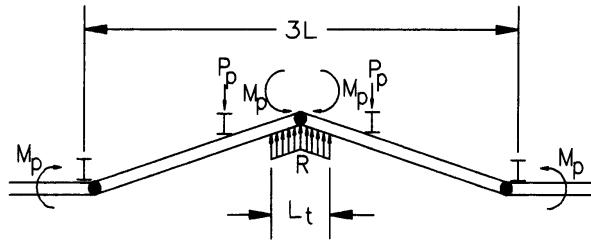

A basis for applying inelastic analysis is shown in Figure CA13.3.2-1.

Single-Span Failure Mode

Two-Span Failure Mode

Three-Span Failure Mode

**Figure CA13.3.2-1—Possible Failure Modes for Post-and-Beam Railings**

- For failure modes involving an odd number of railing spans,  $N$ :

$$R = \frac{16M_p + (N-1)(N+1)P_p L}{2NL - L_t} \quad (\text{A13.3.2-1})$$

- For failure modes involving an even number of railing spans,  $N$ :

$$R = \frac{16 M_p + N^2 P_p L}{2NL - L_t} \quad (\text{A13.3.2-2})$$

This design procedure is applicable to concrete and metal post and beam railings.

The post on each end of the plastic mechanism must be able to resist the rail or beam shear.

where:

- $L$  = post spacing or single-span (ft)
- $M_p$  = inelastic or yield line resistance of all of the rails contributing to a plastic hinge (kip-ft)
- $M_{post}$  = plastic moment resistance of a single post (kip-ft)
- $P_p$  = shear force on a single post which corresponds to  $M_{post}$  and is located  $\bar{Y}$  above the deck (kips)
- $R$  = total ultimate resistance, i.e., nominal resistance, of the railing (kips)
- $L_t, L_L$  = transverse length of distributed vehicle impact loads,  $F_t$  and  $F_L$  (ft)

For impact at the end of rail segments that causes the end post to fail, the critical rail nominal resistance,  $R$ , shall be calculated using Eq. A13.3.2-3.

- For any number of railing spans,  $N$ .

$$R = \frac{2M_p + 2P_p L \left( \sum_{i=1}^N i \right)}{2NL - L_t} \quad (\text{A13.3.2-3})$$

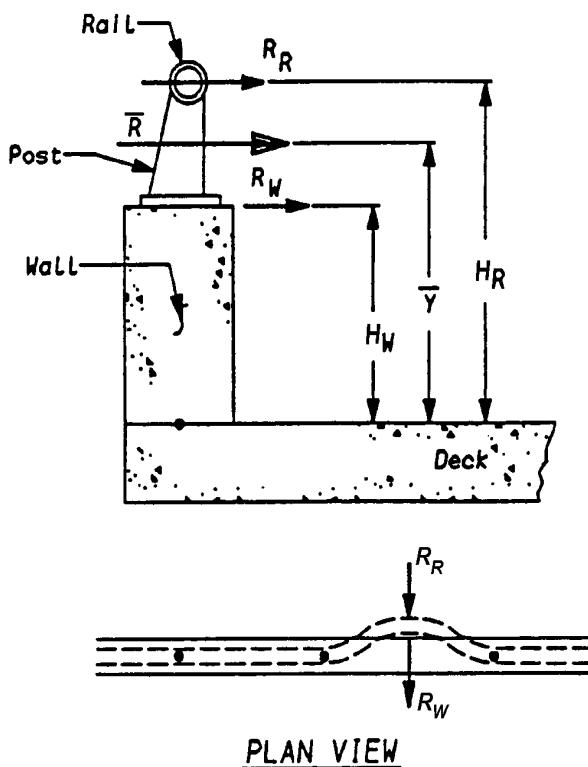

### A13.3.3—Concrete Parapet and Metal Rail

### CA13.3.3

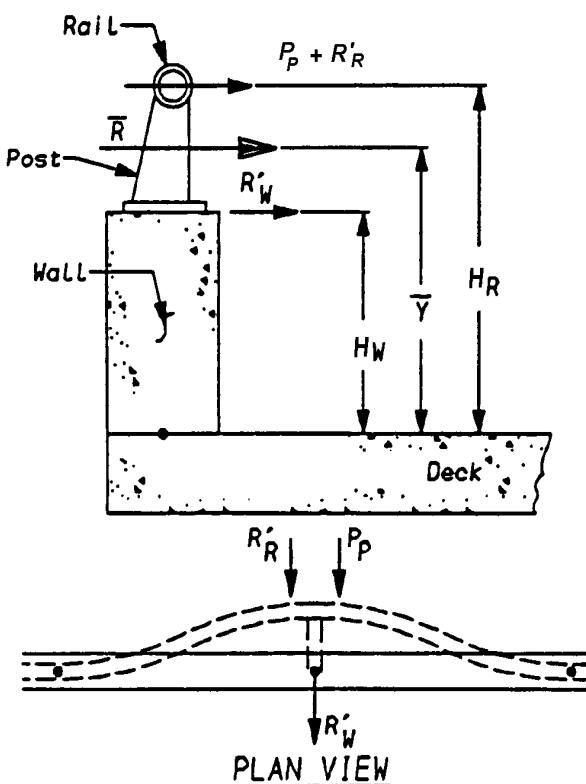

The resistance of each component of a combination bridge rail shall be determined as specified in Articles A13.3.1 and A13.3.2. The flexural strength of the rail shall be determined over one span,  $R_R$ , and over two spans,  $R'_R$ . The resistance of the post on top of the wall,  $P_p$ , including the resistance of the anchor bolts or post shall be determined.

The resistance of the combination parapet and rail shall be taken as the lesser of the resistances determined for the two failure modes shown in Figures A13.3.3-1 and A13.3.3-2.

For multiple rail systems, each of the rails may contribute to the yield mechanism shown schematically in Figure CA13.3.2-1, depending on the rotation corresponding to its vertical position.

### **Figure A13.3.3-1—Concrete Wall and Metal Rail Evaluation—Impact at Midspan of Rail**

**Figure A13.3.3-2—Concrete Wall and Metal Rail Evaluation—Impact at Post**

Where the vehicle impact is at midspan of the metal rail, as illustrated in Figure A13.3.3-1, the flexural resistance of the rail,  $R_R$ , and the maximum strength of the concrete wall,  $R_w$ , shall be added together to determine the combined resultant strength,  $\bar{R}$ , and the effective height,  $\bar{Y}$ , taken as:

$$\bar{R} = R_R + R_w \quad (\text{A13.3.3-1})$$

$$\bar{Y} = \frac{R_R H_R + R_w H_w}{\bar{R}} \quad (\text{A13.3.3-2})$$

The commentary to Article CA13.2 applies.

where:

$R_R$  = ultimate capacity of rail over one span (kips)

$R_w$  = ultimate capacity of wall as specified in Article A13.3.1 (kips)

$H_w$  = height of wall (ft)

$H_R$  = height of rail (ft)

Where the vehicle impact is at a post, as illustrated in Figure A13.3.3-2, the maximum resultant strength,  $\bar{R}$ , shall be taken as the sum of the post capacity,  $P_p$ , the rail strength,  $R'_R$ , and a reduced wall strength,  $R'_w$ , located at a height  $\bar{Y}$ .

$$\bar{R} = P_p + R'_R + R'_w \quad (\text{A13.3.3-3})$$

$$\bar{Y} = \frac{P_p H_R + R'_R H_R + R'_w H_w}{\bar{R}} \quad (\text{A13.3.3-4})$$

in which:

$$R'_w = \frac{R_w H_w - P_p H_R}{H_w} \quad (\text{A13.3.3-5})$$

where:

$P_p$  = ultimate transverse resistance of post (kips)

$R'_R$  = ultimate transverse resistance of rail over two spans (kips)

$R'_w$  = capacity of wall, reduced to resist post load (kips)

$R_w$  = ultimate transverse resistance of wall as specified in Article A13.3.1 (kips)

#### A13.3.4—Wood Barriers

Wood barriers shall be designed by elastic linear analysis with member sections proportioned on the basis of their resistances, specified in Section 8, using the strength limit states and the applicable load combinations specified in Table 3.4.1-1.

It should also be recognized that a maximum effective height,  $\bar{Y}$ , equal to the centroid rail height,  $H_R$ , could be obtained, but at a reduced resultant strength,  $\bar{R}$ , equal to the post capacity,  $P_p$ , and rail capacity,  $R'_R$ , only.

The analysis herein does not consider impacts near open joints in the concrete wall or parapet. The metal rail will help distribute load across such joints. Improved rail resistance will be obtained if the use of expansion and contraction joints is minimized.

For impact near the end of railing segments, the nominal resistance may be calculated as the sum of the wall resistance, calculated using Eq. A13.3.1-3, and the metal rail resistance over one span, calculated using Eq. A13.3.2-3.

#### CA13.3.4

A limit or failure mechanism is not recommended for wood railings.

## A13.4—DECK OVERHANG DESIGN

### A13.4.1—Design Cases

Bridge deck overhangs shall be designed for the following design cases considered separately:

Design Case 1: the transverse and longitudinal forces specified in Article A13.2 Extreme Event Load Combination II limit state

Design Case 2: the vertical forces specified in Article A13.2—Extreme Event Load Combination II limit state

Design Case 3: the loads, specified in Article 3.6.1, that occupy the overhang—Load Combination Strength I limit state

For Design Case 1 and 2, the load factor for dead load,  $\gamma_p$ , shall be taken as 1.0.

The total factored force effect shall be taken as:

$$Q = \sum \eta_i \gamma_i Q_i \quad (\text{A13.4.1-1})$$

where:

$\eta_i$  = load modifier specified in Article 1.3.2

$\gamma_i$  = load factors specified in Tables 3.4.1-1 and 3.4.1-2, unless specified elsewhere

$Q_i$  = force effects from loads specified herein

### A13.4.2—Decks Supporting Concrete Parapet Railings

For Design Case 1, the deck overhang may be designed to provide a flexural resistance,  $M_s$  in kip-ft/ft which, acting coincident with the tensile force  $T$  in kip/ft, specified herein, exceeds  $M_c$  of the parapet at its base. The axial tensile force,  $T$ , may be taken as:

$$T = \frac{R_w}{L_c + 2H} \quad (\text{A13.4.2-1})$$

where:

$R_w$  = parapet resistance specified in Article A13.3.1 (kips)

$L_c$  = critical length of yield line failure pattern (ft)

$H$  = height of wall (ft)

$T$  = tensile force per unit of deck length (kip/ft)

### CA13.4.2

If the deck overhang capacity is less than that specified, the yield line failure mechanism for the parapet may not develop as shown in Figure CA13.3.1-1, and Eqs. A13.3.1-1 and A13.3.1-2 will not be correct.

The crash testing program is oriented toward survival, not necessarily the identification of the ultimate strength of the railing system. This could produce a railing system that is significantly overdesigned, leading to the possibility that the deck overhang is also overdesigned.

Design of the deck overhang for the vertical forces specified in Design Case 2 shall be based on the overhanging portion of the deck.

#### A13.4.3—Decks Supporting Post-and-Beam Railings

##### A13.4.3.1—Overhang Design

For Design Case 1, the moment per ft,  $M_d$ , and thrust per ft of deck,  $T$ , may be taken as:

$$M_d = \frac{M_{post}}{W_b + d_b} \quad (\text{A13.4.3.1-1})$$

$$T = \frac{P_p}{W_b + d_b} \quad (\text{A13.4.3.1-2})$$

For Design Case 2, the punching shear force and overhang moment may be taken as:

$$P_v = \frac{F_v L}{L_v} \quad (\text{A13.4.3.1-3})$$

$$M_d = \frac{P_v X}{b} \quad (\text{A13.4.3.1-4})$$

in which:

$$b = 2X + W_b \leq L \quad (\text{A13.4.3.1-5})$$

where:

$M_{post}$  = plastic moment resistance of a single post (kip-ft)

$P_p$  = shear force on a single post which corresponds to  $M_{post}$  and is located  $\bar{Y}$  above the deck (kips)

$X$  = distance from the outside edge of the post base plate to the section under investigation, as specified in Figure A13.4.3.1-1 (ft)

$W_b$  = width of base plate (in.)

$T$  = tensile force in deck (kip/ft)

$d_b$  = distance from the outer edge of the base plate to the innermost row of bolts, as shown in Figure A13.4.3.1-1 (in.)

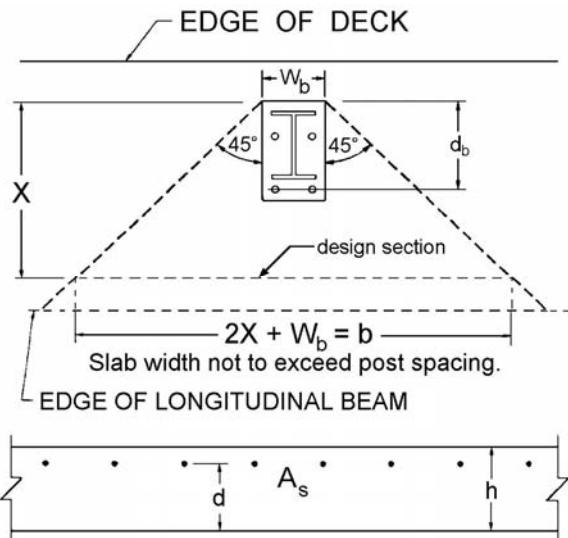

$L$  = post spacing (ft)

$L_v$  = longitudinal distribution of vertical force  $F_v$  on top of railing (ft)

$F_v$  = vertical force of vehicle laying on top of rail after impact forces  $F_t$  and  $F_L$  are over (kips)

##### CA13.4.3.1

Vehicle collision on the beam and post railing systems, such as a metal system with wide flange or tubular posts, imposes large concentrated forces and moments on the deck at the point where the post is attached to the deck.

**Figure A13.4.3.1-1—Effective Length of Cantilever for Carrying Concentrated Post Loads, Transverse or Vertical**

#### A13.4.3.2—Resistance to Punching Shear

For Design Case 1, the factored shear may be taken as:

$$V_u = A_f F_y \quad (\text{A13.4.3.2-1})$$

The factored resistance of deck overhangs to punching shear may be taken as:

$$V_r = \phi V_n \quad (\text{A13.4.3.2-2})$$

$$V_n = v_c \left[ W_b + h + 2 \left( E + \frac{B}{2} + \frac{h}{2} \right) \right] h \quad (\text{A13.4.3.2-3})$$

$$v_c = \left( 0.0633 + \frac{0.1265}{\beta_c} \right) \sqrt{f'_c} \leq 0.1265 \sqrt{f'_c} \quad (\text{A13.4.3.2-4})$$

$$\frac{B}{2} + \frac{h}{2} \leq B \quad (\text{A13.4.3.2-5})$$

in which:

$$\beta_c = W_b / d_b \quad (\text{A13.4.3.2-6})$$

where:

$V_u$  = factored shear force at section (kips)

$A_f$  = area of post compression flange ( $\text{in.}^2$ )

$F_y$  = yield strength of post compression flange (ksi)

$V_r$  = factored shear resistance (kips)

$V_n$  = nominal shear resistance of the section considered (kips)

Previous editions of the Standard Specifications distributed railing or post loads to the slab using similar simplified analysis, e.g., “The effective length of slab resisting post loadings shall be equal to  $E = 0.8x + 3.75$  ft where no parapet is used and equal to  $E = 0.8x + 5.0$  ft where a parapet is used, where  $x$  is the distance in ft from the center of the post to the point under investigation.”

#### CA13.4.3.2

Concrete slabs or decks frequently fail in punching shear resulting from the force in the compression flange of the post,  $C$ . Adequate thickness,  $h$ , edge distance,  $E$ , or base plate size ( $W_b$  or  $B$  or thickness) should be provided to resist this type failure.

$v_c$  = nominal shear resistance provided by tensile stresses in the concrete (ksi)

$W_b$  = width of base plate (in.)

$b$  = length of deck resisting post strength or shear load =  $h + W_b$

$h$  = depth of slab (in.)

$E$  = distance from edge of slab to centroid of compressive stress resultant in post (in.)

$B$  = distance between centroids of tensile and compressive stress resultants in post (in.)

$\beta_c$  = ratio of the long side to the short side of the concentrated load or reaction area

$f'_c$  = 28-day compressive strength of concrete (ksi)

$\phi$  = resistance factor = 1.0

$d_b$  = distance from the outer edge of the base plate to the innermost row of bolts (in.)

The assumed distribution of forces for punching shear shall be as shown in Figure A13.4.3.2-1.

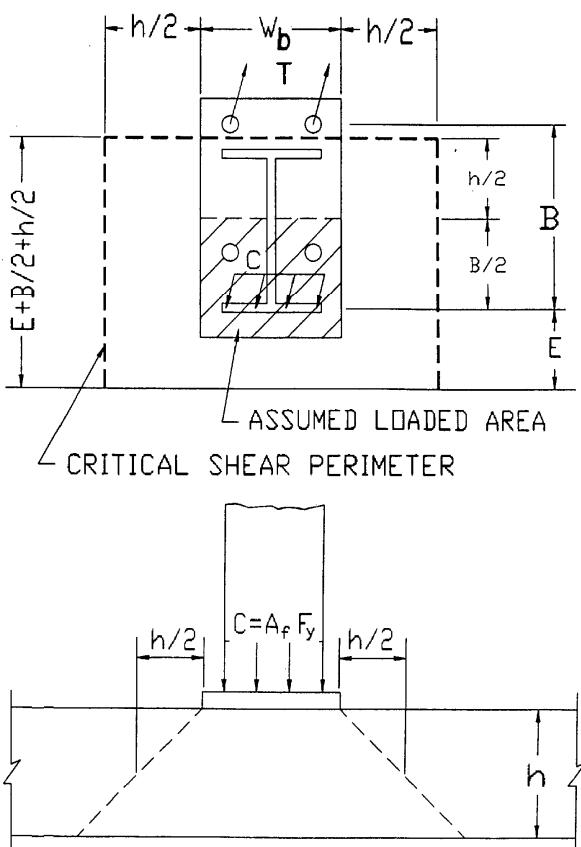

Figure A13.4.3.2-1—Punching Shear Failure Mode

Test results and in-service experience have shown that where deck failures have occurred, the failure mode has been a punching shear-type failure with loss of structural integrity between the concrete and reinforcing steel. Use of various types of shear reinforcement may increase the ultimate strength of the postdeck connection but is ineffective in reducing shear, diagonal tension, or cracking in the deck. Shear resistance can be increased by increasing the slab thickness, base plate width and depth, or edge distance.

## SECTION 14

# JOINTS AND BEARINGS

### 14.1—SCOPE

This Section contains requirements for the design and selection of structural bearings and deck joints.

Units used in this Section shall be taken as kip, in., rad., °F, and Shore Hardness, unless otherwise noted.

### 14.2—DEFINITIONS

*Bearing*—A structural device that transmits loads while facilitating translation and/or rotation.

*Bearing Joint*—A deck joint provided at bearings and other deck supports to facilitate horizontal translation and rotation of abutting structural elements. It may or may not provide for differential vertical translation of these elements.

*Bronze Bearing*—A bearing in which displacements or rotations take place by the sliding of a bronze surface against a mating surface.

*Cotton-Duck-Reinforced Pad (CDP)*—A pad made from closely spaced layers of elastomer and cotton-duck, bonded together during vulcanization.

*Closed Joint*—A deck joint designed to prevent the passage of debris through the joint and to safeguard pedestrian and cycle traffic.

*Compression Seal*—A preformed elastomeric device that is precompressed in the gap of a joint with expected total range of movement less than 2.0 in.

*Construction Joint*—A temporary joint used to permit sequential construction.

*Cycle-Control Joint*—A transverse approach slab joint designed to permit longitudinal cycling of integral bridges and attached approach slabs.

*Damper*—A device that transfers and reduces forces between superstructure elements and/or superstructure and substructure elements, while permitting thermal movements. The device provides damping by dissipating energy under seismic, braking, or other dynamic loads.

*Deck Joint*—A structural discontinuity between two elements, at least one of which is a deck element. It is designed to permit relative translation and/or rotation of abutting structural elements.

*Disc Bearing*—A bearing that accommodates rotation by deformation of a single elastomeric disc molded from a urethane compound. It may be movable, guided, unguided, or fixed. Movement is accommodated by sliding of polished stainless steel on PTFE.

*Double Cylindrical Bearing*—A bearing made from two cylindrical bearings placed on top of each other with their axes at right angles to facilitate rotation about any horizontal axis.

*Fiberglass-Reinforced Pad (FGP)*—A pad made from discrete layers of elastomer and woven fiberglass bonded together during vulcanization.

*Fixed Bearing*—A bearing that prevents differential longitudinal translation of abutting structural elements. It may or may not provide for differential lateral translation or rotation.

*Integral Bridge*—A bridge without deck joints.

*Joint*—A structural discontinuity between two elements. The structural members used to frame or form the discontinuity.

*Joint Seal*—A poured or preformed elastomeric device designed to prevent moisture and debris from penetrating joints.

*Knuckle Bearing*—A bearing in which a concave metal surface rocks on a convex metal surface to provide rotation capability about any horizontal axis.

*Longitudinal*—Parallel with the main span direction of a structure.

*Longitudinal Joint*—A joint parallel to the span direction of a structure provided to separate a deck or superstructure into two independent structural systems.

*Metal Rocker or Roller Bearing*—A bearing that carries vertical load by direct contact between two metal surfaces and that accommodates movement by rocking or rolling of one surface with respect to the other.

*Modular Bridge Joint System (MBJS)*—A sealed joint with two or more elastomeric seals held in place by edgebeams that are anchored to the structural elements (deck, abutment, etc.) and one or more transverse centerbeams that are parallel to the edgebeams. Typically used for movement ranges greater than 4.0 in.

*Movable Bearing*—A bearing that facilitates differential horizontal translation of abutting structural elements in a longitudinal and/or lateral direction. It may or may not provide for rotation.

*Multirotational Bearing*—A bearing consisting of a rotational element of the pot type, disc type, or spherical type when used as a fixed bearing and that may, in addition, have sliding surfaces to accommodate translation when used as an expansion bearing. Translation may be constrained to a specified direction by guide bars.

*Neutral Point*—The point about which all of the cyclic volumetric changes of a structure take place.

*Open Joint*—A joint designed to permit the passage of water and debris through the joint.

*Plain Elastomeric Pad (PEP)*—A pad made exclusively of elastomer, which provides limited translation and rotation.

*Polytetrafluoroethylene (PTFE)*—Also known as Teflon.

*Pot Bearing*—A bearing that carries vertical load by compression of an elastomeric disc confined in a steel cylinder and that accommodates rotation by deformation of the disc.

*Poured Seal*—A seal made from a material that remains flexible (asphaltic, polymeric, or other), which is poured into the gap of a joint and is expected to adhere to the sides of the gap. Typically used only when expected total range of movement is less than 1.5 in.

*PTFE Sliding Bearing*—A bearing that carries vertical load through contact stresses between a PTFE sheet or woven fabric and its mating surface, and that permits movements by sliding of the PTFE over the mating surface.

*Relief Joint*—A deck joint, usually transverse, that is designed to minimize either unintended composite action or the effect of differential horizontal movement between a deck and its supporting structural system.

*Restrainers*—A system of high-strength cables or rods that transfers forces between superstructure elements and/or superstructure and substructure elements under seismic or other dynamic loads after an initial slack is taken up, while permitting thermal movements.

*Root Mean Square*—RMS

*Rotation about the Longitudinal Axis*—Rotation about an axis parallel to the main span direction of the bridge.

*Rotation about the Transverse Axis*—Rotation about an axis parallel to the transverse axis of the bridge.

*Sealed Joint*—A joint provided with a joint seal.

*Shock Transmission Unit (STU)*—A device that provides a temporary rigid link between superstructure elements and/or superstructure and substructure elements under seismic, braking, or other dynamic loads, while permitting thermal movements.

*Single-Support-Bar System (SSB)*—A MBJS designed so that only one support bar is connected to all of the centerbeams. The centerbeam/support bar connection typically consists of a yoke through which the support bar slides.

*Sliding Bearing*—A bearing that accommodates movement by translation of one surface relative to another.

*Steel-Reinforced Elastomeric Bearing*—A bearing made from alternate laminates of steel and elastomer bonded together during vulcanization. Vertical loads are carried by compression of the elastomer. Movements parallel to the reinforcing layers and rotations are accommodated by deformation of the elastomer.

*Strip Seal*—A sealed joint with an extruded elastomeric seal retained by edgebeams that are anchored to the structural elements (deck, abutment, etc). Typically used for expected total movement ranges from 1.5 to 4.0 in., although single seals capable of spanning a 5.0 in. gap are also available.

*Translation*—Horizontal movement of the bridge in the longitudinal or transverse direction.

*Transverse*—The horizontal direction normal to the longitudinal axis of the bridge.

*Waterproofed Joints*—Open or closed joints that have been provided with some form of trough below the joint to contain and conduct deck discharge away from the structure.

*Welded Multiple-Support-Bar System (WMSB)*—A MBJS designed so that each support bar is welded to only one centerbeam. Although some larger WMSB systems have been built and are performing well, WMSB systems are typically impractical for more than nine seals or for movement ranges larger than 27.0 in.

### 14.3—NOTATION

$A$	= plan area of elastomeric element or bearing (in. <sup>2</sup> ) (14.6.3.1)
$A_{Wbot}$	= area of weld at the bottom (in. <sup>2</sup> ) (14.5.6.9.7b)
$A_{Wmid}$	= minimum cross-sectional area of weld (in. <sup>2</sup> ) (14.5.6.9.7b)
$A_{Wtop}$	= area of weld at the top (in. <sup>2</sup> ) (14.5.6.9.7b)
$a_{cr}$	= creep deflection divided by initial dead load deflection (14.7.5.3.6)
$B_a$	= dimensionless coefficient used to determine peak hydrostatic stress (14.7.5.3.3)
$C_\alpha$	= parameter used to determine hydrostatic stress (14.7.5.3.3)
$c$	= minimum vertical clearance between rotating and nonrotating parts (in.); design clearance between piston and pot (in.) (C14.7.3.1) (14.7.4.7)
$D$	= diameter of the projection of the loaded surface of the bearing in the horizontal plane (in.); diameter of pad (in.); diameter of the bearing (in.) (14.7.3.2) (14.7.5.1) (14.7.6.3.5b) (14.7.6.3.5d) (14.7.6.3.6) (14.7.5.3.3) (14.7.5.3.4)
$D_a$	= dimensionless coefficient used to determine shear strain due to axial load (14.7.5.3.3)
$D_d$	= diameter of the disc element (in.) (14.7.8.1) (14.7.8.5)
$D_P$	= internal diameter of pot (in.) (14.7.4.3) (14.7.4.6) (14.7.4.7)
$D_r$	= dimensionless coefficient used to determine shear strain due to rotation (14.7.5.3.3)
$D_1$	= diameter of the rocker or roller surface (in.) (14.7.1.4)
$D_2$	= diameter of the mating surface, positive if the curvatures have the same sign, infinite if the mating surface is flat (in.) (14.7.1.4)
$d$	= diameter of rocker or roller (in.); the diameter of the hole or holes in the bearing (in.) (C14.7.1.4) (C14.7.5.1)
$d_{a1}$	= dimensionless coefficient used to determine shear strain due to axial load (C14.7.5.3.3)
$d_{a2}$	= dimensionless coefficient used to determine shear strain due to axial load (C14.7.5.3.3)
$d_{a3}$	= dimensionless coefficient used to determine shear strain due to axial load (C14.7.5.3.3)
$d_{cb}$	= depth of the centerbeam (in.) (14.5.6.9.7b)
$d_{sb}$	= depth of the support bar (in.) (14.5.6.9.7b)
$E_c$	= effective modulus of elastomeric bearing in compression (ksi); uniaxial compressive stiffness of the CDP bearing pad. It may be taken as 30 ksi in lieu of pad specific test data (ksi) (14.6.3.2) (14.7.6.3.3) (14.7.6.3.5c)
$E_s$	= Young's modulus for steel (ksi) (14.7.1.4)

$F_y$	= specified minimum yield strength of the weakest steel at the contact surface (ksi); yield strength of steel (ksi); yield strength of steel reinforcement (ksi) (14.7.1.4) (14.7.4.6) (14.7.4.7) (14.7.5.3.5)
$G$	= shear modulus of the elastomer (ksi); shear modulus of the CDP (14.6.3.1) (C14.6.3.2) (14.7.5.2) (14.7.5.3.3) (14.7.5.3.4) (C14.7.5.3.6) (14.7.6.2) (14.7.6.3.2) (14.7.6.3.5b) (14.7.6.3.5d) (14.7.6.3.4)
$H_{bu}$	= lateral load transmitted to the superstructure and substructure by bearings from applicable strength and extreme event load combinations in Table 3.4.1-1 (kip) (14.6.3.1)
$H_s$	= horizontal load from applicable service load combinations in Table 3.4.1-1 (kip) (14.7.3.3)
$H_u$	= lateral load from applicable strength and extreme event load combinations in Table 3.4.1-1 (kip) (14.7.4.7)
$h_{p1}$	= pot cavity depth (in.) (C14.7.4.3)
$h_{p2}$	= vertical clearance between top of piston and top of pot wall (in.) (C14.7.4.3)
$h_r$	= depth of elastomeric disc (in.) (14.7.4.3)
$h_{ri}$	= thickness of $i$ th elastomeric layer (in.); thickness of $i$ th internal elastomeric layer (in.); layer thickness for FGP which equals the greatest distance between midpoints of two double fiberglass reinforcement layers (in.); thickness of a PEP (in.); mean thickness of two layers of elastomer bonded to the same reinforcement for FGP when the two layers are of different thicknesses (in.) (14.7.5.1) (14.7.5.3.6) (14.7.5.3.3) (14.7.5.3.5) (14.7.6.3.3) (14.7.6.3.5d) (14.7.6.3.7) (14.7.6.3.2)
$h_{rt}$	= total elastomer thickness (in.); smaller of total elastomer or bearing thickness (in.) (14.6.3.1) (14.6.3.2) (14.7.5.3.2) (14.7.5.3.3) (14.7.5.3.4) (14.7.6.3.5b) (14.7.6.3.4)
$h_s$	= thickness of steel reinforcement (in.) (14.7.5.3.5)
$h_w$	= height of the weld (in.); height from top of rim to underside of piston (in.) (14.5.6.9.7b) (C14.7.4.3) (14.7.4.7)
$I$	= moment of inertia of plan shape of bearing (in. <sup>4</sup> ) (14.6.3.2)
$K$	= rotational stiffness of CDP (kip-in./rad.); bulk modulus (ksi) (C14.6.3.2) (C14.7.5.3.3)
$L$	= projected length of the sliding surface perpendicular to the rotation axis (in.); plan dimension of the bearing perpendicular to the axis of rotation under consideration (generally parallel to the global longitudinal bridge axis) (in.); length of a CDP bearing pad in the plane of rotation (in.) (14.7.3.3) (14.7.5.1) (14.7.5.3.3) (14.7.5.3.4) (14.7.6.3.5b) (14.7.6.3.6) (14.7.6.3.5c)
$M_H$	= horizontal bending moment range in the centerbeam on the critical section located at the weld toe due to horizontal force range (kip-in.) (14.5.6.9.7b)
$M_{OT}$	= overturning moment range from horizontal reaction force (kip-in.) (14.5.6.9.7b)
$M_V$	= vertical bending moment range in the centerbeam on the critical section located at the weld toe due to the vertical force range (kip-in.); component of vertical bending moment range in the support bar due to the vertical reaction force range in the connection located on the critical section at the weld toe (kip-in.) (14.5.6.9.7b)
$M_u$	= moment transmitted to the superstructure and substructure by bearings from applicable strength and extreme event load combinations in Table 3.4.1-1 (kip-in.) (14.6.3.2)
$m$	= modification factor (14.8.3.1) (5.7.5)
$n$	= number of interior layers of elastomer (14.7.5.3.3) (14.7.5.4) (14.7.6.1) (14.7.6.3.5d)
$P_D$	= compressive load at the service limit state (load factor = 1.0) due to permanent loads (kip) (14.7.3.3)
$P_S$	= total compressive load from applicable service load combinations in Table 3.4.1-1 (kip) (14.7.1.4) (14.7.3.2)
$P_u$	= compressive force from applicable strength and extreme event load combinations in Table 3.4.1-1 (kip) (14.6.3.1)
$p$	= allowable bearing at the service limit state (kip/in.) (C14.7.1.4)
$R$	= radius of curved sliding surface (in.) (14.6.3.2) (14.7.3.3)
$R_H$	= horizontal reaction force range in the connection (kip) (14.5.6.9.7b)
$R_o$	= radial distance from center of pot to object in question (e.g., pot wall, anchor bolt, etc.) (in.) (C14.7.4.3)
$R_V$	= vertical reaction force range in the connection (kip) (14.5.6.9.7b)
$S$	= shape factor of the CDP pad computed based on Eq. 14.7.5.1-1 and based on total pad thickness; shape factor of an individual elastomer layer; shape factor of PEP (14.6.3.2) (C14.6.3.2) (C14.7.5.3.6) (14.7.6.3.5b)
$S_i$	= shape factor of the $i$ th layer of an elastomeric bearing; shape factor of the $i$ th internal layer of an elastomeric bearing; shape factor for FGP based upon an $h_{ri}$ layer thickness which equals the greatest distance between midpoints of two double fiberglass reinforcement layers (14.7.5.1) (14.7.5.3.3) (14.7.5.3.4) (14.7.5.4) (14.7.6.1) (14.7.6.3.2) (14.7.6.3.5d)
$S_{RB}$	= combined bending stress range in the centerbeam (ksi); bending stress range in the support bar due to maximum moment including moment from vertical reaction and overturning at the connection (ksi) (14.5.6.9.7b)
$S_{RZ}$	= vertical stress range in the top of the centerbeam-to-support-bar weld from the concurrent reaction of the support beam (ksi); vertical stress range in the bottom of the centerbeam-to-support-bar weld from the vertical and horizontal reaction force ranges in the connection (ksi) (14.5.6.9.7b)
$S_{Wbot}$	= section modulus of the weld at the bottom for bending in the direction of the support bar axis (in. <sup>3</sup> ) (14.5.6.9.7b)

$S_{Wmid}$	= section modulus of the weld at the most narrow cross-section for bending in the direction normal to the centerbeam axis (in. <sup>3</sup> ) (14.5.6.9.7b)
$S_{Wtop}$	= section modulus of the weld at the top for bending in the direction normal to the centerbeam axis (in. <sup>3</sup> ) (14.5.6.9.7b)
$S_{Xcb}$	= vertical section modulus to the bottom of the centerbeam (in. <sup>3</sup> ) (14.5.6.9.7b)
$S_{Xsb}$	= vertical section modulus of the support bar to the top of the support bar (in. <sup>3</sup> ) (14.5.6.9.7b)
$S_{Ycb}$	= horizontal section modulus of the centerbeam (in. <sup>3</sup> ) (14.5.6.9.7b)
$t_b$	= pot base thickness (in.) (14.7.4.6) (14.7.4.7)
$t_p$	= total thickness of CDP pad (in.) (14.6.3.2) (14.7.6.3.5c)
$t_w$	= pot wall thickness (in.) (14.7.4.6) (14.7.4.7)
$W$	= roadway surface gap in a transverse deck joint, measured in the direction of travel at the extreme movement determined using the appropriate strength load combination specified in Table 3.4.1-1 (in.); width of the bearing (in.); length of cylinder (in.); length of cylindrical surface (in.); plan dimension of the bearing parallel to the axis of rotation under consideration (generally parallel to the global transverse bridge axis) (in.) (14.5.3.2) (14.7.1.4) (14.7.3.2) (14.7.3.3) (14.7.5.1) (C14.7.5.3.3) (14.7.5.3.4) (14.7.6.3.5b) (14.7.6.3.5d) (14.7.6.3.6)
$w$	= height of piston rim (in.) (14.7.4.7)
$\alpha$	= parameter used to determine hydrostatic stress (1/rad.) (14.7.5.3.3)
$\gamma_a$	= shear strain caused by axial load (14.7.5.3.3)
$\gamma_{a,cy}$	= shear strain caused by cyclic axial load (14.7.5.3.3)
$\gamma_{a,st}$	= shear strain caused by static axial load (14.7.5.3.3)
$\gamma_r$	= shear strain caused by rotation (14.7.5.3.3)
$\gamma_{r,cy}$	= shear strain caused by rotation from cyclic loads (14.7.5.3.3)
$\gamma_{r,st}$	= shear strain caused by rotation from static loads (14.7.5.3.3)
$\gamma_s$	= shear strain caused by shear displacement (14.7.5.3.3)
$\gamma_{s,cy}$	= shear strain caused by shear displacement from cyclic loads (14.7.5.3.3)
$\gamma_{s,st}$	= shear strain caused by shear displacement from static loads (14.7.5.3.3)
$\beta$	= angle between the vertical and resultant applied load (rad.) (14.7.3.3)
$\Delta F_{TH}$	= constant amplitude fatigue threshold taken from Table 6.6.1.2.5-3 for the detail category of interest (ksi); constant amplitude fatigue threshold for Category A as specified in Article 6.6 (14.5.6.9.7a) (14.7.5.3.5)
$\Delta f$	= force effect, design live load stress range due to the simultaneous application of vertical and horizontal axle loads specified in Article 14.5.6.9.4 and distributed as specified in Article 14.5.6.9.5, and calculated as specified in Article 14.5.6.9.7b (ksi) (14.5.6.9.7a) (14.5.6.9.7b)
$\Delta O$	= maximum horizontal displacement of the bridge superstructure at the service limit state (in.) (14.7.5.3.2)
$\Delta S$	= maximum total shear deformation of the elastomer from applicable service load combinations in Table 3.4.1-1 (in.); maximum total shear deformation of the bearing from applicable service load combinations in Table 3.4.1-1 (in.); maximum total static or cyclic shear deformation of the elastomer from applicable service load combinations in Table 3.4.1-1 (in.) (14.7.5.3.2) (14.7.6.3.4) (14.7.5.3.3)
$\Delta_T$	= design thermal movement range computed in accordance with Article 3.12.2 (in.) (14.7.5.3.2)
$\Delta_u$	= shear deformation from applicable strength and extreme event load combinations in Table 3.4.1-1 (in.) (14.6.3.1)
$\delta_d$	= initial dead load compressive deflection (in.) (14.7.5.3.6)
$\delta_L$	= instantaneous live load compressive deflection (in.) (14.7.5.3.6)
$\delta_{lt}$	= long term dead load compressive deflection (in.) (14.7.5.3.6)
$\delta_u$	= vertical deflection from applicable strength load combinations in Table 3.4.1-1 (in.) (C14.7.4.3)
$\varepsilon$	= compressive strain in an elastomer layer (C14.7.5.3.6)
$\varepsilon_a$	= total of static and cyclic average axial strain taken as positive for compression in which the cyclic component is multiplied by 1.75 from applicable service load combinations in Table 3.4.1-1 (ksi) (14.7.5.3.3) (14.7.5.4)
$\varepsilon_c$	= maximum uniaxial strain due to compression under total load from applicable service load combinations in Table 3.4.1-1 (14.7.6.3.5c)
$\varepsilon_{di}$	= initial dead load compressive strain in $i$ th elastomer layer (14.7.5.3.6)
$\varepsilon_{Li}$	= instantaneous live load compressive strain in $i$ th elastomer layer (14.7.5.3.6)
$\varepsilon_s$	= average compressive strain due to total load from applicable service load combinations in Table 3.4.1-1 (14.7.6.3.3)
$\varepsilon_t$	= maximum uniaxial strain due to combined compression and rotation from applicable service load combinations in Table 3.4.1-1 (14.7.6.3.5c)
$\theta_L$	= maximum rotation of the CDP pad at the service limit state (load factor = 1.0) due to live load (rad.) (14.7.6.3.5c)

$\theta_s$	= maximum service limit state rotation due to total load for bearings unlikely to experience hard contact between metal components (rad.); maximum service limit state design rotation angle specified in Article 14.4.2.1 (rad.); maximum rotation of the CDP pad from applicable service load combinations in Table 3.4.1-1 (rad.); maximum service limit state design rotation angle about any axis of the pad specified in Article 14.4.2.1 (rad.); maximum static or cyclic service limit state design rotation angle of the elastomer specified in Article 14.4.2.1 (rad.); total of static and cyclic maximum service limit state design rotation angles of the elastomer specified in Article 14.4.2.1 in which the cyclic component is multiplied by 1.75 (rad.) (C14.4.2) (14.4.2.1) (14.6.3.2) (14.7.6.3.5c) (14.7.6.3.5b) (14.7.6.3.5d) (14.7.5.3.3) (14.7.5.4)
$\theta_{s,x}$	= maximum service limit state design rotation angle specified in Article 14.4.2.1 about transverse axis (generally parallel to the global transverse bridge axis) (rad.) (14.7.6.3.5b) (14.7.6.3.5d)
$\theta_{s,z}$	= maximum service limit state design rotation angle specified in Article 14.4.2.1 about longitudinal axis (rad.) (generally parallel to the global longitudinal bridge axis) (14.7.6.3.5b) (14.7.6.3.5d)
$\theta_u$	= maximum strength limit state rotation for bearings that may experience hard contact between metal components (rad.); maximum strength limit state rotation for bearings which are less likely to experience hard contact between metal components (rad.); design rotation from applicable strength load combinations in Table 3.4.1-1 or Article 14.4.2.2.1 (rad.); maximum strength limit state design rotation angle specified in Article 14.4.2.2.1 (rad.); maximum strength limit state design rotation angle specified in Article 14.4.2.2.2 (rad.) (C14.4.2) (14.4.2.2.1) (14.4.2.2.2) (C14.7.3.1) (14.7.3.3) (14.7.4.3) (14.7.4.7) (14.7.8.1)
$\lambda$	= compressibility index (C14.7.5.3.3)
$\mu$	= coefficient of friction; coefficient of friction of the PTFE slider (14.6.3.1) (C14.7.8.4)
$\sigma$	= instantaneous live load compressive stress or dead load compressive stress in an individual elastomer layer (ksi) (C14.7.5.3.6)
$\sigma_{hyd}$	= peak hydrostatic stress (ksi) (14.7.5.3.3)
$\sigma_L$	= average compressive stress at the service limit state (load factor = 1.0) due to live load (ksi) (14.7.5.3.5) (14.7.6.3.2)
$\sigma_s$	= average compressive stress due to total load from applicable service load combinations in Table 3.4.1-1 (ksi); average compressive stress due to total load associated with the maximum rotation from applicable service load combinations in Table 3.4.1-1 (ksi); average compressive stress due to total static or cyclic load from applicable service load combinations in Table 3.4.1-1 (ksi); total of static and cyclic average compressive stress in which the cyclic component is multiplied by 1.75 from applicable service load combinations in Table 3.4.1-1 (ksi) (14.7.4.6) (14.7.5.3.4) (14.7.5.3.5) (14.7.6.3.2) (14.7.6.3.3) (14.7.6.3.4) (14.6.3.2) (14.7.6.3.5b) (14.7.6.3.5c) (14.7.6.3.5d) (14.7.5.3.3)
$\sigma_{ss}$	= maximum average contact stress at the service limit state permitted on PTFE by Table 14.7.2.4-1 or on bronze by Table 14.7.7.3-1 (ksi) (14.7.3.2) (14.7.3.3)
$\phi$	= resistance factor (14.6.1) (14.7.3.2) (C14.7.4.7)
$\phi_{tension}$	= resistance factor for tension for anchors governed by the steel (14.5.6.9.6)
$\phi_{shear}$	= resistance factor for shear for anchors governed by the steel (14.5.6.9.6)
$\phi_{A\ tension}$	= resistance factor for tension for anchors governed by the concrete, Condition A, supplemental reinforcement in the failure area (14.5.6.9.6)
$\phi_{A\ shear}$	= resistance factor for shear for anchors governed by the concrete, Condition A, supplemental reinforcement in the failure area (14.5.6.9.6)
$\phi_{B\ tension}$	= resistance factor for tension for anchors governed by the concrete, Condition B, no supplemental reinforcement in the failure area (14.5.6.9.6)
$\phi_{B\ shear}$	= resistance factor for shear for anchors governed by the concrete, Condition B, no supplemental reinforcement in the failure area (14.5.6.9.6)
$\Psi$	= subtended semiangle of the curved surface (rad.) (14.7.3.3)

## 14.4—MOVEMENTS AND LOADS

### 14.4.1—General

The selection and layout of the joints and bearings shall allow for deformations due to temperature and other time-dependent causes and shall be consistent with the proper functioning of the bridge.

### C14.4.1

The joints and bearings should allow movements due to temperature changes, creep and shrinkage, elastic shortening due to prestressing, traffic loading, construction tolerances or other effects. If these movements are

Deck joints and bearings shall be designed to resist loads and accommodate movements at the service and strength limit states and to satisfy the requirements of the fatigue and fracture limit state. The loads induced on the joints, bearings, and structural members depend on the stiffness of the individual elements and the tolerances achieved during fabrication and erection. These influences shall be taken into account when calculating design loads for the elements. No damage due to joint or bearing movement shall be permitted at the service limit state, and no irreparable damage shall occur at the strength limit state. At the extreme event limit state, bearings which are designed to act as fuses or sustain irreparable damage may be permitted by the Owner provided loss of span is prevented.

Translational and rotational movements of the bridge shall be considered in the design of MBJS and bearings. The sequence of construction shall be considered, and all critical combinations of load and movement shall be considered in the design. Rotations about two horizontal axes and the vertical axis shall be considered. The movements shall include those caused by the loads, deformations, and displacements caused by creep, shrinkage and thermal effects, and inaccuracies in installation. In all cases, both instantaneous and long-term effects shall be considered. The influence of dynamic load allowance shall be included for MBJS, but need not be included for bearings. The most adverse combination shall be tabulated for the bearings in a rational form such as shown in Figure C14.4.1-1.

For determining force effects in joints, bearings, and adjacent structural elements, the influence of their stiffnesses and the expected tolerances achieved during fabrication and erection shall be considered.

The three-dimensional effects of translational and rotational movements of the bridge shall be considered in the design of MBJS and bearings.

Both instantaneous and long-term effects shall be considered in the design of joints and bearings.

The effects of curvature, skew, rotations, and support restraint shall be recognized in the analysis.

The forces resulting from transverse or longitudinal prestressing of the concrete deck or steel girders shall be considered in the design of the bearings.

restrained, large horizontal forces may result. If the bridge deck is cast-in-place or precast concrete, the bearings at a single support should permit transverse expansion and contraction. Externally applied transverse loads such as wind, earthquake, or traffic braking forces may be carried either on a small number of bearings near the centerline of the bridge or by an independent guide system. The latter is likely to be needed if the horizontal forces are large and fusing or irreparable damage is not permitted.

See Article C14.6.5.3 for discussion concerning bearings which are designed to act as fuses at the extreme event limit state.

Distribution of vertical load among bearings may adversely affect individual bearings. This is particularly critical when the girders are stiff in bending and torsion and bearings are stiff in compression, and the construction method does not allow minor misalignments to be corrected.

Bridge movements arise from a number of different causes. Simplified estimates of bridge movements, particularly on bridges with complex geometry, may lead to improper estimation of the direction of motion and, as a result, an improper selection of the bearing or joint system. Curved and skewed bridges have transverse as well as longitudinal movement due to temperature effects and creep or shrinkage. Transverse movement of the superstructure relative to the substructure may become significant for very wide bridges. Relatively wide curved and skewed bridges often undergo significant diagonal thermal movement, which introduces large transverse movements or large transverse forces if the bridge is restrained against such movements. Rotations caused by permissible levels of misalignment during installation should also be considered, and in many cases they will be larger than the live load rotations.

The neutral axis of a girder that acts compositely with its bridge deck is typically close to the underside of the deck. As a result, the neutral axis of the beam and the center of rotation of the bearing seldom coincide. Under these conditions, end rotation of the girder induces either horizontal movements or forces at the bottom flange or bearing level. The location of bearings off the neutral axes of the girders can also create horizontal forces due to elastic shortening of the girders when subjected to vertical loads at continuous supports.

The failure of bridge bearings or joint seals may ultimately lead to deterioration or damage to the bridge.

Each bearing and MBJS should be clearly identified in design documents, and all requirements should be identified. One possible format for this information is shown in Figure C14.4.1-1 for limit states other than extreme event.

When integral piers or abutments are used, the substructure and superstructure are connected such that additional restraints against superstructure rotation are introduced.

In curved bridges, thermal stresses are minimized when bearings are oriented such that they permit free translation along rays from a single point. With bearings arranged to permit such movement along these rays, there will be no thermal forces generated when the superstructure temperature changes uniformly. Any other orientation of the bearings will induce thermal forces into the superstructure and substructure. However, other considerations often make impractical the orientation along rays from a single point.

Prestressing of the deck causes changes in the vertical reactions due to the eccentricity of the forces, which creates restoring forces. Effects of creep and shrinkage also should be considered.

**Figure C14.4.1-1—Typical Bridge Bearing Schedule (continued)****14.4.2—Design Requirements**

The minimum thermal movements shall be computed from the extreme temperature specified in Article 3.12.2 and the estimated setting temperatures. Design loads shall be based on the load combinations and load factors specified in Section 3.

**C14.4.2**

Rotations are considered at the service and strength limit states as appropriate for different types of bearings. Bearings must accommodate movements in addition to supporting loads, so displacements, and in particular rotations, are needed for design. Live load rotations are typically less than 0.005 rad., but the total rotation due to fabrication and setting tolerances for seats, bearings, and

girders may be significantly larger than this. Therefore, the total design rotation is found by summing rotations due to dead and live load and adding allowances for profile grade effects and the tolerances described above. Article 14.8.2 specifies when a tapered plate shall be used if the rotation due to permanent load at the service limit state (load factor = 1.0) becomes excessive. An Owner may reduce the fabrication and setting tolerance allowances if justified by a suitable quality control plan; therefore, these tolerance limits are stated as recommendations rather than absolute limits.

Failure of deformable components such as elastomeric bearings is generally governed by a gradual deterioration under many cycles of load rather than sudden failure under a single load application. Further, the design limits for elastomeric bearings were originally developed under ASD service load conditions rather than the strength limit state loads considered during development of the high load multirotational bearing systems. Unless smaller tolerances can be justified,  $\theta_s$  for elastomeric components is the service limit state rotation plus 0.005 rad.

Metal or concrete components are susceptible to damage under a single rotation that causes metal-to-metal contact, and so they must be designed using the strength limit state rotations. Unless smaller tolerances can be justified,  $\theta_u$  is the strength limit state rotation plus 0.01 rad.

Disc bearings are less likely to experience metal-to-metal contact than other High Load Multirotational (HLMR) bearings because the load element is unconfined. As a result, the total allowance for rotation is consequently smaller for a disc bearing than other HLMR bearings; however, the proof load test, as specified in the *AASHTO LRFD Bridge Construction Specifications*, assures against metal-to-metal contact.

#### 14.4.2.1—Elastomeric Pads and Steel Reinforced Elastomeric Bearings

The maximum service limit state rotation due to total load,  $\theta_s$ , for bearings unlikely to experience hard contact between metal components shall be taken as the sum of:

- The rotations from applicable service load combinations in Table 3.4.1-1, and
- An allowance for uncertainties, which shall be taken as 0.005 rad. unless an approved quality control plan justifies a smaller value.

The static and cyclic components of  $\theta_s$  shall be considered separately when design is according to Article 14.7.5.3.3.

#### **14.4.2.2—High Load Multirotational (HLMR) Bearings**

##### *14.4.2.2.1—Pot Bearings and Curved Sliding Surface Bearings*

The maximum strength limit state rotation,  $\theta_u$ , for bearings such as pot bearings and curved sliding surfaces that may potentially experience hard contact between metal components shall be taken as the sum of:

- The rotations from applicable strength load combinations in Table 3.4.1-1;
- The maximum rotation caused by fabrication and installation tolerances, which shall be taken as 0.005 rad. unless an approved quality control plan justifies a smaller value; and
- An allowance for uncertainties, which shall be taken as 0.005 rad. unless an approved quality control plan justifies a smaller value.

##### *14.4.2.2.2—Disc Bearings*

The maximum strength limit state rotation,  $\theta_u$ , for disc bearings which are less likely to experience hard contact between metal components due to their unconfined load element, shall be taken as the sum of:

- The rotations from applicable strength load combinations in Table 3.4.1-1, and
- An allowance for uncertainties, which shall be taken as 0.005 rad. unless an approved quality control plan justifies a smaller value.

### **14.5—BRIDGE JOINTS**

#### **14.5.1—Requirements**

##### **14.5.1.1—General**

Deck joints shall consist of components arranged to accommodate the translation and rotation of the structure at the joint.

The type of joints and surface gaps shall accommodate the movement of motorcycles, bicycles, and pedestrians, as required, and shall neither significantly impair the riding characteristics of the roadway nor cause damage to vehicles.

The joints shall be detailed to prevent damage to the structure from water, deicing chemicals, and roadway debris.

Longitudinal deck joints shall be provided only where necessary to modify the effects of differential lateral and/or vertical movement between the superstructure and substructure.

##### **C14.5.1.1**

To accommodate differential lateral movement, elastomeric bearings or combination bearings with the capacity for lateral movement should be used instead of longitudinal joints where practical.

Joints and joint anchors for grid and timber decks and orthotropic deck superstructures require special details.

#### 14.5.1.2—Structural Design

Joints and their supports shall be designed to withstand force effects for the appropriate design limit state or states over the range of movements for the appropriate design limit state or states, as specified in Section 3. Resistance factors and modifiers shall be taken as specified in Sections 1, 5, 6, 7, and 8, as appropriate.

In snow regions, joint armor, armor connections, and anchors shall be designed to resist force effects that may be imposed on the joints by snagging snowplow blades. The edgebeams and anchorages of strip seals and MBJS with a skew exceeding 20 degrees in snow regions that do not incorporate protection methods such as those discussed in Article 14.5.3.3 shall be designed for the strength limit state with a minimum snowplow load acting as a horizontal line load on the top surface of the edgebeam in a direction perpendicular to the edgebeam of 0.12 kips/in. for a total length of 10.0 ft anywhere along the edgebeam in either direction. This load includes dynamic load allowance.

The following factors shall be considered in determining force effects and movements:

- Properties of materials in the structure, including coefficient of thermal expansion, modulus of elasticity, and Poisson's ratio;
- Effects of temperature, creep, and shrinkage;
- Sizes of structural components;
- Construction tolerances;
- Method and sequence of construction;
- Skew and curvature;
- Resistance of the joints to movements;
- Approach pavement growth;
- Substructure movements due to embankment construction;
- Foundation movements associated with the consolidation and stabilization of subsoils;
- Structural restraints; and
- Static and dynamic structural responses and their interaction.

#### C14.5.1.2

The strength limit state for the edgebeams of strip seals and MBJS and anchorage to the concrete or other elements should be checked with this snowplow load if the skew of the joint exceeds 20 degrees relative to a line transverse to the traveling direction. For smaller skews, the blades, which are skewed, will not strike an edgebeam all at once. Protection methods such as those discussed in Article 14.5.3.3 may eliminate the need to design for this snowplow load.

Snowplow blade angles vary regionally. Unless protection methods such as those discussed in Article 14.5.3.3 are used, agencies should avoid MBJS installations with skew that is within three degrees of the plow angle used in that region, to avoid having the plow drop into the gap between centerbeams.

The snowplow load was estimated from snowplow manufacturer information as the force required to deflect a spring-activated blade with 2.0 in. of compression and ten degrees of deflection. The snowplow load includes the effect of impact so the dynamic load allowance should not be applied. The snowplow load should be multiplied by the appropriate strength limit state load factor for live load.

Superstructure movements include those due to placement of bridge decks, volumetric changes, such as shrinkage, temperature, moisture and creep, passage of vehicular and pedestrian traffic, pressure of wind, and the action of earthquakes. Substructure movements include differential settlement of piers and abutments, tilting, flexure, and horizontal translation of wall-type abutments responding to the placement of backfill as well as shifting of stub abutments due to the consolidation of embankments and in-situ soils.

Any horizontal movement of a bridge superstructure will be opposed by the resistance of bridge bearings to movement and the rigidity or flexural resistance of substructure elements. The rolling resistance of rocker and rollers, the shear resistance of elastomeric bearings, or the frictional resistance of bearing sliding surfaces will oppose movement. In addition, the rigidity of abutments and the relative flexibility of piers of various heights and foundation types will affect the magnitude of bearing movement and the bearing forces opposing movement.

Rigid approach pavements composed of cobblestone, brick, or jointed concrete will experience growth or substantial longitudinal pressure due to restrained growth. To protect bridge structures from these potentially destructive pressures and to preserve the movement range of deck joints and the performance of joint seals, either effective pavement pressure relief joints or pavement anchors should be provided in approach pavements, as described in *Transportation Research Record 1113*.

The length of superstructure affecting the movement at one of its joints shall be the length from the joint being considered to the structure's neutral point.

For a curved superstructure that is laterally unrestrained by guided bearings, the direction of longitudinal movement at a bearing joint may be assumed to be parallel to the chord of the deck centerline taken from the joint to the neutral point of the structure.

The potential for unaligned longitudinal and rotational movement of the superstructure at a joint should be considered in designing the vertical joints in curbs and raised barriers and in determining the appropriate position and orientation of closure or bridging plates.

#### 14.5.1.3—Geometry

The moving surfaces of the joint shall be designed to work in concert with the bearings to avoid binding the joints and adversely affecting force effects imposed on bearings.

#### 14.5.1.4—Materials

The materials shall be selected so as to ensure that they are elastically, thermally, and chemically compatible. Where substantial differences exist, material interfaces shall be formulated to provide fully functional systems.

Materials, other than elastomers, should have a service life of not less than 75 yr. Elastomers for joint seals and troughs should provide a service life not less than 25 yr.

Joints exposed to traffic should have a skid-resistant surface treatment, and all parts shall be resistant to attrition and vehicular impact.

Except for high-strength bolts, fasteners for joints exposed to deicing chemicals shall be made of stainless steel.

#### 14.5.1.5—Maintenance

Deck joints shall be designed to operate with a minimum of maintenance for the design life of the bridge.

Detailing should permit access to the joints from below the deck and provide sufficient area for maintenance.

Mechanical and elastomeric components of the joint shall be replaceable.

Joints shall be designed to facilitate vertical extension to accommodate roadway overlays.

#### 14.5.2—Selection

##### 14.5.2.1—Number of Joints

The number of movable deck joints in a structure should be minimized. Preference shall be given to continuous deck systems and superstructures and, where appropriate, integral bridges.

When horizontal movement at the ends of a superstructure are due to volumetric changes, the forces generated within the structure in resistance to these changes are balanced. The neutral point can be located by estimating these forces, taking into account the relative resistance of bearings and substructures to movement. The length of superstructure contributing to movement at a particular joint can then be determined.

#### C14.5.1.3

For square or slightly skewed bridge layouts, moderate roadway grades at the joint and minimum changes in both horizontal and vertical joint alignment may be preferred in order to simplify the movements of joints and to enhance the performance of the structure.

#### C14.5.1.4

Preference should be given to those materials that are least sensitive to field compounding and installation variables and to those that can be repaired and altered by nonspecialized maintenance forces. Preference should also be given to those components and devices that will likely be available when replacements are needed.

#### C14.5.1.5

The position of bearings, structural components, joints and abutment backwalls, and the configuration of pier tops should be chosen so as to provide sufficient space and convenient access to joints from below the deck. Inspection hatches, ladders, platforms, and/or catwalks shall be provided for the deck joints of large bridges not directly accessible from the ground.

##### C14.5.2.1

Integral bridges, bridges without movable deck joints, should be considered where the length of superstructure and flexibility of substructures are such that secondary stresses due to restrained movement are controlled within tolerable limits.

The need for a fully functional cycle-control joint shall be investigated on approaches of integral bridges.

Movable joints may be provided at abutments of single-span structures exposed to appreciable differential settlement. Intermediate deck joints should be considered for multiple-span bridges where differential settlement would result in significant overstresses.

Where a floorbeam design that can tolerate differential longitudinal movements resulting from relative temperature and live load response of the deck and independent supporting members, such as girders and trusses, is not practical, relief joints in the deck slab, movable joints in the stringers, and movable bearings between the stringers and floorbeams should be used.

Long-span deck-type structures with steel stringers that are slightly skewed, continuous, and composite can withstand substantial differential settlement without significant secondary stresses. Consequently, intermediate deck joints are rarely necessary for multiple-span bridges supported by secure foundations, i.e., piles, bedrock, dense subsoils, etc. Because the stresses induced by settlement can alter the point of inflection, a more conservative control of fatigue-prone detail locations is appropriate.

Guidance on the movements of the substructure can be found in Articles 10.5.2, 10.6.2, 10.7.2, and 10.8.2.

#### **14.5.2.2—Location of Joints**

Deck joints should be avoided over roadways, railroads, sidewalks, other public areas, and at the low point of sag vertical curves.

Deck joints should be positioned with respect to abutment backwalls and wingwalls to prevent the discharge of deck drainage that accumulates in the joint recesses onto bridge seats.

Open deck joints should be located only where drainage can be directed to bypass the bearings and discharged directly below the joint.

Closed or waterproof deck joints should be provided where joints are located directly above structural members and bearings that would be adversely affected by debris accumulation. Where deicing chemicals are used on bridge decks, sealed or waterproofed joints should be provided.

For straight bridges, the longitudinal elements of deck joints, such as plate fingers, curb and barrier plates, and modular bridge joint system support bars, should be placed parallel to the longitudinal axis of the deck. For curved and skewed structures, allowance shall be made for deck end movements consistent with that provided by the bearings.

Where possible, modular bridge joint systems should not be located in the middle of curved bridges to avoid unforeseeable movement demands. Preferably, modular bridge joint systems should not be located near traffic signals or toll areas so as to avoid extreme braking forces.

#### **C14.5.2.2**

Open joints with drainage troughs should not be placed where the use of horizontal drainage conductors would be necessary.

End rotations of deck-type structures occur about axes that are roughly parallel to the centerline of bearings along the bridge seat. In skewed structures, these axes are not normal to the direction of longitudinal movement. Sufficient lateral clearances between plates, open joints, or elastomeric joint devices should be provided to prevent binding due to lack of alignment between longitudinal and rotational movements.

### 14.5.3—Design Requirements

#### 14.5.3.1—Movements during Construction

Where practicable, construction staging should be used to delay construction of abutments and piers located in or adjacent to embankments until the embankments have been placed and consolidated. Otherwise, deck joints should be sized to accommodate the probable abutment and pier movements resulting from embankment consolidation after their construction.

Closure pours in concrete structures may be used to minimize the effect of prestress-induced shortening on the width of seals and the size of bearings.

#### C14.5.3.1

Where it is either desirable or necessary to accommodate settlement or other construction movements prior to deck joint installation and adjustment, the following construction controls may be used:

- Placing abutment embankment prior to pier and abutment excavation and construction,
- Surcharging embankments to accelerate consolidation and adjustment of in-situ soils,
- Backfilling wall-type abutments up to subgrade prior to placing bearings and backwalls above bridge seats, and
- Using deck slab blockouts to allow placing the major portion of span dead loads prior to joint installation.

#### C14.5.3.2

#### 14.5.3.2—Design Movements

A roadway surface gap,  $W$ , in in., in a transverse deck joint, measured in the direction of travel at the maximum movement determined using the appropriate strength load combination specified in Table 3.4.1-1 shall satisfy:

- For single gap:

$$W \leq 4.0 \text{ in.} \quad (14.5.3.2-1)$$

- For multiple modular gaps:

$$W \leq 3.0 \text{ in.} \quad (14.5.3.2-2)$$

For steel and nonprestressed wood superstructures, the minimum opening of a transverse deck joint and roadway surface gap therein shall not be less than 1.0 in. for movements determined using the appropriate strength load combination specified in Table 3.4.1-1. For concrete superstructures, consideration shall be given to the opening of joints due to creep and shrinkage that may require initial minimum openings of less than 1.0 in. at the strength limit state.

Unless more appropriate criteria are available, the maximum surface gap of longitudinal roadway joints shall not exceed 1.0 in. at the strength limit state.

At the maximum movement determined using the appropriate strength load combination specified in Table 3.4.1-1, the opening between adjacent fingers on a finger plate shall not exceed:

- 2.0 in. for longitudinal openings greater than 8.0 in., or
- 3.0 in. for longitudinal openings 8.0 in. or less.

The finger overlap at the maximum movement shall be not less than 1.5 in. at the strength limit state.

Where bicycles are anticipated in the roadway, the use of special covering floor plates in shoulder areas shall be considered.

Safe operation of motorcycles is one of the prime considerations in choosing the size of openings for finger plate joints.

**14.5.3.3—Protection**

Deck joints shall be designed to accommodate the effects of vehicular traffic, pavement maintenance equipment, and other long-term environmentally induced damage.

Joints in concrete decks should be armored with steel shapes, weldments, or castings. Such armor shall be recessed below roadway surfaces and be protected from snowplows.

Jointed approach pavements shall be provided with pressure relief joints and/or pavement anchors. Approaches to integral bridges shall be provided with cycle control pavement joints.

**C14.5.3.3**

Snowplow protection for deck joint armor and joint seals may consist of:

- Concrete buffer strips 12.0 to 18.0 in. wide with joint armor recessed 0.25 to 0.375 in. below the surface of such strips,
- Tapered steel ribs protruding up to 0.50 in. above roadway surfaces to lift the plow blades as they pass over the joints,
- Recesses in flexible pavement to position armor below anticipated rutting, but not so deep as to pond water.

Additional precautions to prevent damage by snowplows should be considered where the skew of the joints coincides with the skew of the plow blades, typically 30 degrees to 35 degrees.

**14.5.3.4—Bridging Plates**

Joint bridging plates and finger plates should be designed as cantilever members capable of supporting wheel loads at the strength limit state.

The differential settlement between the two sides of a joint bridging plate shall be investigated. If the differential settlement cannot be either reduced to acceptable levels or accommodated in the design and detailing of the bridging plates and their supports, a more suitable joint should be used.

Rigid bridging plates shall not be used at elastomeric bearings or hangers unless they are designed as cantilever members, and the contract documents require them to be installed to prevent binding of the joints due to horizontal and vertical movement at bearings.

**C14.5.3.4**

Where binding of bridging plates can occur at bearing joints due to differential vertical translation of abutting structural elements or due to the longitudinal movement of bridging plates and bearings on different planes, the plates can be subjected to the total dead and live load superstructure reaction. Where bridging plates are not capable of resisting such loads, they may fail and become a hazard to the movement of vehicular traffic.

Thick elastomeric bearings responding to the application of vertical load or short hangers responding to longitudinal deck movements may cause appreciable differential vertical translation of abutting structural elements at bearing joints. To accommodate such movements, an appropriate type of sealed joint or a waterproofed open joint, rather than a structural joint with rigid bridging plates or fingers, should be provided.

**14.5.3.5—Armor**

Joint-edge armor embedded in concrete substrates should be pierced by 0.75-in. minimum-diameter vertical vent holes spaced on not more than 18.0 in. centers.

Metal surfaces wider than 12.0 in. that are exposed to vehicular traffic shall be provided with an antiskid treatment.

**C14.5.3.5**

Vent holes are necessary to help expel entrapped air and facilitate the attainment of a solid concrete substrate under joint edge armor.

The contract documents should require hand packing of concrete under joint armor.

### 14.5.3.6—Anchors

Armor anchors or shear connectors should be provided to ensure composite behavior between the concrete substrate and the joint hardware and to prevent subsurface corrosion by sealing the boundaries between the armor and concrete substrate. Anchors for edgebeams of strip seals and MBJS shall be designed for the snowplow load as required in Article 14.5.1.2.

Anchors for roadway joint armor shall be directly connected to structural supports or extended to effectively engage the reinforced concrete substrate.

The free edges of roadway armor, more than 3.0 in. from other anchors or attachments, shall be provided with 0.50-in. diameter end-welded studs not less than 4.0 in. long spaced at not more than 12.0 in. from other anchors or attachments. The edges of sidewalk and barrier armor shall be similarly anchored.

### 14.5.3.7—Bolts

Anchor bolts for bridging plates, joint seals, and joint anchors shall be fully torqued high-strength bolts. The interbedding of nonmetallic substrates in connections with high-strength bolts shall be avoided. Cast-in-place anchors shall be used in new concrete. Expansion anchors, countersunk anchor bolts, and grouted anchors shall not be used in new construction.

### 14.5.4—Fabrication

Shapes or plates shall be of sufficient thickness to stiffen the assembly and minimize distortion due to welding.

To ensure appropriate fit and function, the contract documents should require that:

- Joint components be fully assembled in the shop for inspection and approval,
- Joints and seals be shipped to the job-site fully assembled, and
- Assembled joints in lengths up to 60.0 ft be furnished without intermediate field splices.

### 14.5.5—Installation

#### 14.5.5.1—Adjustment

The setting temperature of the bridge or any component thereof shall be taken as the actual air temperature averaged over the 24-hour period immediately preceding the setting event.

### C14.5.3.6

Snow plow impact should also be considered in designing anchors.

### C14.5.3.7

Grouted anchors may be used for maintenance of existing joints.

### C14.5.4

Joint straightness and fit of components should be enhanced by the use of shapes, bars, and plates 0.50 in. or thicker.

Construction procedures and practices should be developed to allow joint adjustment for installation temperatures without altering the orientation of joint parts established during shop assembly.

### C14.5.5.1

Except for short bridges where installation temperature variations would have only a negligible effect on joint width, plans for each expansion joint should include required joint installation widths for a range of probable installation temperatures. For concrete structures, use of a concrete thermometer and measurement of temperature in expansion joints between superstructure units may be considered.

For long structures, an allowance shall be included in the specified joint widths to account for the inaccuracies inherent in establishing installation temperatures and for superstructure movements that may take place during the time between the setting of the joint width and completion of joint installation. In the design of joints for long structures, preference should be given to those devices, details, and procedures that will allow joint adjustment and completion in the shortest possible time.

Connections of joint supports to primary members should allow horizontal, vertical, and rotational adjustments.

Construction joints and blockouts should be used where practicable to permit the placement of backfill and the major structure components prior to joint placement and adjustment.

#### **14.5.5.2—Temporary Supports**

Deck joints shall be furnished with temporary devices to support joint components in proper position until permanent connections are made or until encasing concrete has achieved an initial set. Such supports shall provide for adjustment of joint widths for variations in installation temperatures.

#### **14.5.5.3—Field Splices**

Joint designs shall include details for transverse field splices for staged construction and for joints longer than 60.0 ft. Where practicable, splices should be located outside of wheel paths and gutter areas.

Details in splices should be selected to maximize fatigue life.

Field splices provided for staged construction shall be located with respect to other construction joints to provide sufficient room to make splice connections.

When a field splice is required, the contract documents should require that permanent seals not be placed until after joint installation has been completed. Where practicable, only those seals that can be installed in one continuous piece should be used. Where field splicing is unavoidable, splices should be vulcanized.

#### **14.5.6—Considerations for Specific Joint Types**

##### **14.5.6.1—Open Joints**

Open deck joints shall permit the free flow of water through the joint. Open deck joints should not be used where deicing chemicals are applied. Piers and abutments at open joints shall satisfy the requirements of Article 2.5.2 in order to prevent the accumulation of water and debris.

An offset chart for installation of the expansion joints is recommended to account for uncertainty in the setting temperature at the time of design. The designer may provide offset charts in appropriate increments and include the chart on the design drawings. Placement of the expansion joint hardware during deck forming should accommodate differences between setting temperature and an assumed design installation temperature.

Construction procedures that will allow major structure dead load movements to occur prior to placement and adjustment of deck joints should be used.

#### **C14.5.5.2**

Temporary attachments should be released to avoid damaging anchorage encasements due to movement of superstructures responding to rapid temperature changes.

For long structures with steel primary members, instructions should be included in the contract documents to ensure the removal of temporary supports or release of their connections as soon as possible after concrete placement.

#### **C14.5.5.3**

Splices for less critical portions of joints or for lightly loaded joints should be provided with connections rigid enough to withstand displacement if joint armor is used as a form during concrete placement.

#### **C14.5.6.1**

Under certain conditions, open deck joints can provide an effective and economical solution. In general, open joints are well-suited for secondary highways where little sand and salt are applied during the winter. They are not suited for urban areas where the costs of provisions for deck joint drainage are high.

Satisfactory performance depends upon an effective deck drainage system, control of deck discharge through joints, and containment and disposal of runoff from the site. It is essential that surface drainage and roadway debris not be permitted to accumulate on any part of the structure below such joints.

Protection against the deleterious effects of deck drainage may include shaping structural surfaces to prevent the retention of roadway debris and providing surfaces with deflectors, shields, covers, and coatings.

#### 14.5.6.2—Closed Joints

Sealed deck joints shall seal the surface of the deck, including curbs, sidewalks, medians, and, where necessary, parapet and barrier walls. The sealed deck joint shall prevent the accumulation of water and debris, which may restrict its operation. Closed or waterproof joints exposed to roadway drainage shall have structure surfaces below the joint shaped and protected as required for open joints.

Joint seals should be watertight and extrude debris when closing.

Drainage accumulated in joint recesses and seal depressions shall not be discharged on bridge seats or other horizontal portions of the structure.

Where joint movement is accommodated by a change in the geometry of elastomeric glands or membranes, the glands or membranes shall not come into direct contact with the wheels of vehicles.

#### 14.5.6.3—Waterproofed Joints

Waterproofing systems for joints, including joint troughs, collectors, and downspouts, shall be designed to collect, conduct, and discharge deck drainage away from the structure.

In the design of drainage troughs, consideration should be given to:

- Trough slopes of not less than 1.0 in./ft;
- Open-ended troughs or troughs with large discharge openings;
- Prefabricated troughs;
- Troughs composed of reinforced elastomers, stainless steel, or other metal with durable coatings;
- Stainless steel fasteners;
- Troughs that are replaceable from below the joint;
- Troughs that can be flushed from the roadway surface; and
- Welded metal joints and vulcanized elastomeric splices.

#### C14.5.6.2

Completely effective joint seals have yet to be developed for some situations, particularly where there are severely skewed joints with raised curbs or barriers, and especially where joints are subjected to substantial movements. Consequently, some type of open or closed joint, protected as appropriate, should be considered instead of a sealed joint.

Sheet and strip seals that are depressed below the roadway surface and that are shaped like gutters will fill with debris. They may burst upon closing, unless the joints that they seal are extended straight to the deck edges where accumulated water and debris can be discharged clear of the structure. To allow this extension and safe discharge, it may be necessary to move the backwalls and bridge seats of some abutment types forward until the backwalls are flush with the wingwalls, or to reposition the wingwalls so that they do not obstruct the ends of the deck joints.

#### 14.5.6.4—Joint Seals

Seals shall accommodate all anticipated movements.

In the choice of a seal type, consideration should be given to seals that:

- Are preformed or prefabricated,
- Can be replaced without major joint modification,
- Do not support vehicular wheel loads,
- Can be placed in one continuous piece,
- Are recessed below joint armor surface,
- Are mechanically anchored, and
- Respond to joint width changes without substantial resistance.

Elastomeric material for seals should be:

- Durable, of virgin neoprene or natural rubber and reinforced with steel or fabric laminates;
- Vulcanized;
- Verified by long-term cyclic testing; and
- Connected by adhesives that are chemically cured.

#### 14.5.6.5—Poured Seals

Unless data supports a smaller joint width, the joint width for poured seals should be at least 6.0 times the anticipated joint movement determined using the appropriate strength load combination specified in Table 3.4.1-1.

Sealant bond to metal and masonry materials should be documented by national test methods.

#### 14.5.6.6—Compression and Cellular Seals

Where seals with heavy webbing are exposed to the full movement range, joints shall not be skewed more than 20 degrees.

Compression seals for bearing joints shall not be less than 2.5 in. nor more than 6.0 in. wide when uncompressed and shall be specified in width increments in multiples of 0.5 in.

Primary roadway seals shall be furnished without splices or cuts, unless specifically approved by the Engineer.

In gutter and curb areas, roadway seals shall be bent up in gradual curves to retain roadway drainage. Ends of roadway seals shall be protected by securely attached vented caps or covers. Secondary seals in curbs and barrier areas may be cut and bent as necessary to aid in bending and insertion into the joint.

Closed cell seals shall not be used in joints where they would be subjected to sustained compression, unless seal and adhesive adequacy have been documented by long-term demonstration tests for similar applications.

#### C14.5.6.5

Poured seals should be used only for joints exposed to small movements and for applications where watertightness is of secondary importance.

#### C14.5.6.6

Compression seals should be used only in those structures where the joint movement range can be accurately predicted.

Performance of compression and cellular seals is improved when concrete joint recesses are made by saw-cutting in a single pass, rather than by being cast with the aid of removable forms.

#### **14.5.6.7—Sheet and Strip Seals**

In the selection and application of either sheet or strip seals, consideration should be given to:

- Joint designs for which glands with anchorages not exposed to vehicular loadings,
- Joint designs that allow complete closure without detrimental effects to the glands,
- Joint designs where the elastomeric glands extend straight to deck edges rather than being bent up at curbs or barriers,
- Decks with sufficient crown or superelevation to ensure lateral drainage of accumulated water and debris,
- Glands that are shaped to expel debris, and
- Glands without abrupt changes in either horizontal or vertical alignment.

Sheet and strip seals should be spliced only when specifically approved by the engineer.

#### **14.5.6.8—Plank Seals**

Application of plank seals should be limited to structures on secondary roads with light truck traffic, and that have unskewed or slightly skewed joints.

Consideration should be given to:

- Seals that are provided in one continuous piece for the length of the joint,
- Seals with splices that are vulcanized, and
- Anchorages that can withstand the forces necessary to stretch or compress the seal.

#### **14.5.6.9—Modular Bridge Joint Systems (MBJS)**

##### *14.5.6.9.1—General*

These Articles of the specifications address the performance requirements, strength limit state design, and fatigue limit state design of modular bridge joint systems (MBJS).

These Specifications were developed primarily for, and shall be applied to, the two common types of MBJS, multiple and single support bar systems, including swivel-joint systems.

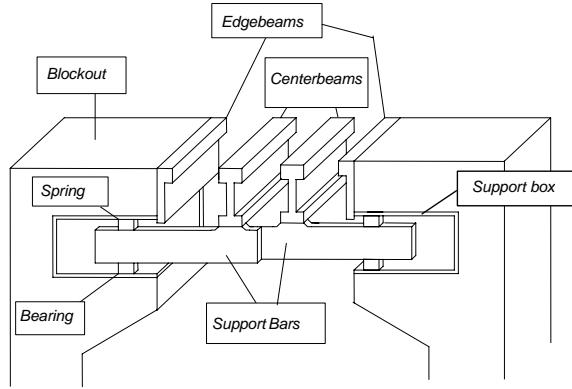

#### **C14.5.6.8**

Plank-type seals should not be used in joints with unpredictable movement ranges.

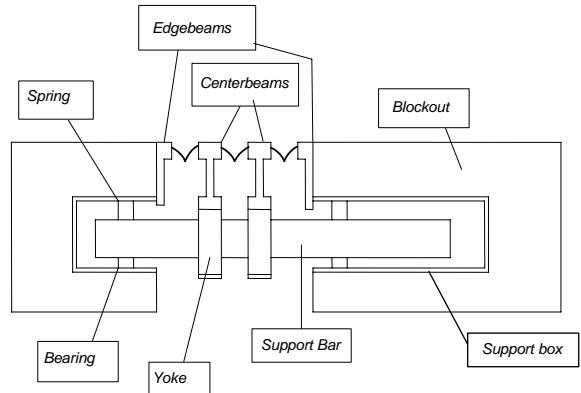

#### *C14.5.6.9.1*

These MBJS design specifications provide a rational and conservative method for the design of the main load carrying steel components of MBJS. These Specifications do not specifically address the functional design of MBJS or the design of the elastomeric parts. These Specifications are based on research described in Dexter et al. (1997), which contains extensive discussion of the loads and measured dynamic response of MBJS and the fatigue resistance of common MBJS details. Fatigue test procedures were developed for the structural details as well.

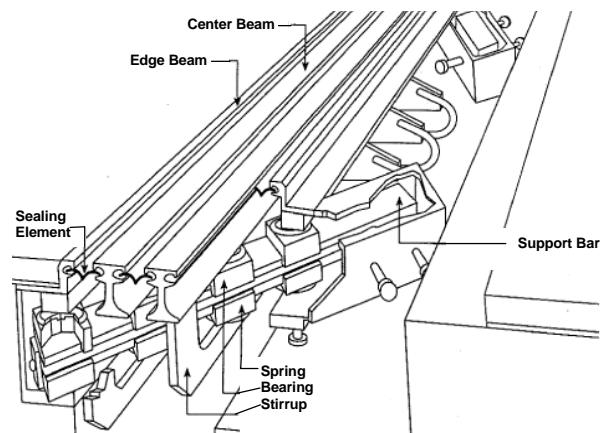

Common types of MBJS are shown in Figures C14.5.6.9.1-1 through C14.5.6.9.1-3.

**Figure C14.5.6.9.1-1—Cut-Away View of Typical Welded-Multiple-Support-Bar (WMSB) Modular Bridge Joint System (MBJS) Showing Support Bars Sliding within Support Boxes**

**Figure C14.5.6.9.1-2—Cross-Section View of Typical Single-Support-Bar (SSB) Modular Bridge Joint System (MBJS) Showing Multiple Centerbeams with Yokes Sliding on a Single Support Bar**

**Figure C14.5.6.9.1-3—Cut-Away View of a “Swivel Joint,” i.e., a Special Type of Single-Support-Bar (SSB) Modular Bridge Joint System (MBJS) with a Swiveling Single Support Bar**

#### 14.5.6.9.2—Performance Requirements

The required minimum MBJS movement range capabilities for the six possible degrees of freedom given in Table 14.5.6.9.2-1 shall be added to the maximum movement and rotations calculated for the entire range of seals in the MBJS determined using the appropriate strength load combination specified in Table 3.4.1-1.

#### C14.5.6.9.2

The MBJS should be designed and detailed to minimize excessive noise or vibration during the passage of traffic.

A common problem with MBJS is that the seals fill with debris. Traffic passing over the joint can work the seal from its anchorage by compacting this debris. MBJS systems can eject most of this debris in the traffic lanes if the seals are opened to near their maximum opening. Therefore, it is prudent to provide for additional movement capacity.

MBJS should permit movements in all six degrees of freedom, i.e., translations in all three directions and rotations about all three axes. While it is mandatory to provide at least 1.0 in. movement in the longitudinal direction, as shown in Table 14.5.6.9.2-1, no more than 2.0 in. should be provided in addition to the maximum calculated movement if feasible. Also, more than 1.0 in. should not be added if it causes a further seal to be used. In the five degrees of freedom other than the longitudinal direction, the MBJS should provide the maximum calculated movement in conjunction with providing for at least the minimum additional movement ranges shown in Table 14.5.6.9.2-1. Half of the movement range shall be assumed to occur in each direction about the mean position. Some bridges may require greater than the additional specified minimum values.

The designer should consider showing the total estimated transverse and vertical movement in each direction, as well as the rotation in each direction about the three principal axes on the contract plans. Vertical movement due to vertical grade, with horizontal bearings, and vertical movement due to girder end rotation may also be considered.

Further design guidelines and recommendations can be found in Chapter 19 of the *AASHTO LRFD Bridge Construction Specifications* and Dexter et al. (1997).

**Table 14.5.6.9.2-1—Additional Minimum Movement Range Capability for MBJS**

Type of Movement	Minimum Design Movement Range*
Longitudinal Displacement	Estimated Movement + 1.0 in.
Transverse Movement	1.0 in.
Vertical Movement	1.0 in.
Rotation around Longitudinal Axis	1°
Rotation Around Transverse Axis	1°
Rotation Around Vertical Axis	0.5°

\* Total movement ranges presented in the table are twice the plus or minus movement.

#### 14.5.6.9.3—Testing and Calculation Requirements

MBJS shall satisfy all test specifications detailed in Appendix A of the *AASHTO LRFD Bridge Construction Specifications*.

Each configuration of MBJS shall be designed for the strength and fatigue, and fracture limit states as specified in Articles 14.5.6.9.6 and 14.5.6.9.7.

#### 14.5.6.9.4—Loads and Load Factors

Edgebeams, anchors, centerbeams, support bars, connections between centerbeams and support bars, support boxes, and connections, if any, to elements of the structure, such as girders, truss chords, crossbeams, etc., and other structural components shall be designed for the strength and fatigue and fracture limit states for the simultaneous application of vertical and horizontal axle loads. The edgebeams and anchors of MBJS in snow regions shall also be designed for the strength limit state for the snowplow load defined in Article 14.5.1.2. The design lane load need not be considered for MBJS.

The two wheel loads from each axle shall be centered 72.0 in. apart transversely. Each wheel load shall be distributed to the various edgebeams and centerbeams as specified in Article 14.5.6.9.5. The fraction of the wheel loads applied to each member shall be line loads applied at the center of the top surface of a member with a width of 20.0 in.

For the strength limit state, the vertical wheel loads shall be from the design tandem specified in Article 3.6.1.2.3; the wheel loads from the design truck in Article 3.6.1.2.2 need not be considered for the strength limit state of MBJS. Both of the tandem axles shall be considered in the design if the joint opening exceeds 4.0 ft. The vertical wheel load shall be increased by the dynamic load allowance specified for deck joints in Table 3.6.2.1-1.

The horizontal load for the strength limit state shall be 20 percent of the vertical wheel load ( $LL + IM$ ), applied along the same line at the top surface of the centerbeam or edgebeam. For MBJS installed on vertical grades in excess of five percent, the additional horizontal component due to grade shall be added to the horizontal wheel load.

To investigate the strength limit state, the axles shall be oriented and positioned transversely to maximize the force effect under consideration.

The vertical wheel load ranges for the fatigue limit state shall be from the largest axle load from the three-axle design truck specified in Article 3.6.1.2.2. For fatigue limit state design of MBJS, this axle load shall be considered as the total load on a tandem, i.e., the total load shall be split into two axle loads spaced 4.0 ft apart. Both of these tandem axles shall be considered in the design if the joint opening exceeds 4.0 ft. The vertical load range shall be increased by the dynamic load allowance specified for deck joints in Table 3.6.2.1-1. The load factors to consider shall be as specified in Table 3.4.1-1 for the Fatigue I case.

#### C14.5.6.9.4

The vertical axle load for fatigue limit state design is one-half the 32.0 kip axle load of the design truck specified in Article 3.6.1.2.2 or 16.0 kips. This reduction recognizes that the main axles of the design truck are a simplification of actual tandem axles. The simplification is not satisfactory for MBJS and other expansion joints because expansion joints experience a separate stress cycle for each individual axle.

For strength limit state design, there are two load combinations that could be considered. However, recognizing that each main axle of the design truck should actually be treated as 32.0 kip tandems, it is clear the 50.0 kip design tandem, which is not used for fatigue limit state design, will govern for strength limit state design.

The loads specified for fatigue limit state design actually represent load ranges. When these loads are applied to a structural analysis model with no dead load applied to the model, the moment, force, or stress that is computed everywhere represents a moment, force or stress range. In service, these stress ranges are partly due to the downward load and partly due to upward rebound from the dynamic impact effect.

The dynamic load allowance (impact factor) specified for deck joints of 75 percent was developed from field testing of MBJS conducted in Europe and was confirmed in field tests described in Dexter et al. (1997). The stress range due to the load plus this dynamic load allowance represents the sum of the downward part of that stress range and the upward part of the stress range due to rebound. Measurements, described in Dexter et al. (1997), showed that the maximum downward amplification of the static load is 32 percent, with about 31 percent rebound in the upward direction.

The vertical axle load range with impact for fatigue limit state design is one-half of the largest axle load of the design truck specified in Article 3.6.1.2.2, multiplied by 1.75 to include the dynamic load allowance, multiplied by a load factor of 1.5 (or  $2.0 \times 0.75$ ), as specified in Table 3.4.1-1 for the Fatigue I case, or 42.0 kips. The 0.75 load factor transforms axles of an HS20 truck to those of an HS15 fatigue truck, which is presumed to represent the effective stress range. The factor 2.0 amplifies the effective stress range for the fatigue limit state to the presumed maximum expected stress range which with impact is required to be less than the fatigue threshold in Article 14.5.6.9.7a. It is the intent of the fatigue design specifications that the static load without impact considered (24.0 kips or 42.0 kips/1.75) should be infrequently exceeded, see Dexter et al. (1997).

The horizontal load ranges for the fatigue limit state shall be at least 20 percent of the vertical wheel load range ( $LL + IM$ ) for fatigue. For MBJS installed on vertical grades in excess of five percent, the additional horizontal component due to grade shall be added to the horizontal wheel load range.

To investigate the fatigue limit state, the axles shall be oriented perpendicular to the travel direction only, but shall be positioned transversely to maximize the force effect under consideration. In bridges with a skew greater than 14 degrees, the two wheel loads from an axle may not be positioned on a centerbeam simultaneously, and the maximum stress ranges at a critical detail on the centerbeam may be the difference between the stresses due to the application of each wheel load separately.

Field measurements were taken at a variety of locations; so typical truck excitations should be reflected in the dynamic load allowance. However, a joint located on a structure with significant settlement or deterioration of the approach roadway may be exposed to a dynamic load allowance 20 percent greater due to dynamic excitation of the trucks.

MBJS with centerbeam spans less than 4.0 ft are reported to have lower dynamic effects (Pattis, 1993; Tschemmernegg and Pattis, 1994). The fatigue limit state design provisions of Article 14.5.6.9.7 happen to also limit the spans of typical 5.0 in. deep centerbeams to around 4.0 ft anyway, so there is no need for a specific limitation of the span.

At sites with a tight horizontal curve (less than 490-ft radius) the vertical moments could be about 20 percent higher than would be expected. An increase in the dynamic load allowance for cases where there is a tight horizontal curve is not considered necessary if the speed of trucks on these curves is limited. In this case, the dynamic impact will be less than for trucks at full speed and the decreased dynamic impact will approximately offset the increased vertical load due to the horizontal curve.

The dynamic load allowance is very conservative when applied to the vertical load for strength limit state design, since in strength limit state design peak loads, not load ranges, are of interest. In the measurements made on MBJS in the field, the maximum downward vertical moment was only 1.32 times the static moment. There are usually no consequences of this conservative simplification since the proportions of the members are typically governed by fatigue and not strength.

The horizontal loads are taken as 20 percent of the vertical load plus the dynamic load allowance. In-service measurements, described in Dexter et al. (1997), indicate that the 20 percent horizontal load range is the largest expected from traffic at steady speeds, including the effect of acceleration and routine braking. The 20 percent horizontal load range for fatigue limit state design represents ten percent forward and ten percent backward.

Where strength limit state design is considered, the 20 percent horizontal load requirement corresponds to a peak load of 20 percent applied in one direction. The 20 percent horizontal peak load is appropriate for strength limit state design. However, the field measurements, described in Dexter et al. (1997), show that the horizontal force effects resulting from extreme braking can be much greater than at steady speeds. Therefore, the 20 percent peak horizontal load represents the extreme braking for strength limit state design. For fatigue limit state design, these extreme events occur so infrequently that they do not usually need to be taken into account in most cases.

Special consideration should be given to the horizontal forces if the MBJS is located near a traffic light, stop sign, or toll facility or if the centerbeam is unusually wide.

#### 14.5.6.9.5—Distribution of Wheel Loads

Each edgebeam shall be designed for 50 percent of the vertical and horizontal wheel loads specified in Article 14.5.6.9.4.

Table 14.5.6.9.5-1 specifies the centerbeam distribution factor, i.e., the percentage of the design vertical and horizontal wheel loads specified in Article 14.5.6.9.4 that shall be applied to an individual centerbeam for the design of that centerbeam and associated support bars. Distribution factors shall be interpolated for centerbeam top flange widths not given in the table, but in no case shall the distribution factor be taken as less than 50 percent. The remainder of the load shall be divided equally and applied to the two adjacent centerbeams or edgebeams.

**Table—14.5.6.9.5-1 Centerbeam Distribution Factors**

Width of Centerbeam Top Flange	Distribution Factor
2.5 in. (or less)	50%
3.0 in.	60%
4.0 in.	70%
4.75 in.	80%

#### C14.5.6.9.5

For the convenience of the designer, the vertical axle load range with impact for fatigue limit state design on one centerbeam 2.5 in. or less in width is 21.0 kips. On the centerbeam, each fraction of the wheel load of 10.5 kips is spaced 72.0 in. apart distributed over a width of 20.0 in. with a magnitude of 0.525 kips/in.

The distribution factor, i.e., the fraction of the design wheel load range assigned to a single centerbeam, is a function of applied load, tire pressure, gap width, and centerbeam height mismatch. Unfortunately, many of the factors affecting the distribution factor are difficult to quantify individually and even more difficult to incorporate in an equation or graph. Existing methods to estimate the distribution factor do not incorporate all of these variables and consequently can be susceptible to error when used outside the originally intended range. In view of this uncertainty, a simplified tabular method is used to estimate the distribution factor. Alternative methods are permitted if they are based on documented test data.

Wheel load distribution factors shown in Table 14.5.6.9.5-1 are based on field and laboratory testing, described in Dexter et al. (1997), and were found to be in acceptable agreement with the findings of other researchers. These distribution factors are based on the worst-case assumption of maximum joint opening (maximum gap width). Calculating the stress ranges at maximum gap opening is approximately 21 percent too conservative for fatigue limit state design. However, as explained in Dexter et al. (1997), this conservatism compensates for a lack of conservatism in the AASHTO fatigue design truck axle load.

For comparison to the fatigue threshold, the factored static axle load range, without the dynamic load allowance, would be 24.0 kips (or 42.0 kips/1.75, as discussed in Article C14.5.6.9.4). The static axle load range at the fatigue limit state is supposed to represent an axle load that is rarely exceeded. However, the fatigue limit state design load is multiplied by a distribution factor that is 21 percent too large, so in effect, this is equivalent to a static axle load range at the fatigue limit state of 29.0 kips that should be rarely exceeded, if correct distribution factors were used. This is more consistent with the statistics of weigh-in-motion data where axle loads with exceedence levels of 0.01 percent were up to 36.0 kips, see Schilling (1990) or Nowak and Laman (1995).

A mitigating factor on the impact of these larger axle loads is that the distribution factor decreases with increasing axle load. Because of this effect, measurements reported in Dexter et al. (1997) show that as the axle load is increased from 24.0 to 36.0 kips, an increase of 50 percent, the load on one centerbeam increases from 12.6 to only 14.6 kips, an increase of only 16 percent.

Even though maximum gap opening occurs only rarely, it is an appropriate assumption for checking the Strength-I limit state. No additional conservatism is warranted in this case, however, because the dynamic load allowance is about 32 percent too conservative for strength limit state design only, as discussed in Article C14.5.6.9.

Another advantage of using the conservative distribution factors is that it may compensate for ignoring the effect of potential centerbeam height mismatch. Laboratory studies show that a height mismatch of 0.125 in. resulted in a 24 percent increase in the measured distribution factor, see Dexter et al. (1997). Although such mismatch is not common presently, and recent construction specifications are supposed to preclude this mismatch, it is prudent to anticipate that it may occur.

#### 14.5.6.9.6—Strength Limit State Design Requirements

Where the MBJS is analyzed for the strength limit state, the gap between centerbeams shall be assumed to be at the fully opened position, typically 3.0 in.

The MBJS shall be designed to withstand the force effects for the strength limit state specified in Article 6.5.4 by applying the provisions of Articles 6.12 and 6.13, as applicable. All sections shall be compact, satisfying the provisions of Articles A6.1, A6.2, A6.3.2, and A6.3.3. MBJS shall be designed to withstand the load combination for the Strength I limit state that is specified in Table 3.4.1-1 for the simultaneous application of vertical and horizontal axle loads specified in Article 14.5.6.9.4. Dead loads need not be included. Loads shall be distributed as specified in Article 14.5.6.9.5.

Anchors shall be investigated at the strength limit state due to vertical wheel loads without the horizontal wheel loads using the requirements of Article 6.10.10.4.3. The anchors shall be checked separately for the horizontal wheel loads at the strength limit state. In snow regions, another separate analysis shall be performed for the anchors for the snowplow load defined in Article 14.5.1.2. Pullout or breakout at the strength limit state under each of these loads shall be investigated by the latest ACI 318 (*Building Code Requirements for Structural Concrete*), using the following resistance factors:

- For anchors governed by the steel, the resistance factors are:

$$\begin{aligned}\phi_{tension} &= 0.80 \\ \phi_{shear} &= 0.75\end{aligned}$$

- For anchors governed by the concrete, the load factors for Condition A, supplemental reinforcement in the failure area, are:

$$\begin{aligned}\phi_{A \text{ tension}} &= 0.85 \\ \phi_{A \text{ shear}} &= 0.85\end{aligned}$$

- For anchors governed by the concrete, the load factors for Condition B, no supplemental reinforcement, are:

#### C14.5.6.9.6

Anchorage calculations for strength and fatigue limit states are presented in Dexter et al. (2002). A prescriptive design was found that satisfies the strength and fatigue limit state requirements presented in this specification, including the snowplow load. This design may be adopted without presenting explicit calculations. This design consists of a steel edgebeam minimum thickness 0.375 in. with Grade 50 (50.0 ksi yield) 0.5 in. diameter welded headed anchors (studs) with length of anchor of 6.0 in. spaced every 12.0 in. The welded headed anchor shall have minimum cover depth of 3.0 in., except where over the support boxes, where the cover depth is 2.0 in.

Analyzing the centerbeam as a continuous beam over rigid supports has been found to give good agreement with measured strains for loads in the vertical direction. For loads in the horizontal direction, the continuous beam model is conservative. For the loads in the horizontal direction, more accurate results can be achieved by treating the centerbeams and support bars as a coplanar frame pinned at the ends of the support bars.

Maximum centerbeam stresses in interior spans are typically generated with one of the wheel loads centered in the span. However, if the span lengths are the same, the exterior spans (first from the curb) will typically govern the design. In an optimum design, this exterior span should be about ten percent less than typical interior spans.

The vertical and horizontal wheel loads are idealized as line loads along the centerlines of the centerbeams, i.e., it is not necessary to take into account eccentricity of the forces on the centerbeam. The maximum reaction of the centerbeam against the support bar is generated when the wheel load is centered over the support bar. This situation may govern for the throat of the centerbeam/support bar weld, for design of the stirrup of a single-support-bar system, or for design of the support bar.

MBJS installed on skewed structures may require special attention in the design process.

$$\phi_{B \text{ tension}} = 0.75$$

$$\phi_{B \text{ shear}} = 0.75$$

**14.5.6.9.7—Fatigue Limit State Design Requirements**

**14.5.6.9.7a—General**

MBJS structural members, including centerbeams, support bars, connections, bolted and welded splices, and attachments, shall meet the fracture toughness requirements in Article 6.6.2. Bolts subject to tensile fatigue shall satisfy the provisions of Article 6.13.2.10.3.

MBJS structural members, including centerbeams, support bars, connections, bolted and welded splices, and attachments, shall be designed for the fatigue limit state as specified in Article 6.6.1.2 and as modified and supplemented herein.

Each detail shall satisfy:

$$\Delta f \leq (\Delta F)_{TH} \quad (14.5.6.9.7a-1)$$

where:

$\Delta f$  = force effect, design live load stress range due to the simultaneous application of vertical and horizontal axle loads specified in Article 14.5.6.9.4 and distributed as specified in Article 14.5.6.9.5, and calculated as specified in Article 14.5.6.9.7b (ksi)

$\Delta F_{TH}$  = constant amplitude fatigue threshold taken from Table 6.6.1.2.5-3 for the detail category of interest (ksi)

The fatigue detail categories for the centerbeam-to-support-bar connection, shop splice, field splice, or other critical details shall be established by the fatigue testing as required by Article 14.5.6.9.3. All other details shall have been included in the test specimen. Details that did not crack during the fatigue test shall be considered noncritical. The fatigue detail categories for noncritical details shall be determined using Table 6.6.1.2.3-1.

Anchors and edgebeams shall be investigated for the fatigue limit state considering the force effects from vertical and horizontal wheel loads. Shear connectors and other anchors shall be designed for the fatigue limit state to resist the vertical wheel loads according to the provisions of Article 6.10.10.2 for the Fatigue I case defined in Article 3.4.1. The force effects from the horizontal wheel loads need not be investigated for standard welded headed anchors.

Edgebeams shall be at least 0.375 in. thick. Edgebeams with standard welded headed anchors spaced at most every 12.0 in. need not be investigated for in-plane bending for the fatigue limit state.

**C14.5.6.9.7a**

The fatigue limit state strength of particular details in aluminum are approximately one-third the fatigue limit state strength of the same details in steel and, therefore, aluminum is typically not used in MBJS.

Yield strength and fracture toughness and weld quality have not been noted as particular problems for MBJS.

The design of the MBJS will typically be governed by the stress range at fatigue limit state critical details. The static strength limit state must also be checked according to the requirements of Article 14.5.6.9.6, but will typically not govern the design unless the total opening range and the support bar span is very large. Alternate design methods and criteria may be used if such methods can be shown through testing and/or analysis to yield fatigue-resistant and safe designs. The target reliability level for the fatigue limit state is 97.5 percent probability of no fatigue cracks over the lifetime of the MBJS.

Provisions are not included for a finite life fatigue limit state design (Fatigue II case, as defined in Article 3.4.1). Typically, most structures that require a modular expansion joint carry enough truck traffic to justify an infinite-life fatigue limit state design approach (Fatigue I case, as defined in Article 3.4.1). Furthermore, uncertainty regarding the number of axles per truck and the number of fatigue cycles per axle would make a finite life design approach difficult, and little cost is added to the MBJS by designing for infinite fatigue life.

The intent of this procedure is to assure that the stress range from the fatigue limit state load range is less than the CAFL and thereby ensuring essentially an infinite fatigue life.

Fatigue-critical MBJS details include:

- The connection between the centerbeams and the support bars;
- Connection of any attachments to the centerbeams (e.g., horizontal stabilizers or outriggers); and
- Shop and/or field splices in the centerbeams.

MBJS details can in many cases be clearly associated with analogous details in the bridge design specifications. In other cases, the association is not clear and must be demonstrated through full-scale fatigue testing.

The detail of primary concern is the connection between the centerbeams and the support bars. A typical full-penetration welded connection, which was shown previously, can be associated with Category C. Fillet welded connections have very poor fatigue resistance and should not be allowed.

Bolted connections should be classified as a Category D detail, with respect to the bending stress range in the centerbeam. As in any construction, more than one bolt must be used in bolted connections.

The bolted connections in single-support-bar MBJS usually involve a yoke or stirrup through which the support bar slides and/or swivels. Field-welded splices of the centerbeams and edgebeams are also prone to fatigue. In new construction, it may be possible to make a full-penetration welded splice in the field before the joint is lowered into the blockout. However, in reconstruction work, the joint is often installed in several sections at a time to maintain traffic. In these cases, the splice must be made after the joint is installed. Because of the difficulty in access and position, obtaining a full-penetration butt weld in the field after the joint is installed may be impossible, especially if there is more than one centerbeam. Partial-penetration splice joints have inherently poor fatigue resistance and should not be allowed.

Bolted splices have been used and no cracking of these bolted splice details has been reported. The bolted splice plates behave like a hinge, i.e., they do not take bending moments. As a result, such details are subjected only to small shear stress ranges and need not be explicitly designed for the fatigue limit state. However, the hinge in the span creates greater bending moments at the support bar connection, therefore, the span with the field splice must be much smaller than the typical spans to reduce the applied stress ranges at the support bar connection.

Thin stainless-steel slider plates are often welded like cover plates on the support bars. The fatigue strength of the ends of cover plates is Category E. However, there have not been any reports of fatigue cracks at these slider plate details in MBJS. The lack of problems may be because the support bar bending stress range is much lower at the location of the slider plate ends than at the centerbeam connection, which is the detail that typically governs the fatigue limit state design of the support bar. Also, it is possible that the fatigue strength is greater than that of conventional cover plates, perhaps because of the thinness of the slider plate.

The fatigue limit state of the support bars or centerbeams should also be checked at the location of welded attachments to react against the horizontal equidistant devices. In addition to checking the equidistant device attachments with respect to the stress range in the support bar, there is also some bending load in the attachment itself. The equidistant devices take part of the horizontal load, especially in single-support bar systems. The horizontal load is also transferred through friction in the bearings and springs of the centerbeam connection. However, since this transfer is influenced by the dynamic behavior of the MBJS, it is very difficult to quantify the load in the attachments.

These attachments are thoroughly tested in the Opening Movement Vibration Test required in Article 14.5.6.9.3. If the equidistant device attachments have no reported problems in the Opening Movement Vibration Test, they need not be explicitly designed as a loaded attachment for the fatigue limit state. If there were a

#### 14.5.6.9.7b—Design Stress Range

The design stress ranges,  $\Delta f$ , at all fatigue critical details shall be obtained from structural analyses of the modular joint system due to the simultaneous application of vertical and horizontal axle loads specified in Article 14.5.6.9.4 and distributed as specified in Article 14.5.6.9.5. The MBJS shall be analyzed with a gap opening no smaller than the midrange configuration and no smaller than half of maximum gap opening. For each detail, the structural analysis shall include the worst-case position of the axle load to maximize the design stress range at that particular detail.

The nominal stress ranges,  $\Delta f$ , shall be calculated as follows for specific types of MBJS:

- Single-Support-Bar Systems

- Centerbeam: The design bending stress range,  $\Delta f$ , in the centerbeam at a critical section adjacent to a welded or bolted stirrup shall be the sum of the stress ranges in the centerbeam resulting from horizontal and vertical bending at the critical section. The effects of stresses in any load-bearing attachments, such as the stirrup or yoke, need not be considered when calculating the stress range in the centerbeam. For bolted single-support-bar systems, stress ranges shall be calculated on the net section.
- Stirrup: The design stress range,  $\Delta f$ , in the stirrup or yoke shall consider the force effects of the vertical reaction force range between the centerbeam and support bar. The stress range shall be calculated by assuming a load range in the stirrup that is greater than or equal to 30 percent of the total vertical reaction force range. The calculation of the design stress range in the stirrup or yoke need not consider the effects of stresses in the centerbeam. The effects of horizontal loads may be neglected in the fatigue limit state design of the stirrup.

- Welded Multiple-Support-Bar Systems

- Centerbeam Weld Toe Cracking, i.e., Type A Cracking: The design stress range,  $\Delta f$ , for Type A cracking shall include the concurrent effects of vertical and horizontal bending stress ranges in the centerbeam,  $S_{RB}$ , and the vertical stress ranges in the top of the weld,  $S_{RZ}$ , as shown in Figure 14.5.6.9.7b-1. The design stress range for Type A cracking shall be determined as:

fatigue problem with these attachments, it would be discovered in the Opening Movement Vibration Test.

#### C14.5.6.9.7b

Since the design axle load and distribution factors represent a “worst case”, the structural analysis for fatigue limit state design need not represent conditions worse than average. Therefore, for fatigue loading, the assumed gap can be equal to or greater than the midrange of the gap, typically 1.5 in., which is probably close to the mean or average opening. The gap primarily affects the support bar span.

See Article C14.5.6.9.6 for guidelines on the structural analysis. MBJS installed on skewed structures may require special attention in the design process.

On structures with joint skews greater than 14 degrees, it can be shown that the wheels at either end of an axle will not roll over a particular centerbeam simultaneously. This asymmetric loading could significantly affect the stress range at fatigue sensitive details, either favorably or adversely. Nevertheless, a skewed centerbeam span is subjected to a range of moments that includes the negative moment from the wheel in the adjoining span, followed or preceded by the positive moment from the wheel in the span.

The stress states at the potential crack locations in these connections are multiaxial and very complicated. Simplified assumptions are used to derive the design stress range at the details of interest for common types of MBJS. Experience has shown that these simplified assumptions are sufficient provided that the same assumptions are applied in calculating the applied stress range for plotting the fatigue test data from which the design detail category was determined.

The design stress range should be estimated at a critical section at the weld toe. For example, Figure C14.5.6.9.7b-1 shows a typical moment diagram for the support bar showing the critical section. The support bar design bending stress range is a result of the sum of the bending moment created by the applied centerbeam reaction and the additional overturning moment developed by the horizontal force applied at the top of the centerbeam.

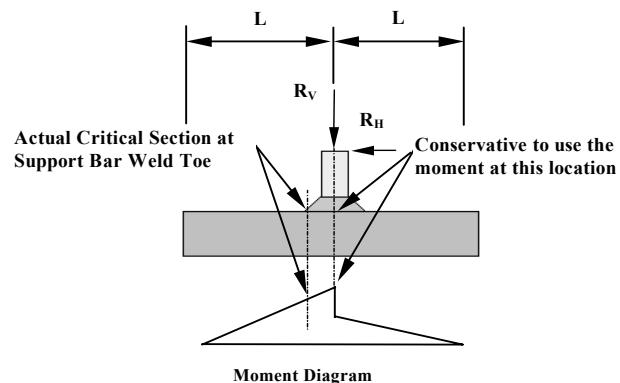

Figure C14.5.6.9.7b-1—Typical Moment Diagram for a Support Bar

$$\Delta f = \sqrt{S_{RB}^2 + S_{RZ}^2} \quad (14.5.6.9.7b-1)$$

in which:

$$S_{RB} = \frac{M_V}{S_{xcb}} + \frac{M_H}{S_{Ycb}} \quad (14.5.6.9.7b-2)$$

$$S_{RZ} = \frac{M_{OT}}{S_{Wtop}} + \frac{R_V}{A_{Wtop}} \quad (14.5.6.9.7b-3)$$

$$M_{OT} = R_H d_{cb} \quad (14.5.6.9.7b-4)$$

where:

$S_{RB}$  = combined bending stress range in the centerbeam (ksi)

$M_V$  = vertical bending moment range in the centerbeam on the critical section located at the weld toe due to the vertical force range (kip-in.)

$M_H$  = horizontal bending moment range in the centerbeam on the critical section located at the weld toe due to horizontal force range (kip-in.)

$M_{OT}$  = overturning moment range from horizontal reaction force (kip-in.)

$S_{xcb}$  = vertical section modulus to the bottom of the centerbeam (in.<sup>3</sup>)

$S_{Ycb}$  = horizontal section modulus of the centerbeam (in.<sup>3</sup>)

$S_{RZ}$  = vertical stress range in the top of the centerbeam-to-support-bar weld from the concurrent reaction of the support beam (ksi)

$R_V$  = vertical reaction force range in the connection (kip)

$R_H$  = horizontal reaction force range in the connection (kip)

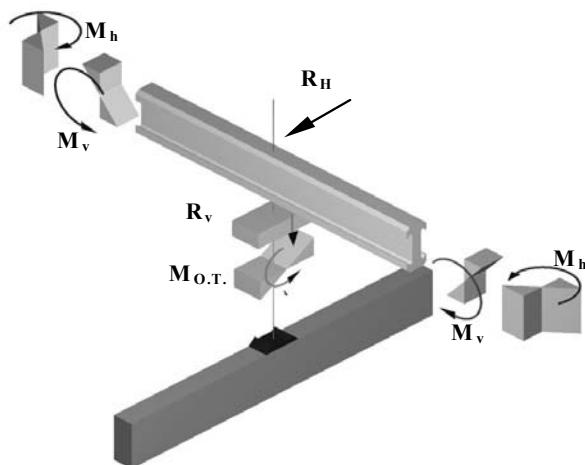

$d_{cb}$  = depth of the centerbeam (in.)

$S_{Wtop}$  = section modulus of the weld at the top for bending in the direction normal to the centerbeam axis (in.<sup>3</sup>)

$A_{Wtop}$  = area of weld at the top (in.<sup>2</sup>)

It is conservative to estimate the moments at the centerline of the centerbeam as shown.

For all details except the welded-multiple-support-bar centerbeam to support bar connection, the design stress range can be calculated using the design moment at the location of interest. Special equations for calculating the stress range are provided for welded multiple-support-bar MBJS. These special equations are based on cracking that has been observed in fatigue tests of welded multiple-support-bar MBJS. For the case of welded multiple-support bar centerbeam to support bar connections, the design stress range is obtained by taking the square root of the sum of the squares of the horizontal stress ranges in the centerbeam or support bar and vertical stress ranges in the weld. Note this method of combining the stresses ignores the contribution of shear stresses in the region. Shear stresses are ignored in this procedure since they are typically small and very difficult to determine accurately. More details are provided in Dexter et al. (1997).

**Figure 14.5.6.9.7b-1—Force Effects Associated with Type A Cracking**

- Support Bar Weld Toe Cracking, i.e., Type B Cracking: The design stress range,  $\Delta f$ , for Type B cracking shall include the concurrent effects of vertical bending stress ranges in the support bar,  $S_{RB}$ , and the vertical stress ranges in bottom of the weld,  $S_{RZ}$ , as shown in Figure 14.5.6.9.7b-2. The design stress range,  $\Delta f$ , for Type B cracking shall be determined as:

$$\Delta f = \sqrt{S_{RB}^2 + S_{RZ}^2} \quad (14.5.6.9.7b-5)$$

in which:

$$S_{RB} = \frac{M_V}{S_{Xsb}} + \frac{1}{2} \frac{R_H \left( d_{cb} + h_w + \frac{1}{2} d_{sb} \right)}{S_{Xsb}} \quad (14.5.6.9.7b-6)$$

$$S_{RZ} = \frac{R_H (d_{cb} + h_w)}{S_{Wbot}} + \frac{R_v}{A_{Wbot}} \quad (14.5.6.9.7b-7)$$

where:

$S_{RB}$  = bending stress range in the support bar due to maximum moment including moment from vertical reaction and overturning at the connection (ksi)

$M_V$  = component of vertical bending moment range in the support bar due to the vertical reaction force range in the connection located on the critical section at the weld toe (kip-in.)

$S_{Xsb}$  = vertical section modulus of the support bar to the top of the support bar (in.<sup>3</sup>)

$h_w$  = height of the weld (in.)

- $d_{sb}$  = depth of the support bar (in.)
- $S_{RZ}$  = vertical stress range in the bottom of the centerbeam-to-support-bar weld from the vertical and horizontal reaction force ranges in the connection (ksi)
- $S_{Wbot}$  = section modulus of the weld at the bottom for bending in the direction of the support bar axis (in.<sup>3</sup>)
- $A_{Wbot}$  = area of weld at the bottom (in.<sup>2</sup>)

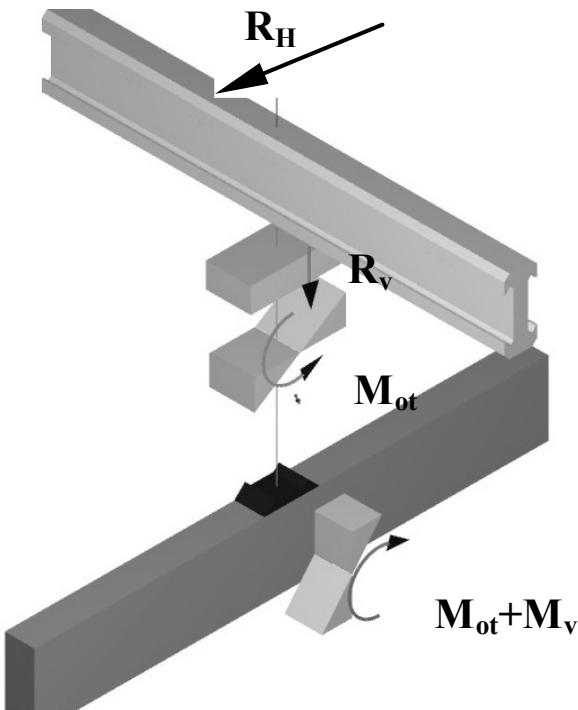

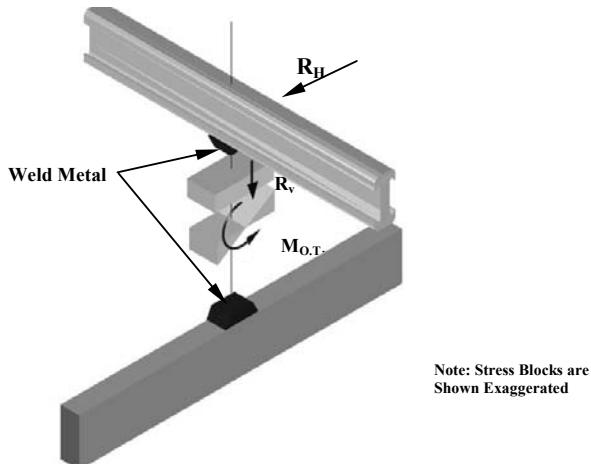

Figure 14.5.6.9.7b-2—Force Effects Associated with Type B Cracking

- Cracking Through the Throat of the Weld, i.e., Type C Cracking: The design stress range,  $\Delta f$ , for Type C cracking is the vertical stress, range,  $S_{RZ}$ , at the most narrow cross-section of the centerbeam-to-support-bar weld from the vertical and horizontal reaction force ranges in the connection, as shown in Figure 14.5.6.9.7b-3. The design stress range,  $\Delta f$ , for Type C cracking shall be determined as:

$$\Delta f = \frac{R_V}{A_{Wmid}} + \frac{R_H \left( d_{cb} + \frac{1}{2} h_w \right)}{S_{Wmid}} \quad (14.5.6.9.7b-8)$$

where:

- $S_{Wmid}$  = section modulus of the weld at the most narrow cross-section for bending in the direction normal to the centerbeam axis ( $\text{in.}^3$ )  
 $A_{Wmid}$  = minimum cross-sectional area of weld ( $\text{in.}^2$ )

**Figure 14.5.6.9.7b-3—Force Effects Associated with Type C Cracking**

## 14.6—REQUIREMENTS FOR BEARINGS

### 14.6.1—General

Bearings may be fixed or movable as required for the bridge design. Movable bearings may include guides to control the direction of translation. Fixed and guided bearings shall be designed to resist all appropriate loads and restrain unwanted translation.

Unless otherwise noted, the resistance factor for bearings,  $\phi$ , shall be taken as 1.0.

Bearings subject to net uplift at any limit state shall be secured by tie-downs or anchorages.

The magnitude and direction of movements and the loads to be used in the design of the bearing shall be clearly defined in the contract documents.

Combinations of different types of fixed or movable bearings should not be used at the same expansion joint, bent, or pier, unless the effects of differing deflection and rotation characteristics on the bearings and the structure are accounted for in the design.

Multirotational bearings conforming to the provisions of this Section should not be used where vertical loads are less than 20 percent of the vertical bearing capacity.

All bearings shall be evaluated for component and connection strength and bearing stability.

Where two bearings are used at a support of box girders, the vertical reactions should be computed with consideration of torque resisted by the pair of bearings.

### C14.6.1

Bearings support relatively large loads while accommodating large translation or rotations.

The behavior of bearings is quite variable, and there is very little experimental evidence to precisely define  $\phi$  for each limit state.  $\phi$  is taken to be equal to 1.0 in many parts of Article 14.6 where a more refined estimate is not warranted. The resistance factors are often embedded in the design equations and based on judgment and experience, but they are generally thought to be conservative.

Differing deflection and rotational characteristics may result in damage to the bearings and/or structure.

Bearings loaded to less than 20 percent of their vertical capacity require special design (FHWA, 1991).

Bearings can provide a certain degree of horizontal load resistance by limiting the radius of the spherical surface. However, the ability to resist horizontal loads is a function of the vertical reaction on the bearing, which could drop during earthquakes or other extreme event loadings. In general, bearings are not recommended for horizontal to vertical load ratios of over 40 percent unless the bearings are intended to act as fuses or irreparable damage is permitted.

## 14.6.2—Characteristics

The bearing chosen for a particular application shall have appropriate load and movement capabilities. Table 14.6.2-1 and Figure 14.6.2-1 may be used as a guide when comparing the different bearing systems.

The following terminology shall apply to Table 14.6.2-1:

S = Suitable

U = Unsuitable

L = Suitable for limited applications

R = May be suitable, but requires special considerations or additional elements such as sliders or guideways

Long. = Longitudinal axis

Trans. = Transverse axis

Vert. = Vertical axis

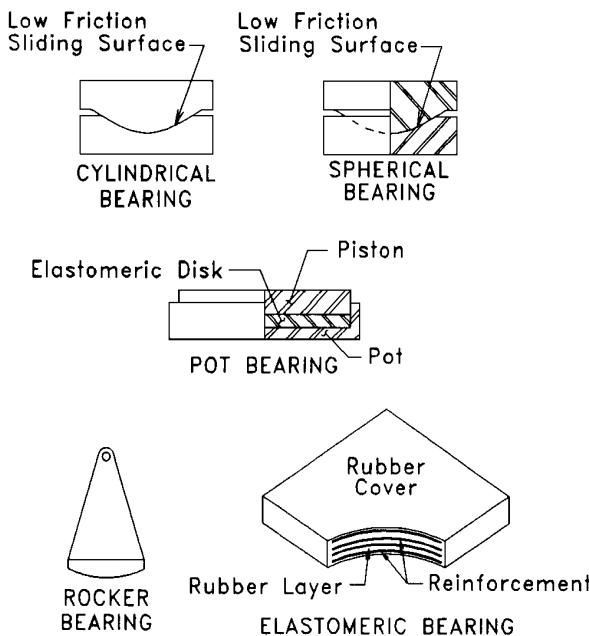

## C14.6.2

Practical bearings will often combine more than one function to achieve the desired results. For example, a pot bearing may be combined with a PTFE sliding surface to permit translation and rotation.

Information in Table 14.6.2-1 is based on general judgment and observation, and there will obviously be some exceptions. Bearings listed as suitable for a specific application are likely to be suitable with little or no effort on the part of the Engineer other than good design and detailing practice. Bearings listed as unsuitable are likely to be marginal, even if the Engineer makes extraordinary efforts to make the bearing work properly. Bearings listed as suitable for limited application may work if the load and rotation requirements are not excessive.

**Table 14.6.2-1—Bearing Suitability**

Type of Bearing	Movement		Rotation about Bridge Axis Indicated			Resistance to Loads		
	Long.	Trans.	Long.	Trans.	Vert.	Long.	Trans.	Vert.
Plain Elastomeric Pad	S	S	S	S	L	L	L	L
Fiberglass-Reinforced Pad	S	S	S	S	L	L	L	L

**Figure 14.6.2-1—Common Bearing Types**

### 14.6.3—Force Effects Resulting from Restraint of Movement at the Bearing

#### 14.6.3.1—Horizontal Force and Movement

Horizontal forces and moments induced in the bridge by restraint of movement at the bearings shall be determined using the movements and bearing characteristics specified in Article 14.7. For bearings with elastomeric elements, these characteristics should include, but are not limited to, the consideration of increased shear modulus,  $G$ , at temperatures below 73°F.

Expansion bearings and their supports shall be designed in a manner such that the structure can undergo movements to accommodate the seismic and other extreme event displacement determined using the provisions in Section 3 without collapse. Adequate support length shall be provided for all bearings in accordance with Article 4.7.4.4.

The Engineer shall determine the number of bearings required to resist the loads specified in Section 3 with consideration of the potential for unequal participation due to tolerances, unintended misalignments, the capacity of the individual bearings, and the skew.

Consideration should be given to the use of field adjustable elements to provide near simultaneous engagement of the intended number of bearings.

#### C14.6.3.1

Restraint of movement results in a corresponding force or moment in the structure. These force effects should be calculated taking into account the stiffness of the bridge and the bearings. The latter should be estimated by the methods outlined in Article 14.7. In some cases, the bearing stiffness depends on time and temperature, as well as on the movement. For example, the designer should take note that in cold temperatures which approach the appropriate minimum specified zone temperatures, the shear modulus,  $G$ , of an elastomer may be as much as four times that at 73°F. See Article 14.7.5.2 and AASHTO M 251 for more information.

Expansion bearings should allow sufficient movement in their unrestrained direction to prevent premature failure due to seismic and other extreme event displacements.

Often, bearings do not resist load simultaneously, and damage to only some of the bearings at one end of a span is not uncommon. When this occurs, high load concentrations can result at the location of the undamaged bearings, which should be taken into account. The number of bearings engaged should be based on type, design, and detailing of the bearings used, and on the bridge skew. Skew angles under 15 degrees are usually ignored. Skew

At the strength and extreme event limit states, horizontal forces transmitted to the superstructure and substructure by bearings,  $H_{bu}$ , shall be taken as those induced by sliding friction, rolling friction, or shear deformation of a flexible element in the bearing.

Sliding friction force shall be taken as:

$$H_{bu} = \mu P_u \quad (14.6.3.1-1)$$

where:

$H_{bu}$  = lateral load transmitted to the superstructure and substructure by bearings from applicable strength and extreme event load combinations in Table 3.4.1-1 (kip)

$\mu$  = coefficient of friction

$P_u$  = compressive force from applicable strength and extreme event load combinations in Table 3.4.1-1 (kip)

The force due to the deformation of an elastomeric element shall be taken as:

$$H_{bu} = GA \frac{\Delta_u}{h_{rt}} \quad (14.6.3.1-2)$$

where:

$G$  = shear modulus of the elastomer (ksi)

$A$  = plan area of elastomeric element or bearing ( $\text{in.}^2$ )

$\Delta_u$  = shear deformation from applicable strength and extreme event load combinations in Table 3.4.1-1 (in.)

$h_{rt}$  = total elastomer thickness (in.)

Strength and extreme event limit states rolling forces shall be determined by testing.

#### 14.6.3.2—Moment

At the strength and extreme event limit states, both the substructure and superstructure shall be designed for the largest moment,  $M_u$ , transferred by the bearing.

For curved sliding bearings without a companion flat sliding surface,  $M_u$  shall be taken as:

$$M_u = \mu P_u R \quad (14.6.3.2-1)$$

For curved sliding bearings with a companion flat sliding surface,  $M_u$  shall be taken as:

angles over 30 degrees are usually considered significant and need to be considered in analysis. Skewed bridges have a tendency to rotate under seismic loading, and bearings should be designed and detailed to accommodate this effect.

Horizontal forces transmitted to other bridge elements by bearings do not include forces associated with the deformations of stiff bearing elements or hard metal-on-metal contact of bearing components because provisions in Article 14.7 are intended to avoid such contact.

Maximum extreme event limit state forces should be considered when the bearing is not intended to act as a fuse or irreparable damage is not permitted.

Special consideration should be given to bearings that support large horizontal loads relative to the vertical load (SCEF, 1991).

Eq. 14.6.3.1-1 is a function of vertical forces and friction, and is a measure of the maximum horizontal force which could be transmitted to the superstructure or substructure before slip occurs. Eq. A13.3.2-2 is also a measure of the maximum transmitted horizontal force, but is dependant primarily upon the shear modulus (stiffness) of the elastomer and applied lateral forces such as braking.

#### C14.6.3.2

Maximum extreme event limit state forces should be considered when the bearing is not intended to act as a fuse or irreparable damage is not permitted.

The tangential force in curved sliding bearings is caused by friction resistance at the curved surface, and it acts about the center of the curved surface.  $M_u$  is the moment due to this force that is transmitted by the bearing. The moment imposed on individual components of the bridge structure may be different from  $M_u$  depending on the location of the axis of rotation and can be calculated by a rational method.

$$M_u = 2\mu P_u R \quad (14.6.3.2-2)$$

where:

$M_u$  = moment transmitted to the superstructure and substructure by bearings from applicable strength and extreme event load combinations in Table 3.4.1-1 (kip-in.)

$R$  = radius of curved sliding surface (in.)

For unconfined elastomeric bearings and pads,  $M_u$  shall be taken as:

$$M_u = 1.60(0.5E_c I) \frac{\theta_s}{h_{rt}} \quad (14.6.3.2-3)$$

where:

$I$  = moment of inertia of plan shape of bearing (in.<sup>4</sup>)

$E_c$  = effective modulus of elastomeric bearing in compression (ksi)

$\theta_s$  = maximum service limit state design rotation angle specified in Article 14.4.2.1 (rad.)

$h_{rt}$  = total elastomer thickness (in.)

For CDP,  $M_u$  shall be taken as:

$$M_u = 1.25(4.5 - 2.2S + 0.6\sigma_s) \frac{E_c I}{t_p} \theta_s \quad (14.6.3.2-4)$$

where:

$E_c$  = uniaxial compressive stiffness of the CDP bearing pad. It may be taken as 30 ksi in lieu of pad-specific test data (ksi)

$t_p$  = total thickness of CDP pad (in.)

$S$  = shape factor of the CDP pad computed based on Eq. 14.7.5.1-1 and based on total pad thickness

$\sigma_s$  = average compressive stress due to total load associated with the maximum rotation from applicable service load combinations in Table 3.4.1-1 (ksi)

$\theta_s$  = maximum rotation of the CDP pad from applicable service load combinations in Table 3.4.1-1 (rad.)

The load-deflection curve of an elastomeric bearing is nonlinear, so  $E_c$  is load dependent. One acceptable approximation for the effective modulus is:

$$E_c = 6GS^2 \quad (C14.6.3.2-1)$$

where:

$S$  = shape factor of an individual elastomer layer

$G$  = shear modulus of the elastomer (ksi)

The factor 1.60 in Eq. 14.6.3.2-3 is an average multiplier on total load on the bearing to estimate a strength limit state load,  $M_u$ , based on a service limit state rotation,  $\theta_s$ .

The factor 1.25 in Eq. 14.6.3.2-4 is a multiplier on total load on the bearing to estimate a strength limit state load,  $M_u$ , based on a service limit state rotation,  $\theta_s$ , and stress,  $\sigma_s$ .

The rotational stiffness,  $K$ , of CDP is provided by:

$$K = (4.5 - 2.2S + 0.6\sigma_s) \frac{E_c I}{t_p} \quad (C14.6.3.2-2)$$

The moment,  $M_u$ , may be crucial for the design of CDP, because movable CDP are normally designed with PTFE sliding surfaces to develop the translational movement capacity.  $M_u$  in the bearing pad results in edge bearing stress on the PTFE in addition to the average compressive stress. The PTFE on CDP pads is unconfined, and this moment may limit the bearing stress on the PTFE to a stress somewhat smaller than permitted on the CDP alone.

#### 14.6.4—Fabrication, Installation, Testing, and Shipping

The provisions for fabrication, installation, testing, and shipping of bearings, specified in Section 18, “Bearing Devices,” of the *AASHTO LRFD Bridge Construction Specifications*, shall apply.

The setting temperature of the bridge or any component thereof shall be taken as the actual air temperature averaged over the 24-hour period immediately preceding the setting event.

#### C14.6.4

Some jurisdictions have provided additional guidance beyond that provided in the *AASHTO LRFD Bridge Construction Specifications* with respect to the fabrication, installation, testing, and shipping of multirotational-type bearings (SCEF, 1991).

Setting temperature is used in installing expansion bearings.

An offset chart for girder erection and alignment of the bearings is recommended to account for uncertainty in the setting temperature at the time of design. Offset charts should be defined in appropriate increments and included in the design drawings so that the position of the bearing can be adjusted to account for differences between setting temperature and an assumed design installation temperature.

#### 14.6.5—Seismic and Other Extreme Event Provisions for Bearings

##### 14.6.5.1—General

This Article shall apply to the analysis, design and detailing of bearings to accommodate the effects of earthquakes and, as appropriate, other extreme events for which the horizontal loading component is very large.

These provisions shall be applied in addition to all other applicable code requirements. The bearing-type selection shall consider the criteria described in Article 14.6.5.3 in the early stages of design.

##### 14.6.5.2—Applicability

These provisions shall apply to pin, roller, rocker, and bronze or copper-alloy sliding bearings, elastomeric bearings, spherical bearings, and pot and disc bearings in common slab-on-girder bridges but not to isolation-type bearings or structural fuse bearings designed primarily for the effects of extreme event dynamic horizontal loadings.

Although the strategy taken herein assumes that inelastic action is confined to properly detailed hinge areas in substructures, alternative concepts that utilize movement at the bearings to dissipate extreme event horizontal and/or vertical forces may also be considered. Where alternate strategies may be used, all ramifications of the increased movements and the predictability of the associated forces and transfer of forces shall be considered in the design and details.

##### 14.6.5.3—Design Criteria

The selection, and the seismic or other extreme event horizontal loading design of bearings shall be related to the strength and stiffness characteristics of both the superstructure and the substructure.

##### C14.6.5.1

Extreme events other than earthquakes for which the horizontal loading component is very large include vehicle collisions, ship collisions, and high-velocity winds.

##### C14.6.5.2

Provisions for the design, specification, testing, and acceptance of isolation bearings are given in AASHTO (1999).

##### C14.6.5.3

The commentary provided below specifically addresses seismic design considerations. However, it is also applicable to other extreme event horizontal loadings such as vehicle and ship collisions which are dynamic in

Bearing design shall be consistent with the intended seismic or other extreme event response of the whole bridge system.

Where rigid-type bearings are used, the seismic or other horizontal extreme event forces from the superstructure shall be assumed to be transmitted through diaphragms or cross-frames and their connections to the bearings and then to the substructure without reduction due to local inelastic action along that load path. However, forces may be reduced in situations where the end-diaphragms in the superstructure have been specifically designed and detailed for inelastic action, in accordance with generally accepted provisions for ductile end-diaphragms.

As a minimum, bearings, restraints, and anchorages shall be designed to resist the forces specified in Article 3.10.9.

nature but can have a very short duration. Accounting for the effects of other extreme events such as wind or waves may require special considerations that are not fully addressed in these specifications for bearing design.

Bearings have a significant effect on the overall seismic response of a bridge. They provide the seismic load transfer link between a stiff and massive superstructure and a stiff and massive substructure. As a result, very high (and difficult-to-predict) load concentrations can occur in the bearing components. The primary functions of the bearings are to resist the vertical loads due to dead load and live load and to allow for superstructure movements due to live load and temperature changes. Allowance for translation is made by means of rollers, rocker, or shear deformation of an elastomer, or through the provision of a sliding surface of bronze or copper alloy or PTFE. Allowance for rotation is made by hinges, confined or unconfined elastomers, or spherical sliding surfaces. Resistance to translation is provided by bearing components or additional restraining elements.

Historically, bearings have been very susceptible to seismic loads. Unequal loading during seismic events and much higher loads than anticipated have caused various types and levels of bearing damage. To allow movements, bearings often contain elements vulnerable to high loads and impacts.

The performance of bearings during past earthquakes needs to be evaluated in context with the overall performance of the bridge and the performance of the superstructure and substructure elements connected to the bearings. Rigid bearings have been associated with damage to the end cross-frames and the supporting pier or abutment concrete. In some cases, bearing damage and slippage has prevented more extensive damage.

The criteria for seismic design of bearings should consider the strength and stiffness characteristics of the superstructure and substructure. To minimize damage, the seismic load resisting system made of the end cross-frame or diaphragms, bearings, and substructure should allow a certain degree of energy dissipation, movement, or plastic deformation even if those effects are not quantified as they would be for seismic isolation bearings or structural fuses.

Based on their horizontal stiffness, bearings may be divided into four categories:

- Rigid bearings that transmit seismic loads without any movement or deformations;
- Deformable bearings that transmit seismic loads limited by plastic deformations or restricted slippage of bearing components;
- Seismic isolation type bearings that transmit reduced seismic loads, limited by energy dissipation; and,
- Structural fuses that are designed to fail at a prescribed load.

For the deformable-type bearing, limited and repairable bearing damage and displacement may be allowed for the design earthquake.

When both the superstructure and the substructure components adjacent to the bearing are very stiff, a deformable-type bearing should be considered.

Seismic isolation-type bearings are not within the scope of these provisions, but they should also be considered.

Elastomeric bearings have been demonstrated to result in reduced force transmission to substructure.

Elastomeric bearings having less than full rigidity, but not designed explicitly as seismic isolators or fuses, may be used under any circumstance. If used, they shall either be designed to accommodate imposed seismic or other horizontal extreme event loads, or, if survival of the elastomeric bearing itself is not required, other means such as restrainers, STUs, widened support lengths, or dampers shall be provided to prevent unseating of the superstructure.

A bearing may also be designed to act as a “structural fuse” that will fail at a predetermined load changing the articulation of the structure, possibly changing its period and hence seismic response, and probably resulting in increased movements. This strategy is permitted as an alternative to these provisions under Article 14.6.5.2. Such an alternative would require full consideration of forces and movements and of bearing repair/replacement details. It also requires the designer to address the inherent difficulty of detailing a structural element to fail reliably at predetermined load.

## 14.7—SPECIAL DESIGN PROVISIONS FOR BEARINGS

### 14.7.1—Metal Rocker and Roller Bearings

#### 14.7.1.1—General

The rotation axis of the bearing shall be aligned with the axis about which the largest rotations of the supported member occur. Provision shall be made to ensure that the bearing alignment does not change during the life of the bridge. Multiple roller bearings shall be connected by gearing to ensure that individual rollers remain parallel to each other and at their original spacing.

Metal rocker and roller bearings shall be detailed so that they can be easily inspected and maintained.

Rockers should be avoided wherever practical and, when used, their movements and tendency to tip under seismic actions shall be considered in the design and details.

#### C14.7.1.1

Cylindrical bearings contain no deformable parts and are susceptible to damage if the superstructure rotates about an axis perpendicular to the axis of the bearing. Thus, they are unsuitable for bridges in which the axis of rotation may vary significantly under different situations, such as bridges with a large skew. They are also unsuitable for use in seismic regions because the transverse shear caused by earthquake loading can cause substantial overturning moment.

Good maintenance is essential if mechanical bearings are to perform properly. Dirt attracts and holds moisture, which, combined with high local contact stresses, can promote stress corrosion. Metal bearings, in particular, must be designed for easy maintenance.

Rockers can be suitable for applications in which the horizontal movement of the superstructure, relative to the substructure, is well within the available movement range after consideration of other applicable movements.

### 14.7.1.2—Materials

Rocker and roller bearings shall be made of stainless steel conforming to [ASTM A240](#), as specified in Article 6.4.7, or of structural steel conforming to AASHTO M 169 ([ASTM A108](#)), M 102M/M 102 ([ASTM A668/A668M](#)), or M 270M/M 270 ([ASTM A709/A709M](#)), Grades 36, 50, or 50W. Material properties of these steels shall be taken as specified in Table 6.4.1-1 and Table 6.4.2-1.

### C14.7.1.2

Carbon steel has been the traditional steel used in mechanical bearings because of its good mechanical properties. Surface hardening may be considered. Corrosion resistance is also important. The use of stainless steel for the contact surfaces may prove economical when life-cycle costs are considered. Weathering steels should be used with caution as their resistance to corrosion is often significantly reduced by mechanical wear at the surface.

### 14.7.1.3—Geometric Requirements

The dimensions of the bearing shall be chosen taking into account both the contact stresses and the movement of the contact point due to rolling.

Each individual curved contact surface shall have a constant radius. Bearings with more than one curved surface shall be symmetric about a line joining the centers of their two curved surfaces.

If pintles or gear mechanisms are used to guide the bearing, their geometry should be such as to permit free movement of the bearing.

Bearings shall be designed to be stable. If the bearing has two separate cylindrical faces, each of which rolls on a flat plate, stability may be achieved by making the distance between the two contact lines no greater than the sum of the radii of the two cylindrical surfaces.

### C14.7.1.3

The choice of radius for a curved surface is a compromise: a large radius results in low contact stresses but large rotations of the point of contact and vice versa. The latter could be important if, for example, a rotational bearing is surmounted by a PTFE slider because the PTFE is sensitive to eccentric loading.

### 14.7.1.4—Contact Stresses

At the service limit state, the contact load,  $P_s$ , shall satisfy:

- For cylindrical surfaces:

$$P_s \leq 8 \frac{WD_1}{\left(1 - \frac{D_1}{D_2}\right)} \left( \frac{F_y^2}{E_s} \right) \quad (14.7.1.4-1)$$

- For spherical surfaces:

$$P_s \leq 40 \left( \frac{D_1}{1 - \frac{D_1}{D_2}} \right)^2 \frac{F_y^3}{E_s^2} \quad (14.7.1.4-2)$$

where:

$D_1$  = diameter of the rocker or roller surface (in.)

### C14.7.1.4

The service limit state loads are limited so that the contact causes calculated shear stresses no higher than  $0.55 F_y$  or surface compression stresses no higher than  $1.65 F_y$ . The maximum compressive stress is at the surface, and the maximum shear stress occurs just below it.

The formulas were derived from the theoretical value for contact stress between elastic bodies (Roark and Young, 1976). They are based on the assumption that the width of the contact area is much less than the diameter of the curved surface.

If two surfaces have curves of the opposite sign, the value of  $D_2$  is negative. This would be an unusual situation in bridge bearings.

If careful inspection indicates that existing bearings which do not satisfy these provisions are performing well and there is no evidence of rutting or ridging, which may be evidence of local yielding, then reuse of the bearing may be viable. Evaluation of roller and rocker bearings with flat mating surfaces may proceed using the following historical provision:

Bearing per linear in. on expansion rockers and rollers at the service limit state shall not exceed the values obtained by the following formulas:

Diameters up to 25.0 in.

$$p = \frac{F_y - 13}{20} (0.6d) \quad (\text{C14.7.1.4-1})$$

Diameters 25.0 to 125.0 in.

$$p = \frac{F_y - 13}{20} 3\sqrt{d} \quad (\text{C14.7.1.4-2})$$

where:

$p$  = allowable bearing at the service limit state (kip/in.)

$d$  = diameter of rocker or roller (in.)

$F_y$  = specified minimum yield strength of the weakest steel at the contact surface (ksi)

If loads are increased significantly by the rehabilitation or the mating surface is curved, complying with the current provisions may be more appropriate.

The two diameters have the same sign if the centers of the two curved surfaces in contact are on the same side of the contact surface, such as is the case when a circular shaft fits in a circular hole.

$D_2$  = diameter of the mating surface (in.) taken as:

- Positive if the curvatures have the same sign, and
- Infinite if the mating surface is flat.

$F_y$  = specified minimum yield strength of the weakest steel at the contact surface (ksi)

$E_s$  = Young's modulus for steel (ksi)

$W$  = width of the bearing (in.)

#### 14.7.2—PTFE Sliding Surfaces

PTFE may be used in sliding surfaces of bridge bearings to accommodate translation or rotation. All PTFE surfaces other than guides shall satisfy the requirements specified herein. Curved PTFE surfaces shall also satisfy Article 14.7.3.

##### 14.7.2.1—PTFE Surface

The PTFE surface shall be made from pure virgin PTFE resin satisfying the requirements of [ASTM D4894](#) or [D4895](#). It shall be fabricated as unfilled sheet, filled sheet, or fabric woven from PTFE and other fibers.

Unfilled sheets shall be made from PTFE resin alone. Filled sheets shall be made from PTFE resin uniformly blended with glass fibers, carbon fibers, or other chemically inert filler. The filler content shall not exceed 15 percent for glass fibers and 25 percent for carbon fibers.

##### C14.7.2

PTFE, is also known as TFE and is commonly used in bridge bearings in the United States. This Article does not cover guides. The friction requirements for guides are less stringent, and a wider variety of materials and fabrication methods can be used for them.

##### C14.7.2.1

PTFE may be provided in sheets or in mats woven from fibers. The sheets may be filled with reinforcing fibers to reduce creep, i.e., cold flow, and wear, or they may be made from pure resin. The friction coefficient depends on many factors, such as sliding speed, contact pressure, lubrication, temperature, and properties such as the finish of the mating surface (Campbell and Kong, 1987). The material properties that influence the friction coefficient are not well understood, but the crystalline structure of the PTFE is known to be important, and it is strongly affected by the quality control exercised during the manufacturing process.

Sheet PTFE may contain dimples to act as reservoirs for lubricant. Unlubricated PTFE may also contain dimples. Their diameter shall not exceed 0.32 in. at the surface of the PTFE, and their depth shall be not less than 0.08 in. and not more than half the thickness of the PTFE. The reservoirs shall be uniformly distributed over the surface area and shall cover more than 20 percent but less than 30 percent of the contact surface. Dimples should not be placed to intersect the edge of the contact area. Lubricant shall be silicone grease, which satisfies Military Specification MIL-S-8660.

Woven fiber PTFE shall be made from pure PTFE fibers. Reinforced woven fiber PTFE shall be made by interweaving high-strength fibers, such as glass, with the PTFE in such a way that the reinforcing fibers do not appear on the sliding face of the finished fabric.

#### **14.7.2.2—Mating Surface**

The PTFE shall be used in conjunction with a mating surface. Flat mating surfaces shall be stainless steel, and curved mating surfaces shall be stainless steel or anodized aluminum. Flat surfaces shall be stainless steel, Type 304, conforming to either [ASTM A167](#) or [A264](#), and shall be provided with a surface finish of 8.0  $\mu\text{-in}$ . RMS or better. Finishes on curved metallic surfaces shall not exceed 16.0  $\mu\text{-in}$ . RMS. The mating surface shall be large enough to cover the PTFE at all times.

Unfilled dimples can act as reservoirs for contaminants (dust, etc.) which can help to keep these contaminants from the contact surface.

#### **C14.7.2.2**

Stainless steel is the most commonly used mating surface for PTFE sliding surfaces. Anodized aluminum has been sometimes used in spherical and cylindrical bearings produced in other countries and may be considered if documentation of experience, acceptable to the Owner, is provided. The finish of this mating surface is extremely important because it affects the coefficient of friction. [ASTM A240](#), Type 304, stainless steel, with a surface finish of 16.0  $\mu\text{-in}$ . RMS or better, is appropriate, but the surface measurements are inherently inexact, and hence it is not a specified alternative. Friction testing is required for the PTFE and its mating surface because of the many variables involved.

#### **14.7.2.3—Minimum Thickness**

##### **14.7.2.3.1—PTFE**

For all applications, the thickness of the PTFE shall be at least 0.0625 in. after compression. Recessed sheet PTFE shall be at least 0.1875 in. thick when the maximum dimension of the PTFE is less than or equal to 24.0 in., and 0.25 in. when the maximum dimension of the PTFE is greater than 24.0 in. Woven fabric PTFE, which is mechanically interlocked over a metallic substrate, shall have a minimum thickness of 0.0625 in. and a maximum thickness of 0.125 in. over the highest point of the substrate.

##### **C14.7.2.3.1**

A minimum thickness is specified to ensure uniform bearing and to allow for wear.

During the first few cycles of movement, small amounts of PTFE transfer to the mating surface and contribute to the very low friction achieved subsequently. This wear is acceptable and desirable.

PTFE continues to wear with time (Campbell and Kong, 1987) and movement; wear is exacerbated by deteriorated or rough surfaces. Wear is undesirable because it usually causes higher friction and reduces the thickness of the remaining PTFE. Unlubricated, flat PTFE wears more severely than the lubricated material. The evidence on the rate of wear is tentative. High travel speeds, such as those associated with traffic movements, appear to be more damaging than the slow ones due to thermal movements. However, they may be avoided by placing the sliding surface on an elastomeric bearing that will absorb small longitudinal movements. No further allowance for wear is made in this Specification due to the limited research available to quantify or estimate the wear as a function of time and travel. However, wear may ultimately cause the need for replacement of the PTFE, so it is wise to allow for future replacement in the original design.

### 14.7.2.3.2—Stainless Steel Mating Surfaces

The thickness of the stainless steel mating surface shall be at least 16 gage when the maximum dimension of the surface is less than or equal to 12.0 in. and at least 13 gage when the maximum dimension is larger than 12.0 in.

Backing plate requirements shall be taken as specified in Article 14.7.2.6.2.

### C14.7.2.3.2

The minimum thickness requirements for the mating surface are intended to prevent it from wrinkling or buckling. This surface material is usually quite thin to minimize cost of the highly finished mating surface. Some mating surfaces, particularly those with curved surfaces, are made of carbon steel on which a stainless steel weld is deposited. This welded surface is then finished and polished to achieve the desired finish. Some jurisdictions require a minimum thickness of 0.094 in. for welded overlay after grinding and polishing.

### 14.7.2.4—Contact Pressure

The contact stress between the PTFE and the mating surface shall be determined at the service limit state using the nominal area.

The average contact stress shall be computed by dividing the load by the projection of the contact area on a plane perpendicular to the direction of the load. The contact stress at the edge shall be determined by taking into account the maximum moment transferred by the bearing assuming a linear distribution of stress across the PTFE.

Stresses shall not exceed those given in Table 14.7.2.4-1. Permissible stresses for intermediate filler contents shall be obtained by linear interpolation within Table 14.7.2.4-1.

### C14.7.2.4

The average contact stress shall be determined by dividing the load by the projection of the contact area onto a plane perpendicular to the direction of the load. The edge contact stress shall be determined based on the service limit state load and the maximum service limit state moment transferred by the bearing.

The contact pressure must be limited to prevent excessive creep or plastic flow of the PTFE, which causes the PTFE disc to expand laterally under compressive stress and may contribute to separation or bond failure. The lateral expansion is controlled by recessing the PTFE into a steel plate or by reinforcing the PTFE, but there are adverse consequences associated with both methods. Edge loading may be particularly detrimental because it causes large stress and potential flow in a local area near the edge of the material in hard contact between steel surfaces. The average and edge contact pressure in Table 14.7.2.4-1 are in appropriate proportions to one another relative to the currently available research. Better data may become available in the future. These are in the lower range of those used in Europe.

**Table 14.7.2.4-1—Maximum Contact Stress for PTFE at the Service Limit State (ksi)**

Material	Average Contact Stress (ksi)		Edge Contact Stress (ksi)	
	Permanent Loads	All Loads	Permanent Loads	All Loads
Unconfined PTFE:				
Unfilled Sheets	1.5	2.5	2.0	3.0
Filled Sheets with Maximum Filler Content	3.0	4.5	3.5	5.5
Confined Sheet PTFE	3.0	4.5	3.5	5.5
Woven PTFE Fiber over a Metallic Substrate	3.0	4.5	3.5	5.5
Reinforced Woven PTFE over a Metallic Substrate	4.0	5.5	4.5	7.0

#### 14.7.2.5—Coefficient of Friction

The service limit design coefficient of friction of the PTFE sliding surface shall be taken as specified in Table 14.7.2.5-1. Intermediate values may be determined by interpolation. The coefficient of friction shall be determined by using the stress level associated with the applicable load combination specified in Table 3.4.1-1. Lesser values may be used if verified by tests.

Where friction is required to resist nonseismic loads, the design coefficient of friction under dynamic loading may be taken as not more than ten percent of the values listed in Table 14.7.2.5-1 for the bearing stress and PTFE type indicated.

The coefficients of friction in Table 14.7.2.5-1 are based on a 8.0  $\mu$ -in. finish mating surface. Coefficients of friction for rougher surface finishes must be established by test results in accordance with the *AASHTO LRFD Bridge Construction Specifications*, Chapter 18.

The contract documents shall require certification testing from the production lot of PTFE to ensure that the friction actually achieved in the bearing is appropriate for the bearing design.

#### C14.7.2.5

The friction factor decreases with lubrication and increasing contact stress but increases with sliding velocity (Campbell and Kong, 1987). The coefficient of friction also tends to increase at low temperatures. Static friction is larger than dynamic friction, and the dynamic coefficient of friction is larger for the first cycle of movement than it is for later cycles. Friction increases with increasing roughness of the mating surface and decreasing temperature. The friction factors used in the earlier editions of the AASHTO Standard Specifications are suitable for use with dimpled, lubricated PTFE. They are too small for the flat, dry PTFE commonly used in the United States. These Specifications have been changed to recognize this fact. Nearly all research to date has been performed on dimpled, lubricated PTFE. The coefficients of friction given in Table 14.7.2.5-1 are not applicable to high-velocity movements such as those occurring in seismic events. Seismic velocity coefficients of friction must be determined in accordance with the *AASHTO Guide Specifications for Seismic Isolation Design*. Coefficients of friction, somewhat smaller than those given in Table 14.7.2.5-1, are possible with care and quality control.

Certification testing from the production lot is essential for PTFE sliding surfaces primarily to ensure that the friction actually achieved in the bearing is appropriate for the bearing design. Testing is the only reliable method for certifying the coefficient of friction and bearing behavior.

Contamination of the sliding surface with dirt and dust increases the coefficient of friction and increases the wear of the PTFE. To prevent contamination, the bearing should be sealed by the manufacturer and not separated at the construction site. To prevent contamination and gouging of the PTFE, the stainless steel should normally be on top and should be larger than the PTFE, plus its maximum travel.

Woven PTFE is sometimes formed by weaving pure PTFE strands with a reinforcing material. These reinforcing strands may increase the resistance to creep and cold flow and can be woven so that reinforcing strands do not appear on the sliding surface. This separation is necessary if the coefficients of friction provided in Table 14.7.2.5-1 are to be used.

If there is no lubricant in the dimples, the dimples tend to flatten out filling the dimples, resulting in a surface much like unfilled PTFE.

**Table 14.7.2.5-1—Design Coefficients of Friction—Service Limit State**

	Pressure (ksi)	Coefficient of Friction			
		0.5	1.0	2.0	>3.0
Type PTFE	Temperature (°F)				
Dimpled Lubricated	68	0.04	0.030	0.025	0.020
	-13	0.06	0.045	0.040	0.030
	-49	0.10	0.075	0.060	0.050
Unfilled or Dimpled Unlubricated	68	0.08	0.070	0.050	0.030
	-13	0.20	0.180	0.130	0.100
	-49	0.20	0.180	0.130	0.100
Filled	68	0.24	0.170	0.090	0.060
	-13	0.44	0.320	0.250	0.200
	-49	0.65	0.550	0.450	0.350
Woven	68	0.08	0.070	0.060	0.045
	-13	0.20	0.180	0.130	0.100
	-49	0.20	0.180	0.130	0.100

**14.7.2.6—Attachment****14.7.2.6.1—PTFE**

Sheet PTFE confined in a recess in a rigid metal backing plate for one-half its thickness may be bonded or unbonded.

Sheet PTFE that is not confined shall be bonded to a metal surface or an elastomeric layer with a Shore A durometer hardness of at least 90 by an approved method.

Woven PTFE on a metallic substrate shall be attached to the metallic substrate by mechanical interlocking that can resist a shear force no less than 0.10 times the applied compressive force.

**C14.7.2.6.1**

Recessing is the most effective way of preventing creep in unfilled PTFE. The PTFE discs may also be bonded into the recess, but this is optional and the benefits are debatable. Bonding helps to retain the PTFE in the recess during the service life of the bridge, but it makes replacement of the disc more difficult. If the adhesive is not applied uniformly it can cause an uneven PTFE sliding surface that could lead to premature wear. Some manufacturers cut the PTFE slightly oversize and pre-cool it before installation because this results in a tighter fit at room temperature.

Sometimes PTFE is bonded to the top cover layer of an elastomeric bearing. This layer should be relatively thick and hard to avoid rippling of the PTFE (Roeder et al., 1987). PTFE must be etched prior to epoxy bonding in order to obtain good adhesion. However, ultra-violet light attacks the etching and can lead to delamination, so PTFE exposed to ultra-violet light should not be attached by bonding alone.

**14.7.2.6.2—Mating Surface**

The mating surface for flat sliding surfaces shall be attached to a backing plate by welding in such a way that it remains flat and in full contact with its backing plate throughout its service life. The weld shall be detailed to form an effective moisture seal around the entire perimeter of the mating surface to prevent interface corrosion. The attachment shall be capable of resisting the maximum friction force that can be developed by the bearing under service limit state load combinations. The welds used for the attachment shall be clear of the contact and sliding area of the PTFE surface.

**C14.7.2.6.2**

The restrictions on the attachment of the mating surface are primarily intended to ensure that the surface is flat and retains uniform contact with the PTFE at all times, without adversely affecting the friction of the surface or gouging or cutting the PTFE.

The mating surface of curved sliding surfaces should be machined to the required surface finish from a single piece.

### 14.7.3—Bearings with Curved Sliding Surfaces

#### 14.7.3.1—General

Bearings with curved sliding surfaces shall consist of two metal parts with matching curved surfaces and a low friction sliding interface. The curved surfaces may be either cylindrical or spherical. The material properties, characteristics, and frictional properties of the sliding interface shall satisfy the requirements specified in Articles 14.7.2 and 14.7.7.

The two surfaces of a sliding interface shall have equal nominal radii.

#### C14.7.3.1

These provisions are directed primarily toward spherical or cylindrical bearings with bronze or PTFE sliding surfaces.

Some jurisdictions require that the minimum center thickness of concave spherical surfaces be at least 0.75 in. and that a minimum vertical clearance between the rotating and nonrotating parts be as given by Eqs. C14.7.3.1-1 or C14.7.3.1-2 but not less than 0.125 in.

- For rectangular spherical or curved bearings:

$$c = 0.7D\theta_u + 0.125 \quad (\text{C14.7.3.1-1})$$

- For round spherical or round bearings:

$$c = 0.5D\theta_u + 0.125 \quad (\text{C14.7.3.1-2})$$

where:

$\theta_u$  = design rotation from applicable strength load combinations in Table 3.4.1-1 or Article 14.4.2.2.1 (rad.)

Similarly, the minimum edge thickness on the convex surface has sometimes been limited to 0.75 in. for bearing on concrete and 0.50 in. for bearing on steel.

#### 14.7.3.2—Bearing Resistance

The radius of the curved surface shall be large enough to ensure that the total compressive load at the service limit state on the horizontal projected area of the bearing,  $P_s$ , is less than or equal to the average allowable load as computed from the service stress specified in Articles 14.7.2.4 or 14.7.7.3.

- For cylindrical bearings:

$$P_s \leq \phi DW\sigma_{ss} \quad (\text{C14.7.3.2-1})$$

- For spherical bearings:

$$P_s \leq \phi \frac{\pi D^2 \sigma_{ss}}{4} \quad (\text{C14.7.3.2-2})$$

#### C14.7.3.2

The geometry of a spherical bearing controls its ability to resist lateral loads, its moment-rotation behavior, and its frictional characteristics. The geometry is relatively easy to define, but it has some consequences that are not widely appreciated. The stress may vary over the contact surface of spherical or cylindrical bearings. Cylindrical and spherical surfaces cannot be machined as accurately as a flat smooth surface. It is important that the radius of the convex and concave surfaces be within appropriate limits. If these limits are exceeded the bronze may crack due to hard bearing contact, or there may be excessive wear and damage due to creep or cold flow of the PTFE. The stress limits used in this Section are based on average contact stress levels.

where:

$P_s$  = total compressive load from applicable service load combinations in Table 3.4.1-1 (kip)

$D$  = diameter of the projection of the loaded surface of the bearing in the horizontal plane (in.)

$\sigma_{ss}$  = maximum average contact stress at the service limit state permitted on PTFE by Table 14.7.2.4-1 or on bronze by Table 14.7.7.3-1 (ksi)

$W$  = length of cylinder (in.)

$\phi$  = resistance factor taken as 1.0

### 14.7.3.3—Resistance to Lateral Load

Where bearings are required to resist horizontal loads at the service limit state, an external restraint system shall be provided or:

- For a cylindrical sliding surface, the horizontal load shall satisfy:

$$H_s \leq 2RW\sigma_{ss} \sin(\psi - \beta - \theta_u) \sin \beta \quad (14.7.3.3-1)$$

- For a spherical surface, the horizontal load shall satisfy:

$$H_s \leq \pi R^2 \sigma_{ss} \sin(\psi - \beta - \theta_u) \sin \beta \quad (14.7.3.3-2)$$

in which:

$$\beta = \tan^{-1} \left( \frac{H_s}{P_D} \right) \quad (14.7.3.3-3)$$

and

$$\psi = \sin^{-1} \left( \frac{L}{2R} \right) \quad (14.7.3.3-4)$$

where:

$H_s$  = horizontal load from applicable service load combinations in Table 3.4.1-1 (kip)

$L$  = projected length of the sliding surface perpendicular to the rotation axis (in.)

$P_D$  = compressive load at the service limit state (load factor = 1.0) due to permanent loads (kip)

$R$  = radius of curved sliding surface (in.)

$W$  = length of cylindrical surface (in.)

$\beta$  = angle between the vertical and resultant applied load (rad.)

$\theta_u$  = maximum strength limit state design rotation angle specified in Article 14.4.2.2.1 (rad.)

### C14.7.3.3

The geometry of a curved bearing combined with gravity loads can provide considerable resistance to lateral load. An external restraint is often a more reliable method of resisting large lateral loads at the service and strength limit states, and at the extreme event limit state when the bearing is not intended to act as a fuse or irreparable damage is not permitted.

The applied loads for determination of the angle  $\beta$  and the applied load check are at the service limit state because the stress limits,  $\sigma_{ss}$ , are service-based. The rotation at the strength limit state is utilized because bearings with curved sliding surfaces are susceptible to more serious consequences if overloaded or over rotated.

The geometry of a cylindrical sliding bearing is shown in the deformed position in Figure C14.7.3.3-1.

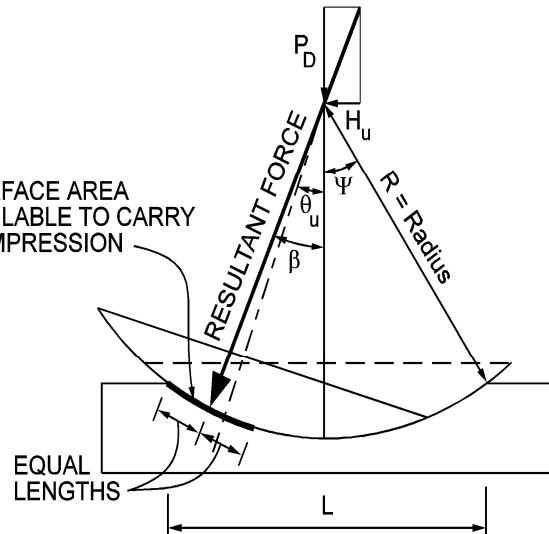

Figure C14.7.3.3-1—Bearing Geometry

$\sigma_{ss}$  = maximum average contact stress at the service limit state permitted on PTFE by Table 14.7.2.4-1 or on bronze by Table 14.7.7.3-1 (ksi)

$\Psi$  = subtended semiangle of the curved surface (rad.)

#### 14.7.4—Pot Bearings

##### 14.7.4.1—General

Where pot bearings are provided with a PTFE slider to provide for both rotation and horizontal movement, such sliding surfaces and any guide systems shall be designed in accordance with the provisions of Articles 14.7.2 and 14.7.9.

The rotational elements of the pot bearing shall consist of at least a pot, a piston, an elastomeric disc, and sealing rings.

For the purpose of establishing the forces and deformations imposed on a pot bearing, the axis of rotation shall be taken as lying in the horizontal plane at midheight of the elastomeric disc.

The minimum vertical load on a pot bearing should not be less than 20 percent of the vertical design load.

##### 14.7.4.2—Materials

The elastomeric disc shall be made from a compound based on virgin natural rubber or virgin neoprene conforming to the requirements of Section 18.3 of the *AASHTO LRFD Bridge Construction Specifications*. The nominal hardness shall lie between 50 and 60 on the Shore A scale.

The pot and piston shall be made from structural steel conforming to AASHTO M 270M/M 270 ([ASTM A709/A709](#)); Grades 36, 50, or 50W; or from stainless steel conforming to [ASTM A240](#). The finish of surfaces in contact with the elastomeric pad shall be smoother than 60  $\mu$ -in. The yield strength and hardness of the piston shall not exceed that of the pot.

Brass sealing rings satisfying Articles 14.7.4.5.2 and 14.7.4.5.3 shall conform to [ASTM B36](#) (half hard) for rings of rectangular cross-section, and Federal Specification QQ-B-626, Composition 2, for rings of circular cross-section.

##### 14.7.4.3—Geometric Requirements

The depth of the elastomeric disc,  $h_r$ , shall satisfy:

$$h_r \geq 3.33D_p\theta_u \quad (14.7.4.3-1)$$

where:

$D_p$  = internal diameter of pot (in.)

$\theta_u$  = maximum strength limit state design rotation angle specified in Article 14.4.2.2.1 (rad.)

##### C14.7.4.2

Softer elastomers permit rotation more readily and are preferred.

Corrosion resistant steels, such as AASHTO M 270M/M 270 ([ASTM A709/A709](#)), Grade 50W, are not recommended for applications where they may come into contact with saltwater or be permanently damp, unless their whole surface is completely corrosion protected. Most pot bearings are machined from a solid plate, so use of high-strength steel to decrease the wall thickness results in only a very small reduction in volume of material used.

Other properties, such as corrosion resistance, ease of machining, electrochemical compatibility with steel girders, availability, and price should also be considered. The provision on relative hardness is mentioned to avoid wear or damage on the inside surface of the pot and the consequent risk of seal failure.

The choice of brass for sealing rings reflects present practice.

##### C14.7.4.3

The requirements of this Article are intended to prevent the seal from escaping and the bearing from locking up even under the most adverse conditions. Use of the design rotation,  $\theta_u$ , means that the designer should account for both the anticipated movements due to loads and those due to fabrication and installation tolerances, including the rotation imposed on the bearing due to out-of-level of other bridge components, such as undersides of prefabricated girders, and permissible misalignments during construction. Vertical deflection

The dimensions of the elements of a pot bearing shall satisfy the following requirements under the least favorable combination of strength limit state displacements and rotations:

- The pot shall be deep enough to permit the seal and piston rim to remain in full contact with the vertical face of the pot wall, and
- Contact or binding between metal components shall not prevent further displacement or rotation.

caused by compressive load should also be taken into account because it will reduce the available clearance. Anchor bolts projecting above the base plate should be taken into consideration when clearance is determined.

Rotation capacity can be increased by using a deeper pot, a thicker elastomeric pad, and a larger vertical clearance between the pot wall and the piston or slider. The minimum thickness of the pad specified herein results in edge deflections due to rotation no greater than 15 percent of the nominal pad thickness. Figure C14.7.4.3-1 and Eqs. C14.7.4.3-1 and C14.7.4.3-2 may be used to verify clearance.

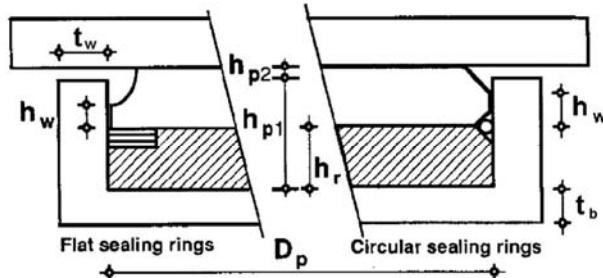

Figure C14.7.4.3-1—Pot Bearing—Critical Dimensions for Clearances

The pot cavity depth,  $h_{p1}$ , may be determined as:

$$h_{p1} \geq (0.5D_p\theta_u) + h_r + h_w \quad (\text{C14.7.4.3-1})$$

where:

$h_r$  = depth of elastomeric disc (in.)

$h_w$  = height from top of rim to underside of piston (in.)

The vertical clearance between top of piston and top of pot wall,  $h_{p2}$  may be determined as:

$$h_{p2} \geq R_o\theta_u + 2\delta_u + 0.125 \quad (\text{C14.7.4.3-2})$$

where:

$\delta_u$  = vertical deflection from applicable strength load combinations in Table 3.4.1-1 (in.)

$R_o$  = radial distance from center of pot to object in question (e.g., pot wall, anchor bolt, etc.) (in.)

Note that Eq. C14.7.4.3-1 does not contain any allowance for vertical deflection  $\delta_u$ . This omission is conservative. The design rotation,  $\theta_u$ , already represents an extreme rotation for use with the strength limit state and requires no further factoring.

$\delta_u$  and  $\theta_u$  may also be considered at the extreme event limit state.

Thicker pads with deeper pots cause smaller strains in the elastomer, and they appear to experience less wear and abrasion. Recessing of the rings into the pad is necessary for satisfactory pad performance, but it also decreases the effective thickness of the pad at that location. Further, the recess has sometimes been cut into the pad, and this cut appears to make the pad susceptible to additional damage. Therefore, it is generally better to use a deeper pot and thicker pad even though this leads to greater material and machining costs.

#### **14.7.4.4—Elastomeric Disc**

The average stress on the elastomer at the service limit state should not exceed 3.5 ksi.

To facilitate rotation, the top and bottom surfaces of the elastomer shall be treated with a lubricant that is not detrimental to the elastomer. Alternatively, thin PTFE discs may be used on the top and bottom of the elastomer.

#### **C14.7.4.4**

The average stress on the elastomeric disc is largely limited by the seal's ability to prevent escape of the elastomer. The 3.5 ksi level has been used as a practical upper limit for some years, and most bearings have performed satisfactorily but a few seal failures have occurred. The experimental research of NCHRP 10-20A showed that greater wear and abrasion due to cyclic rotation occurred when higher stress levels are employed, but this correlation is not strong. As a result, the 3.5 ksi stress limit is retained as a practical design limit.

Lubrication helps prevent abrasion of the elastomer during cyclic rotation, however, research has shown that the beneficial effect of the lubrication tends to be lost with time. Silicon grease has been used with success. It performed well in experiments and is recommended. Thin sheets of PTFE have also been used. These sheets performed quite well in experimental studies, but they are less highly recommended because there is a concern that they may wrinkle and become ineffective. Powdered graphite has been used but has not performed well in rotation experiments. As a result, silicon grease is the preferred lubricant, and powdered graphite is not recommended. PTFE discs are permitted as a method of lubrication, but the user should be aware that some problems have been reported.

#### **14.7.4.5—Sealing Rings**

##### *14.7.4.5.1—General*

A seal shall be used between the pot and the piston. At the service limit state seals shall be adequate to prevent escape of elastomer under compressive load and simultaneously applied cyclic rotations. At the strength limit state, seals shall also be adequate to prevent escape of elastomer under compressive load and simultaneously applied static rotation.

Brass rings satisfying the requirements of either Articles 14.7.4.5.2 or 14.7.4.5.3 may be used without testing to satisfy the above requirements. The Engineer may approve other sealing systems on the basis of experimental evidence.

##### *C14.7.4.5.1*

Failure of seals has been one of the most common problems in pot bearings. Multiple flat brass rings, circular brass rod formed and brazed into a ring, and proprietary plastic rings have been found to be successful. Experimental research suggests that solid circular brass rings provide a tight fit and prevent leakage of the elastomer, but they experience severe wear during cyclic rotation. Experiments suggest that flat brass rings are somewhat more susceptible to elastomer leakage and fracture, but they are less prone to wear. PTFE rings should not be used. The rings should preferably be recessed into the elastomer or vulcanized to it in order to minimize distortion of the elastomer.

Cyclic rotation of the bearing due to temperature variations or traffic loading can cause chafing of the elastomer against the pot wall, which can give rise to some loss of elastomer past the seal. The detail design of the sealing system is important in preventing this. The details of the tests for alternative sealing systems are left to the discretion of the Engineer. However, tests should include cyclic rotation.

#### 14.7.4.5.2—Rings with Rectangular Cross-Sections

Three rectangular rings shall be used. Each ring shall be circular in plan but shall be cut at one point around its circumference. The faces of the cut shall be on a plane at 45 degrees to the vertical and to the tangent of the circumference. The rings shall be oriented so that the cuts on each of the three rings are equally spaced around the circumference of the pot.

The width of each ring shall not be less than either 0.02  $D_p$  or 0.25 in. and shall not exceed 0.75 in. The depth of each shall not be less than 0.2 times its width.

#### 14.7.4.5.3—Rings with Circular Cross-Sections

One circular closed ring shall be used with an outside diameter of  $D_p$ . It shall have a cross-sectional diameter not less than either 0.0175  $D_p$  or 0.15625 in.

#### 14.7.4.6—Pot

The pot shall consist at least of a wall and base. All elements of the pot shall be designed to act as a single structural unit.

The minimum thickness of a base bearing directly against concrete or grout shall satisfy:

- $t_b \geq 0.06D_p$  and (14.7.4.6-1)

- $t_b \geq 0.75$  in. (14.7.4.6-2)

The thickness of a base bearing directly on steel girders or load distribution plates shall satisfy:

- $t_b \geq 0.04D_p$  and (14.7.4.6-3)

- $t_b \geq 0.50$  in. (14.7.4.6-4)

The minimum pot wall thickness,  $t_w$ , for an unguided sliding pot bearing shall satisfy:

$$t_w \geq \frac{D_p \sigma_s}{1.25 F_y} \quad (14.7.4.6-5)$$

and:

$$t_w \geq 0.75 \text{ in.} \quad (14.7.4.6-6)$$

#### C14.7.4.6

Pots are constructed most reliably by machining from a single plate. For very large bearings, this may become prohibitively expensive, so fabrication by welding a ring to a base plate is implicitly accepted. However, the ring must be attached to the plate by a full penetration weld because the wall is subject to significant bending moments where it joins the base plate. The quality of welding should be assured by quality control. The finished inside profile of the pot must satisfy the required shape and tolerances. Straightening and machining may be needed to rectify welding distortions.

The lower bounds on the thickness of the base plate are intended to provide some rigidity to counteract the effects of uneven bearing. If the base plate was to deform significantly, the volume of elastomer would be inadequate to fill the space in the pot, and hard contact could occur between some elements.

Eqs. 14.7.4.6-5 and 14.7.4.6-6 define minimum wall thickness requirements for unguided pot bearings. Eq. 14.7.4.6-5 is based upon hoop strength of the pot walls with the elastomeric disc under hydrostatic compressive stress. This equation is conservative for this application, because it neglects the beneficial effect of the bending strength and stiffness at the pot wall-base interface. However, this equation provides no lateral (horizontal) resistance to the bearing, and it is limited to unguided bearings (Stanton, 1999).

where:

$t_w$  = pot wall thickness (in.)

$F_y$  = yield strength of the steel (ksi)

$D_p$  = internal diameter of pot (in.)

$\sigma_s$  = average compressive stress due to total load from applicable service load combinations in Table 3.4.1-1 (ksi)

The wall thickness ( $t_w$ ) and base thickness ( $t_b$ ) of guided or fixed pots shall also satisfy the requirements of Eq. 14.7.4.7-1 for applicable strength and extreme event load combinations specified in Table 3.4.1-1 which are transferred by the piston to the pot wall.

#### 14.7.4.7—Piston

The piston shall have the same plan shape as the inside of the pot. Its thickness shall be adequate to resist the loads imposed on it, but shall not be less than six percent of the inside diameter of the pot,  $D_p$ , except at the rim.

The perimeter of the piston shall have a contact rim through which horizontal loads may be transmitted. In circular pots, its surface may be either cylindrical or spherical. The body of the piston above the rim shall be set back or tapered to prevent binding. The height,  $w$ , of the piston rim shall be large enough to transmit the strength and extreme event limit states horizontal forces between the pot and the piston.

Where a mechanical device is used to connect the superstructure to the substructure, it shall be designed to resist the greater of  $H_u$  at the support for the strength and extreme event limit states, or 15 percent of the maximum vertical load at the service limit state at that location.

Pot bearings subjected to lateral loads shall be proportioned so that the thickness of the pot wall ( $t_w$ ) and the pot base ( $t_b$ ) shall satisfy:

$$t_w, t_b \geq \sqrt{\frac{25H_u\theta_u}{F_y}} \quad (14.7.4.7-1)$$

Pot bearings that transfer load through the piston shall satisfy:

$$h_w \geq \frac{1.5H_u}{D_p F_y} \quad (14.7.4.7-2)$$

$$h_w \geq 0.125 \text{ in., and} \quad (14.7.4.7-3)$$

$$h_w \geq 0.03D_p \quad (14.7.4.7-4)$$

The limitation of Eq. 14.7.4.6-6 is based upon past manufacturing practice (SCEF, 1991).

The surface finish on the inside of the pot may have considerable impact on bearing performance. A smooth finish reduces rotational resistance and wear and abrasion of the elastomer. It may also improve the performance of the sealing rings, but at present there are no definitive limits as to what the surface finish should ideally be for good bearing performance. Metalization on the inside of the pot tends to cause a rougher surface finish, which leads to significant increases in damage under cyclic rotation; as a result, metalization may not be a good method of protection.

Maximum extreme event limit state forces should be considered when the bearing is not intended to act as a fuse or irreparable damage is not permitted.

#### C14.7.4.7

The required piston thickness is controlled by rigidity and strength. A central internal guide bar fitted in a slot in the piston causes bending moments that are largest where the piston is weakest. In this case, the piston must also be thick enough to supply an adequate grip length for any bolts used to secure the guide bar.

If the piston rotates while a horizontal load is acting, the piston rim will be subject to bearing stresses due to horizontal load and to shear forces. If the rim surface is cylindrical, contact between it and the pot wall will theoretically be along a line when the piston rotates. In practice, some localized yielding is inevitable. If the rim surface forms part of a sphere, the contact area will be finite, providing less potential for local damage. Damage to the pot wall should be avoided because it will jeopardize the effectiveness of the seal. The dimensions of the rim depend on the contact area, and because this is uncertain, the rim should be designed conservatively. Eq. 14.7.4.7-4 is based on consideration of bearing stresses alone, using a strength limit state horizontal force of 0.15 times the vertical service limit state load,  $F_y = 50.0$  ksi and  $\phi = 0.9$ .

The 15 percent factor applied to the service limit state vertical load, embedded in Eq. 14.7.4.7-4 and used in the design of mechanical devices that connect the superstructure to the substructure, approximates a strength limit state horizontal design force.

Maximum extreme event limit state forces should be considered when the bearing is not intended to act as a fuse or irreparable damage is not permitted.  $\theta_u$  may also be considered at the extreme event limit state.

The clearance between piston and pot is critical to the proper functioning of the bearing. In most bearings the finished clearance, after anticorrosion coatings have been applied, should be about 0.02 to 0.04 in., a range that is easily achievable. The equation for minimum clearance is based on geometry. Eq. 14.7.4.7-5 may occasionally

where:

$H_u$  = lateral load from applicable strength and extreme event load combinations in Table 3.4.1-1 (kip)

$\theta_u$  = maximum strength limit state design rotation angle specified in Article 14.4.2.2.1 (rad.)

$F_y$  = yield strength of steel (ksi)

$D_p$  = internal diameter of pot (in.)

$h_w$  = height from top of rim to underside of piston (in.)

$t_w$  = pot wall thickness (in.)

$t_b$  = pot base thickness (in.)

The diameter of the piston rim shall be the inside diameter of the pot less a clearance,  $c$ . The clearance,  $c$ , shall be as small as possible in order to prevent escape of the elastomer but not less than 0.02 in. If the surface of the piston rim is cylindrical, the clearance shall satisfy:

$$c \geq \theta_u \left( h_w - \frac{D_p \theta_u}{2} \right) \quad (14.7.4.7-5)$$

where:

$D_p$  = internal diameter of pot (in.)

$h_w$  = height from top of rim to underside of piston (in.)

$\theta_u$  = maximum strength limit state design rotation angle specified in Article 14.4.2.2.1 (rad.)

#### 14.7.5—Steel-Reinforced Elastomeric Bearings— Method B

##### 14.7.5.1—General

Steel-reinforced elastomeric bearings may be designed using either of two methods commonly referred to as Method A and Method B. Where the provisions of this Article are used, the component shall be taken to meet the requirements of Method B. Where the provisions of Article 14.7.6 are used, the component shall be taken to meet the requirements of Method A.

Steel-reinforced elastomeric bearings shall consist of alternate layers of steel reinforcement and elastomer bonded together. In addition to any internal reinforcement, bearings may have external steel load plates bonded to either or both the upper or lower elastomer layers.

produce a negative number; however, in these instances the minimum value of 0.02 in. controls.

##### C14.7.5.1

The stress limits associated with Method A usually result in a bearing with a lower capacity than a bearing designed using Method B. This increased capacity resulting from the use of Method B requires additional testing and quality control.

Steel-reinforced elastomeric bearings are treated separately from other elastomeric bearings because of their greater strength and superior performance in practice (Roeder et al., 1987; Roeder and Stanton, 1991). The critical parameter in their design is the shear strain in the elastomer at its interface with the steel plates. Axial load, rotation, and shear deformations all cause such shear strains. The design method (Method B) described in this Section accounts directly for those shear strains and provides a versatile means of allowing for different combinations of loadings.

Tapered elastomer layers shall not be used. All internal layers of elastomer shall be of the same thickness. The top and bottom cover layers shall be no thicker than 70 percent of the internal layers.

The shape factor of a layer of an elastomeric bearing,  $S_i$ , shall be taken as the plan area of the layer divided by the area of perimeter free to bulge. Unless noted otherwise, the values of  $S_i$  and  $h_{ri}$  to be used in Articles 14.7.5 and 14.7.6 for steel-reinforced elastomeric bearing design shall be that for an internal layer. For rectangular bearings without holes, the shape factor of a layer may be taken as:

$$S_i = \frac{LW}{2h_{ri}(L+W)} \quad (14.7.5.1-1)$$

where:

$L$  = plan dimension of the bearing perpendicular to the axis of rotation under consideration (generally parallel to the global longitudinal bridge axis) (in.)

$W$  = plan dimension of the bearing parallel to the axis of rotation under consideration (generally parallel to the global transverse bridge axis) (in.)

$h_{ri}$  = thickness of  $i$ th elastomeric layer (in.)

For circular bearings without holes, the shape factor of a layer may be taken as:

$$S_i = \frac{D}{4h_{ri}} \quad (14.7.5.1-2)$$

where:

$D$  = diameter of the projection of the loaded surface of the bearing in the horizontal plane (in.)

Tapered layers cause larger shear strains and bearings made with them fail prematurely due to delamination or rupture of the reinforcement. All internal layers should be the same thickness because the strength and stiffness of the bearing in resisting compressive load are controlled by the thickest layer.

The shape factor,  $S_i$ , is defined in terms of the gross plan dimensions of layer  $i$ . Refinements to account for the difference between gross dimensions and the dimensions of the reinforcement are not warranted because quality control on elastomer thickness has a more dominant influence on bearing behavior. Holes are strongly discouraged in steel-reinforced bearings. However, if holes are used, their effect should be accounted for when calculating the shape factor because they reduce the loaded area and increase the area free to bulge. Suitable shape factor formulae are:

- For rectangular bearings:

$$S_i = \frac{LW - \sum \frac{\pi}{4} d^2}{h_{ri}[2L + 2W + \sum \pi d]} \quad (C14.7.5.1-1)$$

- For circular bearings:

$$S_i = \frac{D^2 - \sum d^2}{4h_{ri}(D + \sum d)} \quad (C14.7.5.1-2)$$

where:

$d$  = the diameter of the hole or holes in the bearing (in.)

Large steel-reinforced elastomeric bearings (defined as those which are thicker than 8 in. or having a plan area greater than 1,000 in.<sup>2</sup>) are more difficult to fabricate than small ones. The consequences of failure are also likely to be more severe in a large bearing. As such, large bearings should be designed according to Method B, which requires additional testing and quality control.

#### 14.7.5.2—Material Properties

The shear modulus of the elastomer at 73°F shall be used as the basis for design.

The elastomer shall have a specified shear modulus between 0.080 and 0.175 ksi. It shall conform to the requirements of Section 18.2 of the *AASHTO LRFD Bridge Construction Specifications* and AASHTO M 251.

The acceptance criteria in AASHTO M 251 shall be followed which:

- permits a variation of  $\pm 15$  percent from the value specified for shear modulus according to the first and second paragraphs of this Article, and
- does not permit a shear modulus below 0.080 ksi.

For design purposes, the shear modulus shall be taken as the least favorable of the values in the ranges described above.

Other properties, such as creep deflection, should be obtained from Table 14.7.6.2-1 or from tests conducted using AASHTO M 251.

For the purposes of bearing design, all bridge sites shall be classified as being in temperature Zones A, B, C, D, or E for which design data are given in Table 14.7.5.2-1. In the absence of more precise information, Figure 14.7.5.2-1 may be used as a guide in selecting the zone required for a given region.

Bearings shall be made from AASHTO low-temperature grades of elastomer as defined in Section 18 of the *AASHTO LRFD Bridge Construction Specifications* and AASHTO M 251. The minimum grade of elastomer required for each low-temperature zone shall be taken as specified in Table 14.7.5.2-1.

Any of the three design options listed below may be used:

- Specify the elastomer with the minimum low-temperature grade indicated in Table 14.7.5.2-1 and determine the shear force transmitted by the bearing as specified in Article 14.6.3.1;
- Specify the elastomer with the minimum low-temperature grade for use when special force provisions are incorporated in the design and provide a low friction sliding surface, in which case the bridge shall be designed to withstand twice the design shear force specified in Article 14.6.3.1; or
- Specify the elastomer with the minimum low-temperature grade for use when special force provisions are incorporated in the design but do not provide a low friction sliding surface, in which case the components of the bridge shall be designed to resist four times the design shear force as specified in Article 14.6.3.1.

#### C14.7.5.2

Shear modulus,  $G$ , is the most important material property for design, and it is, therefore, the primary means of specifying the elastomer. Hardness has been widely used in the past, and is still permitted for Method A design, because the test for it is quick and simple. However, the results obtained from it are variable and correlate only loosely with shear modulus.

Materials with a specified shear modulus greater than 0.175 ksi are prohibited because they generally have a smaller elongation at break and greater stiffness and greater creep than their softer counterparts. This inferior performance is generally attributed to the larger amounts of filler present. Their fatigue behavior does not differ in a clearly discernible way from that of softer materials.

The least favorable value for the shear modulus used in design calculations is dependent upon whether the parameter being calculated is conservatively estimated by over- or under-estimating the shear modulus. The forgiving nature of elastomers tends to compensate for service and installation conditions which are less than ideal. (See Article 14.7.5.3.2.) Despite this, the designer should be cautious about specifying a shear modulus which is at or near the specified upper or lower bounds of 0.175 ksi and 0.080 ksi, respectively.

The zones are defined by their extreme low temperatures or the largest number of consecutive days when the temperature does not rise above 32°F, whichever gives the more severe condition.

Shear modulus increases as the elastomer cools, but the extent of stiffening depends on the elastomer compound, time, and temperature. It is, therefore, important to specify a material with low-temperature properties that are appropriate for the bridge site. In order of preference, the low-temperature classification should be based on:

- The 50-yr temperature history at the site,
- A statistical analysis of a shorter temperature history, or
- Figure 14.7.5.2-1.

Table 14.7.5.2-1 gives the minimum elastomer grade to be used in each zone. A grade suitable for a lower-temperature may be specified by the Engineer, but improvements in low-temperature performance can often be obtained only at the cost of reductions in other properties. This low-temperature classification is intended to limit the force on the bridge substructure to 1.5 times the service limit state design force under extreme environmental conditions.

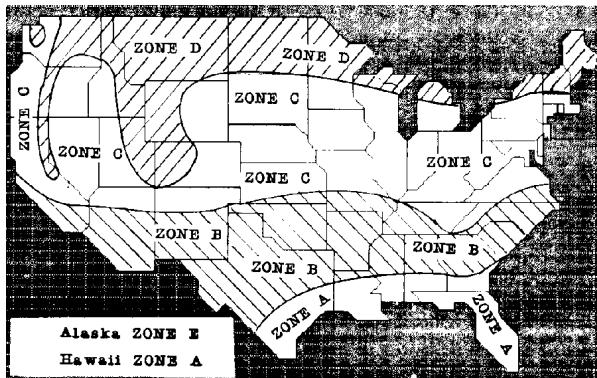

Figure 14.7.5.2-1—Temperature Zones

Table 14.7.5.2-1—Low-Temperature Zones and Minimum Grades of Elastomer

Low-Temperature Zone	A	B	C	D	E
50-yr low temperature (°F)	0	-20	-30	-45	<-45
Maximum number of consecutive days when the temperature does not rise above 32°F	3	7	14	N/A	N/A
Minimum low-temperature elastomer grade	0	2	3	4	5
Minimum low-temperature elastomer grade when special force provisions are incorporated	0	0	2	3	5

### 14.7.5.3—Design Requirements

#### 14.7.5.3.1—Scope

Bearings designed by the provisions herein shall be tested in accordance with the requirements for steel-reinforced elastomeric bearings as specified in Article 18.2 of the *AASHTO LRFD Bridge Construction Specifications* and the AASHTO M 251.

#### 14.7.5.3.2—Shear Deformations

The maximum horizontal displacement of the bridge superstructure,  $\Delta_O$ , shall be taken as 65 percent of the design thermal movement range,  $\Delta_T$ , computed in accordance with Article 3.12.2, combined with movements caused by creep, shrinkage, and post-tensioning.

The maximum shear deformation of the bearing, at the service limit state,  $\Delta_S$ , shall be taken as  $\Delta_O$ , modified to account for the substructure stiffness and construction procedures. If a low friction sliding surface is installed,  $\Delta_S$  need not be taken to be larger than the deformation corresponding to first slip.

The bearing shall satisfy:

$$h_{rt} \geq 2\Delta_S \quad (14.7.5.3.2-1)$$

where:

$h_{rt}$  = total elastomer thickness (in.)

$\Delta_S$  = maximum total shear deformation of the elastomer from applicable service load combinations in Table 3.4.1-1 (in.)

#### C14.7.5.3.1

Steel-reinforced bearings are designed to resist relatively high stresses. Their integrity depends on good quality control during manufacture, which can only be ensured by rigorous testing.

#### C14.7.5.3.2

The shear deformation is limited to  $\pm 0.5 h_{rt}$  in order to avoid rollover at the edges and delamination due to fatigue.

Generally, the installation temperature is within  $\pm 15$  percent of the average of the maximum and minimum design temperatures. Consequently, 65 percent of the thermal movement range is used for design purposes (Roeder, 2002). The forgiving nature of elastomeric bearings more than accounts for actual installation temperatures greater than or less than the likely approximated installation temperature. Additionally, if the bearing is originally set or reset at the average of the design temperature range, 50 percent of the design thermal movement range computed in accordance with Article 3.12.2 may be substituted for 65 percent as specified.

Fatigue tests that formed the basis for this provision were conducted to 20,000 cycles, which represents one expansion/contraction cycle per day for approximately 55 yr (Roeder et al., 1990). The provisions will, therefore, be unconservative if the shear deformation is caused by high-cycle loading due to braking forces or vibration. The maximum shear deformation due to these high-cycle loadings should be restricted to no more than  $\pm 0.10 h_{rt}$ .

unless better information is available. At this strain amplitude, the experiments showed that the bearing has an essentially infinite fatigue life.

If the bridge girders are lifted to allow the bearings to realign after some of the girder shortening has occurred, that may be accounted for in design.

Pier deflections sometimes accommodate a significant portion of the bridge movement, and this may reduce the movement that must be accommodated by the bearing. Construction methods may increase the bearing movement because of poor installation tolerances or poor timing of the bearing installation.

#### 14.7.5.3.3—Combined Compression, Rotation, and Shear

Combinations of axial load, rotation, and shear at the service limit state shall satisfy:

$$(\gamma_{a,st} + \gamma_{r,st} + \gamma_{s,st}) + 1.75(\gamma_{a,cy} + \gamma_{r,cy} + \gamma_{s,cy}) \leq 5.0 \quad (14.7.5.3.3-1)$$

The static component of  $\gamma_a$  shall also satisfy:

$$\gamma_{a,st} \leq 3.0 \quad (14.7.5.3.3-2)$$

where:

$\gamma_a$  = shear strain caused by axial load

$\gamma_r$  = shear strain caused by rotation

$\gamma_s$  = shear strain caused by shear displacement

Subscripts “*st*” and “*cy*” indicate static and cyclic loading, respectively. Cyclic loading shall consist of loads induced by traffic. All other loads may be considered static. In rectangular bearings, the shear strains shall be evaluated for rotation about the axis which is parallel to the transverse axis of the bridge. Evaluation of shear strains for rotation about the axis which is parallel to the longitudinal axis of the bridge should also be considered. For circular bearings, the rotations about two primary orthogonal axes shall be added vectorially, and the shear strains shall be evaluated using the largest sum.

The shear strains  $\gamma_a$ ,  $\gamma_r$ , and  $\gamma_s$ , shall be established by rational analysis, in lieu of which the following approximations are acceptable.

The shear strain due to axial load may be taken as:

$$\gamma_a = D_a \frac{\sigma_s}{GS_i} \quad (14.7.5.3.3-3)$$

in which, for a rectangular bearing:

$$D_a = 1.4 \quad (14.7.5.3.3-4)$$

#### C14.7.5.3.3

Elastomers are almost incompressible, so when a steel-laminated bearing is loaded in compression, the elastomer expands laterally due to the Poisson effect. That expansion is partially restrained by the steel plates to which the elastomer layers are bonded, and the restraint results in bulging of the layers between the plates. The bulging creates shear stresses at the bonded interface between the elastomer and steel. If they become large enough, they can cause shear failure of the bond or the elastomer adjacent to it. This is the most common form of damage in steel-laminated elastomeric bearings and is the reason why limitations on the shear strain in the elastomer dominate the design requirements.

The cyclic components of the loading are multiplied by an amplification factor of 1.75 in Eq. 14.7.5.3.3-1. This reflects the results of tests that showed that cyclic shear strain causes more debonding damage than a static shear strain of the same amplitude. This approach of using an explicit summation of the shear strain components coupled with an amplification factor on cyclic components is found in other specifications, such as the European EN 1337.

In some cases, the rotations due to dead and live load will have opposite signs, in which case use of the amplification factor of 1.75 could lead to an amplified rotation that is artificially low. This is clearly not consistent with the intent of the amplification factor. In cases where the sense of the loading components in the critical combination is unclear, the sum of the absolute value should be used.

For rectangular bearings, separate evaluations about each primary rotation axis (parallel to the transverse global axis and parallel to the longitudinal global axis of the bridge) may be necessary and appropriate, such as for structures with significant skew. Where rectangular bearings are evaluated about an axis parallel to the global longitudinal axis of the bridge, the definitions of *L* and *W* should be interchanged.

For highly skewed or curved bridges, the girder ends will significantly rotate in both bending and torsion. Circular bearings offer a good alternative.

The constants 1.4 assigned to  $D_a$  and 0.5 assigned to  $D_r$  for rectangular bearings represent simplified values for determining shear strains which are evaluated for rotation about an axis which is parallel to the transverse

and, for a circular bearing:

$$D_a = 1.0 \quad (14.7.5.3.3-5)$$

where:

$D_a$  = dimensionless coefficient used to determine shear strain due to axial load

$G$  = shear modulus of the elastomer (ksi)

$S_i$  = shape factor of the  $i$ th internal layer of an elastomeric bearing

$\sigma_s$  = average compressive stress due to total static or cyclic load from applicable service load combinations in Table 3.4.1-1 (ksi)

The shear strain due to rotation for a rectangular bearing may be taken as:

$$\gamma_r = D_r \left( \frac{L}{h_{ri}} \right)^2 \frac{\theta_s}{n} \quad (14.7.5.3.3-6)$$

in which:

$$D_r = 0.5 \quad (14.7.5.3.3-7)$$

and, for a circular bearing:

$$\gamma_r = D_r \left( \frac{D}{h_{ri}} \right)^2 \frac{\theta_s}{n} \quad (14.7.5.3.3-8)$$

in which:

$$D_r = 0.375 \quad (14.7.5.3.3-9)$$

where:

$D$  = diameter of the bearing (in.)

$D_r$  = dimensionless coefficient used to determine shear strain due to rotation

$h_{ri}$  = thickness of  $i$ th internal elastomeric layer (in.)

$L$  = plan dimension of the bearing perpendicular to the axis of rotation under consideration (generally parallel to the global longitudinal bridge axis) (in.)

axis of the bridge. They were derived from procedures suggested by Stanton et al. (2007).  $D_a$  and  $D_r$  may alternatively be determined with Eqs. C14.7.5.3.3-1 through C14.7.5.3.3-6 about either primary orthogonal axis for rectangular bearings.

$$D_a = \max \left[ d_{a1}, \left( d_{a2} + d_{a3} \times \frac{L}{W} \right) \right] \quad (C14.7.5.3.3-1)$$

$$D_r = \frac{1.552 - 0.627\lambda}{2.233 + 0.156\lambda + \frac{L}{W}} \leq 0.5 \quad (C14.7.5.3.3-2)$$

in which:

$$d_{a1} = 1.06 + 0.210\lambda + 0.413\lambda^2 \quad (C14.7.5.3.3-3)$$

$$d_{a2} = 1.506 - 0.071\lambda + 0.406\lambda^2 \quad (C14.7.5.3.3-4)$$

$$d_{a3} = -0.315 + 0.195\lambda - 0.047\lambda^2 \quad (C14.7.5.3.3-5)$$

$$\lambda = S_i \sqrt{\frac{3G}{K}} \quad (C14.7.5.3.3-6)$$

where:

$K$  = bulk modulus (ksi)

$L$  = plan dimension of the bearing perpendicular to the axis of rotation under consideration (generally parallel to the global longitudinal bridge axis) (in.)

$W$  = plan dimension of the bearing parallel to the axis of rotation under consideration (generally parallel to the global transverse bridge axis) (in.)

$\lambda$  = compressibility index

In the absence of better information, the bulk modulus,  $K$ , may be taken as 450 ksi for all elastomers permissible under this specification for use in steel-reinforced elastomeric bearings.

The compressibility index,  $\lambda$ , represents the effect of finite bulk stiffness of the rubber. For conventional bearings it makes little difference, but in high shape factor bearings it reduces the stiffness below the value that would be computed using an incompressible model (i.e. with  $\lambda = 0$ ).

$n$  = number of interior layers of elastomer, where interior layers are defined as those layers which are bonded on each face. Exterior layers are defined as those layers which are bonded only on one face. When the thickness of the exterior layer of elastomer is equal to or greater than one-half the thickness of an interior layer, the parameter,  $n$ , may be increased by one-half for each such exterior layer.

$\theta_s$  = maximum static or cyclic service limit state design rotation angle of the elastomer specified in Article 14.4.2.1 (rad.)

The shear strain due to shear deformation of any bearing may be taken as:

$$\gamma_s = \frac{\Delta_s}{h_{rt}} \quad (14.7.5.3.3-10)$$

where:

$h_{rt}$  = total elastomer thickness (in.)

$\Delta_s$  = maximum total static or cyclic shear deformation of the elastomer from applicable service load combinations in Table 3.4.1-1 (in.)

In each case, the static and cyclic components of the shear strain shall be considered separately and then combined using Eq. 14.7.5.3.3-1.

In bearings with externally bonded steel plates on both top and bottom, the peak hydrostatic stress shall satisfy:

$$\sigma_{hyd} \leq 2.25G \quad (14.7.5.3.3-11)$$

in which:

$$\sigma_{hyd} = 3GS_i^3 \frac{\theta_s}{n} C_\alpha \quad (14.7.5.3.3-12)$$

$$C_\alpha = \frac{4}{3} \left[ \left( \alpha^2 + \frac{1}{3} \right)^{1.5} - \alpha(1-\alpha^2) \right] \quad (14.7.5.3.3-13)$$

$$\alpha = \frac{\varepsilon_a}{S_i} \frac{n}{\theta_s} \quad (14.7.5.3.3-14)$$

$$\varepsilon_a = \frac{\sigma_s}{3B_a GS_i^2} \quad (14.7.5.3.3-15)$$

for rectangular bearings:

Previous editions of these Specifications contained provisions to prevent net upward movement of any point on the bearing. Recent research (Stanton et al., 2007) has shown that, if the bearing is not equipped with bonded external plates, the sole plate can lift away from the bearing without causing any tension in the elastomer. Furthermore, the compression effects are slightly less severe than in a bearing that is identical except for the presence of bonded external plates, and is subjected to the same loading combination. Thus the "no-lift-off" provisions have been removed.

However, in a bearing equipped with external plates, upward movement of part of the plate can cause internal rupture due to hydrostatic tension. Provisions have been added to address this case. It is expected to control only rarely, and when it does, it is likely to do so during construction, when the axial load is light and the rotation, due to pre-camber, is large. For the construction load case, the cyclic components of the loading will be zero. For bearings with external plates, Eqs. 14.7.5.3.3-1 and 14.7.5.3.3-11 should be checked under all critical loading conditions, including construction, and about both strong and weak axes of rectangular bearings when necessary and appropriate.

$$B_a = 1.6 \quad (14.7.5.3.3-16)$$

and, for circular bearings:

$$B_a = 1.6 \quad (14.7.5.3.3-17)$$

where:

$B_a$  = dimensionless coefficient used to determine peak hydrostatic stress

$\varepsilon_a$  = total of static and cyclic average axial strain taken as positive for compression in which the cyclic component is multiplied by 1.75 from applicable service load combinations in Table 3.4.1-1 (ksi)

$\theta_s$  = total of static and cyclic maximum service limit state design rotation angles of the elastomer specified in Article 14.4.2.1 in which the cyclic component is multiplied by 1.75 (rad.)

$\sigma_s$  = total of static and cyclic average compressive stress in which the cyclic component is multiplied by 1.75 from applicable service load combinations in Table 3.4.1-1 (ksi)

For values of  $\alpha$  greater than one third, the hydrostatic stress is compressive, so Eq. 14.7.5.3.3-11 is satisfied automatically and no further evaluation is necessary.

#### 14.7.5.3.4—Stability of Elastomeric Bearings

Bearings shall be investigated for instability at the service limit state load combinations specified in Table 3.4.1-1.

Bearings satisfying Eq. 14.7.5.3.4-1 shall be considered stable, and no further investigation of stability is required.

$$2A \leq B \quad (14.7.5.3.4-1)$$

in which:

$$A = \frac{1.92 \frac{h_{rt}}{L}}{\sqrt{1 + \frac{2.0L}{W}}} \quad (14.7.5.3.4-2)$$

$$B = \frac{2.67}{(S_i + 2.0)\left(1 + \frac{L}{4.0W}\right)} \quad (14.7.5.3.4-3)$$

where:

$G$  = shear modulus of the elastomer (ksi)

$h_{rt}$  = total elastomer thickness (in.)

The constant 1.6 assigned to  $B_a$  for rectangular and circular bearings represents a simplified value for determining hydrostatic tension which is evaluated for rotation about an axis, which is parallel to the transverse axis of the bridge. It was derived from procedures suggested by Stanton et al. (2007).  $B_a$  for rectangular and circular bearings may alternatively be determined with Eqs. C14.7.5.3.3-7 or C14.7.5.3.3-8 about either primary orthogonal axis.

For rectangular bearings:

$$B_a = (2.31 - 1.86\lambda) + (-0.90 + 0.96\lambda) \times \left[1 - \min\left(\frac{L}{W}, \frac{W}{L}\right)\right]^2 \quad (C14.7.5.3.3-7)$$

and, for circular bearings:

$$B_a = \frac{2}{1 + 2\lambda^2} \quad (C14.7.5.3.3-8)$$

Tests have shown that sharp edges on the internal steel reinforcement layers cause stress concentrations in the elastomer and promote the onset of debonding. The internal steel reinforcement layers should be deburred or otherwise rounded prior to molding the bearing. The design values in Eq. 14.7.5.3.3-1 are consistent with this procedure.

#### C14.7.5.3.4

The average compressive stress is limited to half the predicted buckling stress. The latter is calculated using the buckling theory developed by Gent, modified to account for changes in geometry during compression, and calibrated against experimental results (Gent, 1964; Stanton et al., 1990). This provision will permit taller bearings and reduced shear forces compared to those permitted under previous editions of the AASHTO Standard Specifications.

Eq. 14.7.5.3.4-4 corresponds to buckling in a sidesway mode and is relevant for bridges in which the deck is not rigidly fixed against horizontal translation at any point. This may be the case in many bridges for transverse translation perpendicular to the longitudinal axis. If one point on the bridge is fixed against horizontal movement, the sidesway buckling mode is not possible, and Eq. 14.7.5.3.4-5 should be used. This freedom to move horizontally should be distinguished from the question of whether the bearing is subject to shear deformations relevant to Articles 14.7.5.3.2 and 14.7.5.3.3. In a bridge that is fixed at one end, the bearings at the other end will be subjected to imposed shear deformation but will not be free to translate in the sense relevant to buckling due to the restraint at the opposite end of the bridge.

$L$  = plan dimension of the bearing perpendicular to the axis of rotation under consideration (generally parallel to the global longitudinal bridge axis) (in.)

$S_i$  = shape factor of the  $i$ th internal layer of an elastomeric bearing

$W$  = plan dimension of the bearing parallel to the axis of rotation under consideration (generally parallel to the global transverse bridge axis) (in.)

For a rectangular bearing where  $L$  is greater than  $W$ , stability shall be investigated by interchanging  $L$  and  $W$  in Eqs. 14.7.5.3.4-2 and 14.7.5.3.4-3.

For circular bearings, stability may be investigated by using the equations for a square bearing with  $W = L = 0.8D$ .

For rectangular bearings not satisfying Eq. 14.7.5.3.4-1, the stress due to the total load shall satisfy Eq. 14.7.5.3.4-4 or 14.7.5.3.4-5.

- If the bridge deck is free to translate horizontally:

$$\sigma_s \leq \frac{GS_i}{2A - B} \quad (14.7.5.3.4-4)$$

- If the bridge deck is fixed against horizontal translation:

$$\sigma_s \leq \frac{GS_i}{A - B} \quad (14.7.5.3.4-5)$$

#### 14.7.5.3.5—Reinforcement

The minimum thickness of steel reinforcement,  $h_s$ , shall be .0625 in., as specified in Article 4.5 of AASHTO M 251.

The thickness of the steel reinforcement,  $h_s$ , shall satisfy:

- At the service limit state:

$$h_s \geq \frac{3h_{ri}\sigma_s}{F_y} \quad (14.7.5.3.5-1)$$

- At the fatigue limit state:

$$h_s \geq \frac{2h_{ri}\sigma_L}{\Delta F_{TH}} \quad (14.7.5.3.5-2)$$

where:

$\Delta F_{TH}$  = constant amplitude fatigue threshold for Category A as specified in Article 6.6 (ksi)

$h_{ri}$  = thickness of  $i$ th internal elastomeric layer (in.)

A negative or infinite limit from Eq. 14.7.5.3.4-5 indicates that the bearing is stable and is not dependent on  $\sigma_s$ .

If the value  $A - B \leq 0$ , the bearing is stable and is not dependent on  $\sigma_s$ .

#### C14.7.5.3.5

The reinforcement should sustain the tensile stresses induced by compression of the bearing. With the present load limitations, the minimum steel plate thickness practical for fabrication will usually provide adequate strength.

$\sigma_L$  = average compressive stress at the service limit state (load factor = 1.0) due to live load (ksi)

$\sigma_s$  = average compressive stress due to total load from applicable service load combinations in Table 3.4.1-1 (ksi)

$F_y$  = yield strength of steel reinforcement (ksi)

If holes exist in the reinforcement, the minimum thickness shall be increased by a factor equal to twice the gross width divided by the net width.

#### 14.7.5.3.6—Compressive Deflection

Deflections of elastomeric bearings due to dead load and to instantaneous live load alone shall be considered separately.

Loadings considered in this Article shall be at the service limit state with all load factors equal to 1.0.

Instantaneous live load deflection shall be taken as:

$$\delta_L = \sum \varepsilon_{Li} h_{ri} \quad (14.7.5.3.6-1)$$

where:

$\varepsilon_{Li}$  = instantaneous live load compressive strain in  $i$ th elastomer layer

$h_{ri}$  = thickness of  $i$ th elastomeric layer (in.)

Initial dead load deflection shall be taken as:

$$\delta_d = \sum \varepsilon_{di} h_{ri} \quad (14.7.5.3.6-2)$$

where:

$\varepsilon_{di}$  = initial dead load compressive strain in  $i$ th elastomer layer

$h_{ri}$  = thickness of  $i$ th elastomeric layer (in.)

Long-term dead load deflection, including the effects of creep, shall be taken as:

$$\delta_{lt} = \delta_d + a_{cr} \delta_d \quad (14.7.5.3.6-3)$$

where:

$a_{cr}$  = creep deflection divided by initial dead load deflection

Values for  $\varepsilon_{Li}$  and  $\varepsilon_{di}$  shall be determined from test results or by analysis. Creep effects should be determined from information relevant to the elastomeric compound used. If the engineer does not elect to obtain a value for the ratio,  $a_{cr}$ , from test results using Annex A2 of AASHTO M 251, the values given in Table 14.7.6.2-1 may be used.

Holes in the reinforcement cause stress concentrations. Their use should be discouraged. The required increase in steel thickness accounts for both the material removed and the stress concentrations around the hole.

#### C14.7.5.3.6

Limiting instantaneous live load deflections is important to ensure that deck joints and seals are not damaged. Furthermore, bearings that are too flexible in compression could cause a small step in the road surface at a deck joint when traffic passes from one girder to the other, giving rise to additional impact loading. A maximum relative live load deflection across a joint of 0.125 in. is suggested. Joints and seals that are sensitive to relative deflections may require limits that are tighter than this.

Long-term dead load deflections should be considered where joints and seals between sections of the bridge rest on bearings of different design and when estimating redistribution of forces in continuous bridges caused by settlement.

Laminated elastomeric bearings have a nonlinear load deflection curve in compression. In the absence of information specific to the particular elastomer to be used, Eq. C14.7.5.3.6-1 or Figure C14.7.6.3.3-1 may be used as a guide for calculating dead and live load compressive strains for Eqs. 14.7.5.3.6-1 and 14.7.5.3.6-2.

$$\varepsilon = \frac{\sigma}{6GS^2} \quad (C14.7.5.3.6-1)$$

where:

$\sigma$  = instantaneous live load compressive stress or dead load compressive stress in an individual elastomer layer (ksi)

$S$  = shape factor of an individual elastomer layer

$G$  = shear modulus of the elastomer (ksi)

Eq. C14.7.5.3.6-1 or Figure C14.7.6.3.3-1 may also be used as a guide for specifying an allowable value of compressive strain at the design dead plus live service limit state compressive load when employing Section 8.8.1 of AASHTO M 251.

Guidance for specifying an allowable value for creep when Annex A2 of AASHTO M 251 is employed may be obtained from NCHRP Report 449 or from Table 14.7.6.2-1.

Reliable test data on total deflections are rare because of the difficulties in defining the baseline for deflection. However, the change in deflection due to live load can be reliably predicted either by design aids based on test results or by using theoretically based equations (Stanton and Roeder, 1982). In the latter case, it is important to include the effects of bulk compressibility of the elastomer, especially for high-shape factor bearings.

#### 14.7.5.3.7—Seismic and Other Extreme Event Provisions

Elastomeric expansion bearings shall be provided with adequate seismic and other extreme event resistant anchorage to resist the horizontal forces in excess of those accommodated by shear in the pad unless the bearing is intended to act as a fuse or irreparable damage is permitted. The sole plate and the base plate shall be made wider to accommodate the anchor bolts. Inserts through the elastomer should not be allowed, unless approved by the Engineer. The anchor bolts shall be designed for the combined effect of bending and shear for seismic and other extreme event loads as specified in Article 14.6.5.3. Elastomeric fixed bearings shall be provided with horizontal restraint adequate for the full horizontal load.

#### 14.7.5.4—Anchorage for Bearings without Bonded External Plates

In bearings without externally bonded steel plates, a restraint system shall be used to secure the bearing against horizontal movement if:

$$\frac{\theta_s}{n} \geq \frac{3\epsilon_a}{S_i} \quad (14.7.5.4-1)$$

where:

$n$  = number of interior layers of elastomer, where interior layers are defined as those layers which are bonded on each face. Exterior layers are defined as those layers which are bonded only on one face. When the thickness of the exterior layer of elastomer is equal to or greater than one-half the thickness of an interior layer, the parameter,  $n$ , may be increased by one-half for each such exterior layer.

$S_i$  = shape factor of the  $i$ th internal layer of an elastomeric bearing

$\epsilon_a$  = total of static and cyclic average axial strain taken as positive for compression in which the cyclic component is multiplied by 1.75 from applicable service load combinations in Table 3.4.1-1 (ksi)

#### C14.7.5.3.7

The seismic and other extreme event demands on elastomeric bearings exceed their design limits. Therefore, positive connection between the girder and the substructure concrete is needed. If the bearing is intended to act as a fuse or irreparable damage is permitted, the positive connection need not be designed for the maximum extreme event limit state forces.

Holes in elastomer cause stress concentrations that can lead to tearing of the elastomer during earthquakes.

$\theta_s$  = total of static and cyclic maximum service limit state design rotation angles of the elastomer specified in Article 14.4.2.1 in which the cyclic component is multiplied by 1.75 (rad.)

#### 14.7.6—Elastomeric Pads and Steel-Reinforced Elastomeric Bearings—Method A

##### 14.7.6.1—General

The provisions of this Article shall be taken to apply to the design of:

- Plain elastomeric pads, PEP;
- Pads reinforced with discrete layers of fiberglass, FGP;
- Steel-reinforced elastomeric bearings in which  $S_i^2/n < 22$ , and for which the primary rotation is about the axis parallel to the transverse axis of the bridge; and
- Cotton-duck pads (CDP) with closely spaced layers of cotton duck and manufactured and tested under compression in accordance with Military Specification MIL-C-882E except where superseded by these Specifications.

where:

$n$  = number of interior layers of elastomer, where interior layers are defined as those layers which are bonded on each face. Exterior layers are defined as those layers which are bonded only on one face. When the thickness of the exterior layer of elastomer is equal to or greater than one-half the thickness of an interior layer, the parameter,  $n$ , may be increased by one-half for each such exterior layer.

$S_i$  = shape factor of the  $i$ th internal layer of an elastomeric bearing

Layer thicknesses in FGP may be different from one another. For steel-reinforced elastomeric bearings designed in accordance with the provisions of this Section, internal layers shall be of the same thickness, and cover layers shall be no more than 70 percent of the thickness of internal layers.

The shape factor for PEP, FGP pads and steel-reinforced elastomeric bearings covered by this Article shall be determined as specified in Article 14.7.5.1. The shape factor for CDP shall be based upon the total pad thickness.

##### C14.7.6.1

Elastomeric pads have characteristics different from those of steel-reinforced elastomeric bearings. Plain elastomeric pads are weaker and more flexible because they are restrained from bulging by friction alone (Roeder and Stanton, 1986, 1983). Slip inevitably occurs, especially under dynamic loads, causing larger compressive deflections and higher internal strains in the elastomer.

A limiting value of 20 for  $S_i^2/n$  should be considered when the value of  $n$  is equal to or greater than 3.

In pads reinforced with layers of fiberglass, the reinforcement inhibits the deformations found in plain pads. However, elastomers bond less well to fiberglass, and the fiberglass is weaker than steel, so the fiberglass pad is unable to carry the same loads as a steel-reinforced bearing (Crozier et al., 1979). FGP has the advantage that it can be cut to size from a large sheet of vulcanized material.

CDP are preformed pads that are produced in large sheets and cut to size for specific bridge applications. CDP are reinforced with closely spaced layers of cotton-duck and typically display high compressive stiffness and strength, obtained by the use of very thin elastomeric layers. However, the thin layers also give rise to very high shear and rotational stiffness, which could easily lead to edge loading and a higher shear stiffness than that to be found in layered bearings. These increased shear and rotational stiffnesses lead to larger moments and forces in the bridge and reduced movement and rotational capacity of the bearing pad. As a consequence, CDP is often used with a PTFE slider on top of the elastomer pad (Nordlin et al., 1970).

It is essential that CDP bearing pads be tested and verified to meet the test requirements of Military Specification MIL-C-882E which can be found at: <http://assist.daps.dla.mil>. Note that there is no AASHTO equivalent to this Military Specification. A summary of testing and acceptance criteria for CDP is given below.

These criteria require that:

- A lot of preformed CDP be defined as a single sheet that is continuously formed to a given thickness except that a single lot not exceed 2500 lbs of material;
- A minimum of two samples from each lot shall be tested;
- The samples be 2 in.  $\times$  2 in. with the full sheet thickness;
- The test specimens be cured for four hours at room temperature ( $70^{\circ}\text{F} \pm 10^{\circ}\text{F}$ );
- Each specimen is then to be loaded in compression, perpendicular to the direction of lamination;
- The origin of deflection and compressive strain measurements be taken at a compressive stress of 5 psi;
- The load be increased at a steady rate of 500 lbs/ min. and the deflection be recorded;
- The specimen be loaded to a compressive stress of 10,000 psi without fracture or other failure; and
- The entire lot of CDP be rejected if any of the CDP specimens fail to satisfy either of these test criteria: The average compressive strain of the specimens for that lot is not to be less than 0.075 in./in. nor shall it be greater than 0.175 in./in. at an average compressive stress of 2,000 psi. CDP bearing pads which fail to achieve the 10,000 psi stress limit here fall outside the specified strain range and will not develop the deformation limits permitted in later parts of Article 14.7.

#### 14.7.6.2—Material Properties

The elastomeric-type materials for PEP, FGP, and steel-reinforced elastomeric bearings shall satisfy the requirements of Article 14.7.5.2. In addition, hardness on the Shore A scale may be used as a basis for specification of bearing material. The specified shear modulus shall be between 0.080 ksi and 0.250 ksi, and the nominal hardness shall be between 50 and 70 on the Shore A scale and shall conform to the requirements of Section 18.2 of the *AASHTO LRFD Bridge Construction Specifications* and AASHTO M 251. If the material is specified by its hardness, the shear modulus for design purposes shall be taken as the least favorable value from the range for that hardness given in Table 14.7.6.2-1. Intermediate values may be obtained by interpolation. If the material is specified by shear modulus, it

#### C14.7.6.2

The elastomer requirements for PEP and FGP are the same as those required for steel-reinforced elastomeric bearings. The ranges given in Table 14.7.6.2-1 represent the variations found in practice. If the material is specified by hardness, a safe and presumably different estimate of  $G$  should be taken for each of the design calculations, depending on whether the parameter being calculated is conservatively estimated by over- or under-estimating the shear modulus. Creep varies from one compound to another and is generally more prevalent in harder elastomers or those with a higher shear modulus but is seldom a problem if high-quality materials are used. This is particularly true because the deflection limits are based on serviceability and are likely to be controlled by live

shall be taken for design purposes as the least favorable from the value specified according to the ranges given in Article 14.7.5.2. Other properties, such as creep deflection, are also given in Table 14.7.6.2-1. There is an exception for steel-reinforced elastomeric bearings designed in accordance with the provisions of this Section. The elastomer shall have a specified shear modulus between 0.080 and 0.175 ksi, and a nominal hardness between 50 and 60 on the Shore A scale.

The shear force on the structure induced by deformation of the elastomer in PEP, FGP and steel-reinforced elastomeric bearings shall be based on a  $G$  value not less than that of the elastomer at 73°F. Effects of relaxation shall be ignored.

CDP shall be manufactured to Military Standards MIL-C-882E except where the provisions of these Specifications supersede those provisions. The elastomeric-type materials for CDP shall have a nominal hardness between 50 and 70 on the Shore A scale and meet the requirements of Article 14.7.5.2 as appropriate. The finished CDP shall have a nominal hardness between 85 and 95 on the Shore A scale. The shear modulus for CDP may be estimated using Eq. 14.7.6.3.4-3. The cotton-duck reinforcement shall be either a two-ply cotton yarn or a single-ply 50-50 blend cotton-polyester. The fabric shall have a minimum tensile strength of 150 lb./in. width when tested by the grab method. The fill shall be  $40 \pm 2$  threads per in., and the warp shall be  $50 \pm 1$  threads per in. The CDP provisions included herein shall be taken as only applicable to bearing pads up to 2 in. in total thickness.

load, rather than total load. The creep values given in Table 14.7.6.2-1 are representative of neoprene and are conservative for natural rubber.

CDP is made of elastomers with hardness and properties similar to that used for PEP and FGP. However, the closely spaced layers of duck fabric reduce the indentation and increase the hardness of the finished pad to the 85 to 95 durometer range. Appendix X1 of AASHTO M 251 contains provisions for hardness of elastomers, but not finished CDP. The acceptable range from the specified value for hardness of elastomers is  $\pm 5$  points on the Shore A scale. The acceptable range criteria for elastomers in AASHTO M 251 may also be considered for finished CDP. The cotton-duck requirements are restated from the military specification because the reinforcement is essential to the good performance of these pads.

**Table 14.7.6.2-1—Correlated Material Properties**

	Hardness (Shore A)		
	50	60	70 <sup>1</sup>
Shear Modulus @ 73°F (ksi)	0.095–0.130	0.130–0.200	0.200–0.300
Creep deflection @ 25 yr divided by initial deflection	0.25	0.35	0.45

<sup>1</sup> For PEP and FGP only.

### 14.7.6.3—Design Requirements

#### 14.7.6.3.1—Scope

Steel-reinforced elastomeric bearings may be designed in accordance with this Article, in which case they qualify for the test requirements appropriate for elastomeric pads. For this purpose, they shall be treated as FGP.

The provisions for FGP apply only to pads where the fiberglass is placed in double layers 0.125 in. apart.

The physical properties of neoprene and natural rubber used in these bearings shall conform to AASHTO M 251.

#### CI4.7.6.3.1

The design methods for elastomeric pads are simpler and more conservative than those for steel-reinforced bearings, so the test methods are less stringent than those of Article 14.7.5. Steel-reinforced elastomeric bearings may be made eligible for these less stringent testing procedures by limiting the compressive stress as specified in Article 14.7.6.3.2.

The three types of pad, PEP, FGP, and CDP behave differently, so information relevant to the particular type of pad should be used for design. For example, in PEP, slip at the interface between the elastomer and the material on which it is seated or loaded is dependent on the friction coefficient, and this will be different for pads seated on concrete, steel, grout, epoxy, etc.

## 14.7.6.3.2—Compressive Stress

At the service limit state, the average compressive stresses,  $\sigma_s$  and  $\sigma_L$ , in any layer shall satisfy:

- For PEP:

$$\sigma_s \leq 0.80 \text{ ksi} \quad (14.7.6.3.2-1)$$

- For FGP:

$$\sigma_s \leq 1.00GS_i \text{ and} \quad (14.7.6.3.2-2)$$

$$\sigma_s \leq 0.80 \text{ ksi} \quad (14.7.6.3.2-3)$$

- For CDP:

$$\sigma_s \leq 3.0 \text{ ksi} \quad (14.7.6.3.2-4)$$

$$\sigma_s \leq 2.0 \text{ ksi} \quad (14.7.6.3.2-5)$$

where:

$\sigma_s$  = average compressive stress due to total load from applicable service load combinations in Table 3.4.1-1 (ksi)

$\sigma_L$  = average compressive stress at the service limit state (load factor = 1.0) due to live load (ksi)

In FGP, the value of  $S_i$  used shall be based upon an  $h_{ri}$  layer thickness that equals the greatest distance between midpoints of two double fiberglass reinforcement layers.

For steel-reinforced elastomeric bearings designed in accordance with the provisions of this Article:

$$\sigma_s \leq 1.25GS_i \text{ and} \quad (14.7.6.3.2-6)$$

$$\sigma_s \leq 1.25 \text{ ksi} \quad (14.7.6.3.2-7)$$

where the value of  $S_i$  used shall be that of an internal layer of the bearing.

These stress limits may be increased by ten percent where shear deformation is prevented.

## 14.7.6.3.3—Compressive Deflection

In addition to the provisions of Article 14.7.5.3.6, the following shall also apply.

In lieu of using specific product data, the compressive deflection of a FGP should be taken as 1.5 times the deflection estimated for steel-reinforced bearings of the same shape factor in Article 14.7.5.3.6.

The initial compressive deflection of a PEP or an internal layer of a steel-reinforced elastomeric bearing at

## C14.7.6.3.2

In FGP, the compressive stress is limited to  $G$  times the effective shape factor. Both PEP and FGP are limited to 800 psi for all circumstances, but this upper bound stress limit can be achieved with a thicker rubber layer with FGP.

The CDP stress limits were developed to provide long term serviceability and durability. CDP stiffness and behavior is less sensitive to shape factor. The total maximum compressive stress is limited to 3.0 ksi because experiments showed that CDP does not fail under monotonically compressive stress values significantly larger than this stress limit. CDP, which is subject to compressive stress levels larger than 3.0 ksi, may delaminate under dynamic loadings typical of those experienced by bridge bearings. CDP may experience dramatic failure when maximum compressive strains exceed approximately 0.25. However, bearing pads which meet the strain and stiffness limits which are required by the military specification will not achieve this failure strain under pure compressive load.

The live load stresses are limited to 2.0 ksi, because research shows that delamination is caused by the compressive stress range as well as the maximum compressive level. Live loads control the maximum compressive stress range under repeated loading, and this limit controls the adverse effects of this delamination. Larger compressive strains would result in increased damage to the bridge and the bearing pad and reduced serviceability of the CDP (Lehman et al., 2003).

The reduced stress limit for steel-reinforced elastomeric bearings designed in accordance with these provisions is invoked in order to allow these bearings to be eligible for the less stringent test requirements for elastomeric pads.

## C14.7.6.3.3

The compressive deflection with PEP, FGP, and CDP will be larger and more variable than those of steel-reinforced elastomeric bearings. Appropriate data for these pad types may be used to estimate their deflections. In the absence of such data, the compressive deflection of a PEP and FGP may be estimated at 3 and 1.5 times, respectively, the deflection estimated for steel-reinforced bearings of the same shape factor in Article 14.7.5.3.6.

the service limit state without impact shall not exceed  $0.07h_{ri}$ , where  $h_{ri}$  is the thickness of a PEP (in.) or the thickness of an internal layer of a steel-reinforced elastomeric bearing (in.).

Figure C14.7.6.3.3-1 provides design aids for determining the strain in an elastomer layer for steel reinforced bearings based upon durometer hardness and shape factor.

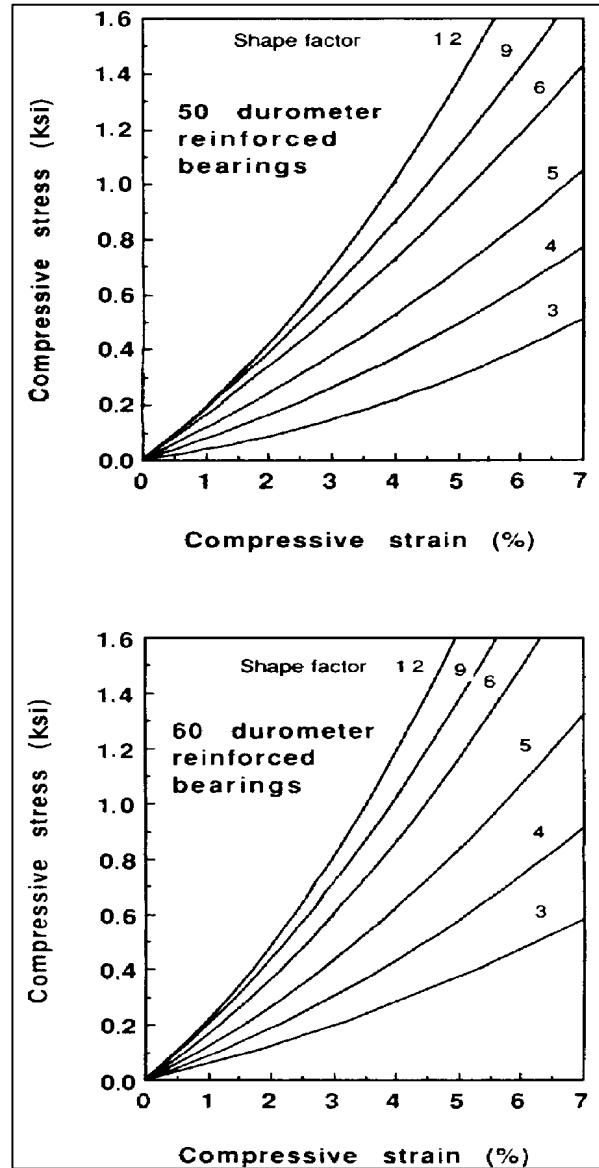

Figure C14.7.6.3.3-1—Stress-Strain Curves

For CDP, the computed compressive strain,  $\varepsilon_s$ , may be taken as:

$$\varepsilon_s = \frac{\sigma_s}{E_c} \quad (14.7.6.3.3-1)$$

where:

$E_c$  = uniaxial compressive stiffness of the CDP bearing pad. It may be taken as 30 ksi in lieu of pad-specific test data (ksi)

CDP is typically very stiff in compression. The shape factor may be computed, but it has a different meaning and less significance to the compressive deflection than it does for FGP and PEP (Roeder et al., 2000). As a result, the maximum compressive deflection for CDP can be based upon an average compressive strain,  $\varepsilon_s$ , for the total bearing pad thickness as computed in Eq. 14.7.6.3.3-1.

$\sigma_s$  = average compressive stress due to total load from applicable service load combinations in Table 3.4.1-1 (ksi)

#### 14.7.6.3.4—Shear

The maximum horizontal superstructure displacement shall be computed in accordance with Article 14.4. The maximum shear deformation of the pad at the service limit state,  $\Delta_s$ , shall be taken as the maximum horizontal superstructure displacement, reduced to account for the pier flexibility and modified for construction procedures. If a low friction sliding surface is used,  $\Delta_s$  need not be taken to be larger than the deformation corresponding to first slip.

The provisions of Article 14.7.5.3.2 shall apply, except that the pad shall be designed as follows:

- For PEP, FGP and steel-reinforced elastomeric bearings:

$$h_r \geq 2\Delta_s \quad (14.7.6.3.4-1)$$

- For CDP:

$$h_r \geq 10\Delta_s \quad (14.7.6.3.4-2)$$

where:

$h_r$  = smaller of total elastomer or bearing thickness (in.)

$\Delta_s$  = maximum total shear deformation of the bearing from applicable service load combinations in Table 3.4.1-1 (in.)

The shear modulus,  $G$ , for CDP for determination of the bearing force in Article 14.6.3.1 may be conservatively estimated as:

$$G = 2\sigma_s \geq 2.0 \text{ ksi} \quad (14.7.6.3.4-3)$$

where:

$\sigma_s$  = average compressive stress due to total load from applicable service load combinations in Table 3.4.1-1 (ksi)

#### 14.7.6.3.5—Rotation

##### 14.7.6.3.5a—General

The provisions of these Articles shall apply at the service limit state. Rotations shall be taken as the maximum sum of the effects of initial lack of parallelism and subsequent girder end rotation due to imposed loads and movements. Stress shall be the maximum stress associated with the load conditions inducing the maximum rotation.

#### C14.7.6.3.4

The deformation in PEP and FGP are limited to  $\pm 0.5 h_r$  because these movements are the maximum tolerable for repeated and long-term strains in the elastomer. These limits are intended to ensure serviceable bearings with no deterioration of performance and they limit the forces that the pad transmits to the structure.

In CDP, the shear deflection is limited to only one-tenth of the total elastomer thickness. There are several reasons for this limitation. First, experiments show that CDP may split and crack at larger shear strains. Second, CDP has much larger shear stiffness than that noted with steel-reinforced elastomeric bearings, PEP and FGP, and so the strain limit assures that CDP pads do not cause dramatically larger bearing forces to the structure than do other bearing systems. Third, the greater shear stiffness means that relative slip between the CDP and the bridge girders is likely if the deformation required of the bearing is too large. Slip may lead to abrasion and deterioration of the pads, as well as other serviceability concerns. Slip may also lead to increased costs because of anchorage and other requirements. Finally, CDP pads are harder than PEP and FGP, and so they are very suitable for the addition of PTFE sliding surfaces to accommodate the required bridge movements. As a result, CDP with large translational movements is invariably designed with PTFE sliding surfaces.

#### C14.7.6.3.5a

Rotation of steel-reinforced elastomeric bearings and elastomeric pads is controlled by preventing uplift between the bearing and the structure and by limiting the shear strains in the elastomer.

Initial lack of parallelism is due to profile grade, dead load deflection, etc. The designer may account for the initial lack of parallelism by providing tapered plates or other means.

## 14.7.6.3.5b—Rotation of PEP

- Rectangular pads shall satisfy:

$$\sigma_s \geq 0.5GS\left(\frac{L}{h_{rt}}\right)^2\theta_{s,x} \text{ and} \quad (14.7.6.3.5b-1)$$

$$\sigma_s \geq 0.5GS\left(\frac{W}{h_{rt}}\right)^2\theta_{s,z} \quad (14.7.6.3.5b-2)$$

- Circular pads shall satisfy:

$$\sigma_s \geq 0.375GS\left(\frac{D}{h_{rt}}\right)^2\theta_s \quad (14.7.6.3.5b-3)$$

where:

$\sigma_s$  = average compressive stress due to total load associated with the maximum rotation from applicable service load combinations in Table 3.4.1-1 (ksi)

$G$  = shear modulus of the elastomer (ksi)

$S$  = shape factor of PEP

$L$  = plan dimension of the bearing perpendicular to the axis of rotation under consideration (generally parallel to the global longitudinal bridge axis) (in.)

$h_{rt}$  = total elastomer thickness (in.)

$W$  = plan dimension of the bearing parallel to the axis of rotation under consideration (generally parallel to the global transverse bridge axis) (in.)

$D$  = diameter of pad (in.)

$\theta_s$  = maximum service limit state design rotation angle about any axis of the pad specified in Article 14.4.2.1 (rad.)

$\theta_{s,x}$  = maximum service limit state design rotation angle specified in Article 14.4.2.1 about transverse axis (generally parallel to the global transverse bridge axis) (rad.)

$\theta_{s,z}$  = maximum service limit state design rotation angle specified in Article 14.4.2.1 about longitudinal axis (generally parallel to the global longitudinal bridge axis) (rad.)

## C14.7.6.3.5b

PEP, FGP, and steel-reinforced elastomeric bearings are quite flexible in compressive loading, and as a consequence very large strains are tolerated, but stresses are kept quite low in Article 14.7.6.3.2. As a consequence, PEP, FGP, and steel-reinforced elastomeric bearings are checked for uplift only, and the equations provided in this Article provide a lower bound stress limit to assure that uplift conditions are met.

Total load shall be construed to be all contributing loads beyond parallelism.

14.7.6.3.5c—*Rotation of CDP*

The maximum compressive strain due to combined compression and rotation of CDP at the service limit state,  $\varepsilon_t$ , shall not exceed:

$$\varepsilon_t = \varepsilon_c + \frac{\theta_s L}{2t_p} < 0.20 \quad (14.7.6.3.5c-1)$$

where:

$$\varepsilon_c = \frac{\sigma_s}{E_c} \quad (14.7.6.3.5c-2)$$

Maximum rotation shall be limited to:

$$\theta_s \leq 0.80 \frac{2t_p \varepsilon_c}{L} \text{ and} \quad (14.7.6.3.5c-3)$$

$$\theta_L \leq 0.20 \frac{2t_p \varepsilon_c}{L} \quad (14.7.6.3.5c-4)$$

where:

$E_c$  = uniaxial compressive stiffness of the CDP bearing pad. It may be taken as 30 ksi in lieu of pad-specific test data

$L$  = length of a CDP bearing pad in the plane of rotation (in.)

$t_p$  = total thickness of CDP pad (in.)

$\varepsilon_c$  = maximum uniaxial strain due to compression under total load from applicable service load combinations in Table 3.4.1-1

$\varepsilon_t$  = maximum uniaxial strain due to combined compression and rotation from applicable service load combinations in Table 3.4.1-1

$\sigma_s$  = average compressive stress due to total load associated with the maximum rotation from applicable service load combinations in Table 3.4.1-1 (ksi)

$\theta_L$  = maximum rotation of the CDP pad at the service limit state (load factor = 1.0) due to live load (rad.)

$\theta_s$  = maximum rotation of the CDP pad from the applicable service load combinations in Table 3.4.1-1 (rad.)

## C14.7.6.3.5c

Rotation, and combined compression and rotation of CDP are controlled by shear strain limits and delamination requirements. Experiments show that CDP that meets the testing requirements of MIL-C-882E will not fracture or fail until a combined compressive strain exceeds 0.25. Creep strains do not contribute to this fracture potential. Design Eq. 14.7.6.3.5c-1 limits this compressive strain to 0.20, because the design is made with service loads, and research shows that the 0.20 strain limit is sufficiently far from the average failure strain to assure a  $\beta$  factor of 3.5 for LRFD design. Delamination due to rotation is associated with uplift or separation between the bearing pad and the load surface. Delamination does not result in a fracture or immediate failure of the bearing pad, but it results in a significant reduction in the bearing service life. Cyclic rotation associated with live loads represents the more severe delamination problem, and Eq. 14.7.6.3.5c-4 provides this design limit. However, research also shows that delamination is also influenced by maximum rotation level. CDP do not recover all of their compressive deformation after unloading, and Eq. 14.7.6.3.5c-3 recognizes approximately 20 percent residual compressive strain and limits uplift due to the maximum rotation in recognition of the delamination potential. Shear strains of the elastomer are a less meaningful measure for CDP than for steel reinforced elastomeric bearings, because shape factor has a different meaning for CDP than for other elastomeric bearing types. CDP is known to have relatively large compressive load capacity, and it is generally accepted that it can tolerate relatively large compressive strains associated with these loads. It should be noted that these compressive strains in CDP are larger than those tolerated in steel reinforced bearings, but they have been justified by experimental results for CDP that meets the requirements of these Specifications. This does not suggest that CDP is generally superior to steel reinforced elastomeric bearings. A well designed steel-reinforced bearing is likely to provide superior long-term performance, but CDP can be designed and manufactured quickly and may provide good performance under a range of conditions.

*14.7.6.3.5d—Rotation of FGP and Steel  
Reinforced Elastomeric Bearings*

*C14.7.6.3.5d*

- Rectangular pads or bearings shall satisfy:

Refer to Article C14.7.6.3.5b.

$$\sigma_s \geq 0.5GS_i \left( \frac{L}{h_{ri}} \right)^2 \frac{\theta_{s,x}}{n} \quad (14.7.6.3.5d-1)$$

$$\sigma_s \geq 0.5GS_i \left( \frac{W}{h_{ri}} \right)^2 \frac{\theta_{s,z}}{n} \quad (14.7.6.3.5d-2)$$

- Circular pads or bearings shall satisfy:

$$\sigma_s \geq 0.375GS_i \left( \frac{D}{h_{ri}} \right)^2 \frac{\theta_s}{n} \quad (14.7.6.3.5d-3)$$

where:

$\sigma_s$  = average compressive stress due to total load associated with the maximum rotation from applicable service load combinations in Table 3.4.1-1 (ksi)

$G$  = shear modulus of the elastomer (ksi)

$S_i$  = shape factor of the  $i$ th internal layer of a steel-reinforced elastomeric bearing, or the layer defined by the greatest distance between midpoints of the double reinforcement layers of an FGP

$L$  = plan dimension of the bearing perpendicular to the axis of rotation under consideration (generally parallel to the global longitudinal bridge axis) (in.)

$h_{ri}$  = thickness of  $i$ th internal elastomeric layer for a steel-reinforced elastomeric bearing, and the greatest distance between midpoints of the double reinforcement layers for an FGP (in.)

$n$  = number of interior layers of elastomer, where interior layers are defined as those layers which are bonded on each face. Exterior layers are defined as those layers which are bonded only on one face. When the thickness of the exterior layer of elastomer is equal to or greater than one-half the thickness of an interior layer, the parameter,  $n$ , may be increased by one-half for each such exterior layer.

$W$  = plan dimension of the bearing parallel to the axis of rotation under consideration (generally parallel to the global transverse bridge axis) (in.)

$D$  = diameter of pad (in.)

$\theta_s$  = maximum service limit state design rotation angle about any axis of the pad specified in Article 14.4.2.1 (rad.)

$\theta_{s,x}$  = maximum service limit state design rotation angle specified in Article 14.4.2.1 about transverse axis (generally parallel to the global transverse bridge axis) (rad.)

$\theta_{s,z}$  = maximum service limit state design rotation angle specified in Article 14.4.2.1 about longitudinal axis (generally parallel to the global longitudinal bridge axis) (rad.)

#### 14.7.6.3.6—*Stability*

To ensure stability, the total thickness of the pad shall not exceed the least of  $L/3$ ,  $W/3$ , or  $D/4$ .

#### C14.7.6.3.6

The stability provisions in this Article are unlikely to have a significant impact upon the design of PEP, since a plain pad which has this geometry would have such a low allowable stress limit that the design would be uneconomical.

The buckling behavior of FGP and CDP is complicated because the mechanics of their behavior is not well understood. The reinforcement layers lack the stiffness of the reinforcement layers in steel-reinforced bearings and so stability theories developed for steel-reinforced bearings do not apply to CDP or FGP. The geometric limits included here are simple and conservative.

#### 14.7.6.3.7—*Reinforcement*

The reinforcement in FGP shall be fiberglass with a strength in each plan direction of at least  $2.2 h_{ri}$  in kip/in. For the purpose of this Article, if the layers of elastomer are of different thicknesses,  $h_{ri}$  shall be taken as the mean thickness of the two layers of the elastomer bonded to the same reinforcement. If the fiberglass reinforcement contains holes, its strength shall be increased over the minimum value specified herein by twice the gross width divided by net width.

Reinforcement for steel-reinforced elastomeric bearings designed in accordance with the provisions of this Article shall conform to the requirements of Article 14.7.5.3.5.

#### C14.7.6.3.7

The reinforcement should be strong enough to sustain the stresses induced in it when the bearing is loaded in compression. For a given compression, thicker elastomer layers lead to higher tension stresses in the reinforcement. It should be possible to relate the minimum reinforcement strength to the compressive stress that is allowed in the bearing in Article 14.7.6.3.2. The relationship has been quantified for FGP. For PEP and CDP, successful past experience is the only guide currently available.

For steel-reinforced elastomeric bearings designed in accordance with the provisions of Article 14.7.6, the equations from Article 14.7.5.3.5 are used. Although these equations are intended for steel-reinforced bearings with a higher allowable stress, the thickness of reinforcing sheets required is not significantly greater than those required by the old Method A.

#### 14.7.6.3.8—*Seismic and Other Extreme Event Provisions*

Expansion bearings designed according to Article 14.7.6 shall be provided with adequate seismic and other extreme event resistant anchorage to resist the horizontal forces in excess of those accommodated by shear in the pad unless the bearing is intended to act as a fuse or irreparable damage is permitted. The provisions of Article 14.7.5.3.7 shall also apply as applicable.

## 14.7.7—Bronze or Copper Alloy Sliding Surfaces

### 14.7.7.1—Materials

Bronze or copper alloy may be used for:

- Flat sliding surfaces to accommodate translational movements,
- Curved sliding surfaces to accommodate translation and limited rotation, and
- Pins or cylinders for shaft bushings of rocker bearings or other bearings with large rotations.

Bronze sliding surfaces or castings shall conform to AASHTO M 107 ([ASTM B22](#)) and shall be made of Alloy C90500, C91100, or C86300, unless otherwise specified. The mating surface shall be structural steel, which has a Brinell hardness value at least 100 points greater than that of the bronze.

### C14.7.7.1

Bronze or copper alloy sliding surfaces have a long history of application in the United States with relatively satisfactory performance of the different materials. However, there is virtually no research to substantiate the properties and characteristics of these bearings. Successful past experience is the best guide currently available.

Historically these bearings have been built from sintered bronze, lubricated bronze, or copper alloy with no distinction between the performance of the different materials. However, the evidence suggests otherwise. Sintered bronze bridge bearings have historically been included in the Standard Specifications. Sintered bronze is manufactured with a metal powder technology, which results in a porous surface structure that is usually filled with a self-lubricating material. There do not appear to be many manufacturers of sintered bronze bridge bearings at this time, and there is some evidence that past bridge bearings of this type have not always performed well. As a result, there is no reference to sintered bronze herein.

Lubricated bronze bearings are produced by a number of manufacturers, and they have a relatively good history of performance. The lubrication is forced into a pattern of recesses, and the lubrication reduces the friction and prolongs the life of the bearing. Plain bronze or copper lacks this self-lubricating quality and would appear to have poorer bearing performance. Some jurisdictions use the following guidelines for lubricant recesses (FHWA, 1991):

- The bearing surfaces should have lubricant recesses consisting of either concentric rings, with or without central circular recesses with a depth at least equal to the width of the rings or recesses.
- The recesses or rings should be arranged in a geometric pattern so that adjacent rows overlap in the direction of motion.
- The entire area of all bearing surfaces that have provision for relative motion should be lubricated by means of the lubricant-filled recesses.
- The lubricant-filled areas should comprise not less than 25 percent of the total bearing surface.
- The lubricating compound should be integrally molded at high pressure and compressed into the rings or recesses and project not less than 0.010 in. above the surrounding bronze plate.

Bronze or copper alloy sliding expansion bearings shall be evaluated for shear capacity and stability under lateral loads.

The mating surface shall be made of steel and be machined to match the geometry of the bronze surface so as to provide uniform bearing and contact.

Bronze or copper-alloy sliding expansion bearings should be evaluated for stability. The sliding plates inset into the metal of the pedestals or sole plates may lift during high horizontal loading. Guidelines for bearing stability evaluations may be found in Gilstad (1990). The shear capacity and stability may be increased by adding anchor bolts inserted through a wider sole plate and set in concrete.

The mating surface is commonly manufactured by a steel fabricator rather than by the bearing manufacturer who produces the bronze surface. This contractual arrangement is discouraged because it can lead to a poor fit between the two components. The bronze is weaker and softer than the steel, and fracture and excessive wear of the bronze may occur if there is inadequate quality control.

#### 14.7.7.2—Coefficient of Friction

The coefficient of friction may be determined by testing. In lieu of such test data, the design coefficient of friction may be taken as 0.1 for self-lubricating bronze components and 0.4 for other types.

#### C14.7.7.2

The best available experimental evidence suggests that lubricated bronze can achieve a coefficient of friction on the order of 0.07 during its early life, while the lubricant projects above the bronze surface. The coefficient of friction is likely to increase to approximately 0.10 after the surface lubrication wears away and the bronze starts to wear down into the recessed lubricant. Copper alloy or plain bronze would cause considerably higher friction. In the absence of better information, conservative coefficients of friction of 0.1 and 0.4, respectively, are recommended for design.

#### 14.7.7.3—Limit on Load

The nominal bearing stress due to combined dead and live load at the service limit state shall not exceed the values given in Table 14.7.7.3-1.

**Table 14.7.7.3-1—Bearing Stress at the Service Limit State**

AASHTO M 107 (ASTM B22) Bronze Alloy	Bearing Stress (ksi)
C90500—Type 1	2.0
C91100—Type 2	2.0
C86300—Type 3	8.0

#### 14.7.7.4—Clearances and Mating Surfaces

The mating surface shall be steel that is accurately machined to match the geometry of the bronze surface and to provide uniform bearing and contact.

## 14.7.8—Disc Bearings

### 14.7.8.1—General

The dimensions of the elements of a disc bearing shall be such that hard contact between metal components, which prevents further displacement or rotation, will not occur under the least favorable combination of design displacements and rotations at the strength limit state.

The disc bearing shall be designed for the maximum strength limit state design rotation,  $\theta_u$ , specified in Article 14.4.2.2.2.

For the purpose of establishing the forces and deformations imposed on a disc bearing, the axis of rotation may be taken as lying in the horizontal plane at midheight of the disc. The urethane disc shall be held in place by a positive location device.

Limiting rings may be used to partially confine the elastomer against lateral expansion. They may consist of steel rings welded to the upper and lower plates or a circular recess in each of those plates.

If a limiting ring is used, the depth of the ring should be at least  $0.03D_d$ , where  $D_d$  is the diameter of the disk element.

### 14.7.8.2—Materials

The elastomeric disc shall be made from a compound based on polyether urethane, using only virgin materials. The hardness shall be between 45 and 65 on the Shore D scale.

The metal components of the bearing shall be made from structural steel conforming to AASHTO M 270/M 270 ([ASTM A709/A709M](#)), Grade 36, 50, or 50W or from stainless steel conforming to [ASTM A240](#).

### C14.7.8.1

A disc bearing functions by deformation of a polyether urethane disc, which should be stiff enough to resist vertical loads without excessive deformation and yet be flexible enough to accommodate the imposed rotations without liftoff or excessive stress on other components, such as PTFE. The urethane disc should be positively located to prevent its slipping out of place.

The primary concerns are that clearances should be maintained and that binding should be avoided even at extreme rotations. The vertical deflection, including creep, of the bearing should be taken into account.

$\theta_u$  may also be considered at the extreme event limit state.

The depth of the limiting ring should be at least  $0.03D_d$  to prevent possible overriding by the urethane disc under extreme rotation conditions.

### C14.7.8.2

*AASHTO LRFD Bridge Construction Specifications*, Article 18.3.2, recognizes two polyether urethane compounds that have performed satisfactorily.

Polyether urethane can be compounded to provide a wide range of hardnesses. The appropriate material properties must be selected as an integral part of the design process because the softest urethanes may require a limiting ring to prevent excessive compressive deflection, whereas the hardest ones may be too stiff and cause too high a resisting moment. Also, harder elastomers generally have higher ratios of creep to elastic deformation.

AASHTO M 270/M 270 ([ASTM A709/A709M](#)), Grades 100 and 100W steel should be used only where their reduced ductility will not be detrimental.

### C14.7.8.3

The primary concerns are that clearances should be maintained and that binding should be avoided even at extreme rotations. The vertical deflection, including creep, of the bearing should be taken into account.

Design of the urethane disc may be based on the assumption that it behaves as a linear elastic material, unrestrained laterally at its top and bottom surfaces. The estimates of resisting moments, so calculated, will be conservative, because they ignore creep, which reduces the moments. However, the compressive deflection due to creep should also be accounted for. Limiting rings stiffen the bearing in compression because they make the bearing behave more like a confined elastomeric bearing, i.e., a pot

### 14.7.8.3—Elastomeric Disc

The elastomeric disc shall be held in location by a positive locator device.

At the service limit state, the disc shall be designed so that:

- Its instantaneous deflection under total load does not exceed ten percent of the thickness of the unstressed disc, and the additional deflection due to creep does not exceed eight percent of the thickness of the unstressed disc;
- The components of the bearing do not lift off each other at any location; and

- The average compressive stress on the disc does not exceed 5.0 ksi. If the outer surface of the disc is not vertical, the stress shall be computed using the smallest plan area of the disc.

If a PTFE slider is used, the stresses on the PTFE slider shall not exceed the values for average and edge stresses given in Article 14.7.2.4 for the service limit state. The effect of moments induced by the urethane disc shall be included in the stress analysis.

#### 14.7.8.4—Shear Resisting Mechanism

In fixed and guided bearings, a shear-resisting mechanism shall be provided to transmit horizontal forces between the upper and lower steel plates. It shall be capable of resisting a horizontal force in any direction equal to the larger of the design shear force at the strength and extreme event limit states or 15 percent of the design vertical load at the service limit state.

The horizontal design clearance between the upper and lower components of the shear-restricting mechanism shall not exceed the value for guide bars given in Article 14.7.9.

bearing. Their influence is conservatively ignored in the linear elastic design approach. Subject to the approval of the Engineer, design methods based on test data are permitted.

No liftoff of components can be tolerated; therefore, any uplift restraint device should have sufficiently small vertical slack to ensure the correct location of all components when the compressive load is reapplied.

Rotational experiments have shown that uplift occurs at relatively small moments and rotations in disc bearings. There are concerns that this could lead to edge loading on PTFE sliding surfaces and increase the potential for damage to the PTFE. Bearings passing the test requirements of Article 18.3.4.4.4 of the LRFD Bridge Construction Specification should assure against any damage to the PTFE.

#### C14.7.8.4

The shear resisting device may be placed either inside or outside the urethane disc. If shear is carried by a separate transfer device external to the bearing, such as opposing concrete blocks, the bearing itself may be unguided.

In unguided bearings, the shear force that should be transmitted through the body of the bearing is  $\mu P$ , where  $\mu$  is the coefficient of friction of the PTFE slider and  $P$  is the vertical load on the bearing. This may be carried by the urethane disc without a separate shear-resisting device, provided that the disc is held in place by positive locating devices, such as recesses in the top and bottom plates.

The 15 percent factor applied to the service limit state vertical load approximates a strength limit state horizontal design force.

Maximum extreme event limit state forces should be considered when the bearing is not intended to act as a fuse or irreparable damage is not permitted.

#### 14.7.8.5—Steel Plates

The provisions of Sections 3, 4, and 6 of these Specifications shall apply as appropriate.

The thickness of each of the upper and lower steel plates shall not be less than  $0.045 D_d$ , where  $D_d$  is the diameter of the disk element, if it is in direct contact with a steel girder or distribution plate, or  $0.06 D_d$  if it bears directly on grout or concrete.

#### 14.7.9—Guides and Restraints

##### 14.7.9.1—General

Guides may be used to prevent movement in one direction. Restraints may be used to permit only limited movement in one or more directions. Guides and restraints shall have a low-friction material at their sliding contact surfaces.

#### C14.7.8.5

The plates should be thick enough to uniformly distribute the concentrated load in the bearing. Distribution plates should be designed in accordance with Article 14.8.

##### C14.7.9.1

Guides are frequently required to control the direction of movement of a bearing. If the horizontal force becomes too large to be carried reliably and economically on a guided bearing, a separate guide system may be used.

### 14.7.9.2—Design Loads

Guides or restraints shall be designed at the strength limit state for the larger of either:

- The horizontal force from applicable strength load combinations specified in Table 3.4.1-1, or
- 15 percent of the total vertical force from applicable service load combinations specified in Table 3.4.1-1 acting on all the bearings at the bent divided by the number of guided bearings at the bent.

Guides and restraints shall be designed for applicable seismic or other extreme event forces using the extreme event limit state load combinations of Table 3.4.1-1 and, in the case of seismic, the provisions in Article 3.10.9.

### 14.7.9.3—Materials

For steel bearings, the guide or restraint shall be made from steel conforming to AASHTO M 270M/M 270 ([ASTM A709/A709M](#)), Grades 36, 50, or 50W or stainless steel conforming to [ASTM A240](#). For aluminum bearings, the guide may also be aluminum.

The low-friction interface material shall be approved by the Engineer.

### 14.7.9.4—Geometric Requirements

Guides shall be parallel, long enough to accommodate the full design displacement of the bearing in the sliding direction, and shall permit a minimum of 0.03125-in. and a maximum of 0.0625-in. free slip in the restrained direction. Guides shall be designed to avoid binding under all design loads and displacements, including rotation.

### 14.7.9.5—Design Basis

#### 14.7.9.5.1—Load Location

The horizontal force acting on the guide or restraint shall be assumed to act at the centroid of the low-friction interface material. Design of the connection between the guide or restraint and the body of the bearing system shall consider both shear and the overturning moments so caused.

### C14.7.9.2

The minimum horizontal design load, taken as ten percent of the factored vertical load, is intended to account for responses that cannot be calculated reliably, such as horizontal bending or twisting of a bridge deck caused by nonuniform or time-dependent thermal effects.

Large ratios of horizontal to vertical load can lead to bearing instability, in which case a separate guide system should be considered.

The 15 percent factor applied to the service limit state vertical load approximates a strength limit state horizontal design force.

Maximum extreme event limit state forces should be considered when the bearing is not intended to act as a fuse or irreparable damage is not permitted.

### C14.7.9.3

Many different low-friction materials have been used in the past. Because the total transverse force at a bent is usually smaller than the total vertical force, the guides may contribute less toward the total longitudinal friction force than the primary sliding surfaces. Thus, material may be used that is more robust but causes higher friction than the primary material. Filled PTFE is common, and other proprietary materials, such as PTFE-impregnated metals, have proven effective.

### C14.7.9.4

Guides must be parallel to avoid binding and inducing longitudinal resistance. The clearances in the transverse direction are fairly tight and are intended to ensure that excessive slack does not exist in the system. Free transverse slip has the advantage that transverse restraint forces are not induced, but if this is the objective a nonguided bearing is preferable. On the other hand, if applied transverse loads are intended to be shared among several bearings, free slip causes the load to be distributed unevenly, possibly leading to overloading of one guide.

#### C14.7.9.5.1

Guides are often bolted to the slider plate to avoid welding distortions. Horizontal forces applied to the guide cause some overturning moment, which must be resisted by the bolts in addition to shear. The tension in the bolt can be reduced by using a wider guide bar. If high-strength bolts are used, the threaded hole in the plate should be deep enough to develop the full tensile strength of the bolt.

Some press-fit guide bar details in common use have proven unsatisfactory in resisting horizontal loads. When analyzing such designs, consideration should be given to the possibility of rolling the bar in the recess (SCEF, 1991).

Where guide bars are recessed into a machined slot, tolerances should be specified to provide a press fit. The guide bar should also be welded or bolted to resist overturning.

Past earthquakes have shown that guide and keeper bars and keeper rings or nuts at the ends of pins and other guiding devices have failed, even under moderate seismic loads. In an experimental investigation of the strength and deformation characteristics of rocker bearings (Mander et al., 1993), it was found that adequately sized pintles are sometimes capable of providing the necessary resistance to seismic loads.

The design and detailing of bearing components resisting lateral loads, including seismic and other extreme event loads determined as specified in Article 14.6.3.1, shall provide adequate strength and ductility. Guide bars and keeper rings or nuts at the ends of pins and similar devices shall either be designed to resist all imposed loads or an alternative load path shall be provided that engages before the relative movement of the substructure and superstructure is excessive.

#### **14.7.9.5.2—Contact Stress**

The contact stress on the low-friction material shall not exceed that recommended by the manufacturer. For PTFE, the stresses at the service limit state shall not exceed those specified in Table 14.7.2.4-1 under sustained loading or 1.25 times those stresses for short-term loading.

#### **C14.7.9.5.2**

Appropriate compressive stresses for proprietary materials should be developed by the Manufacturer and approved by the Engineer on the basis of test evidence. Strength, cold flow, wear, and friction coefficient should be taken into consideration.

On conventional materials, higher stresses are allowed for short-term loading because the limitations in Table 14.7.2.4-1 are based partly on creep considerations. Short-term loading includes wind, earthquake, etc., but not thermal or gravity effects.

#### **14.7.9.6—Attachment of Low-Friction Material**

The low-friction material shall be attached by at least any two of the following three methods:

- Mechanical fastening,
- Bonding, and
- Mechanical interlocking with a metal substrate.

#### **14.7.10—Other Bearing Systems**

Bearing systems made from components not specified in Articles 14.7.1 through 14.7.9 may also be used, subject to the approval of the Engineer. Such bearings shall be adequate to resist the forces and deformations imposed on them at the service and strength limit states without material distress and without inducing deformations detrimental to their proper functioning. At the extreme event limit state, bearings which are designed to act as fuses or sustain irreparable damage may be permitted by the Owner provided loss of span is prevented.

#### **C14.7.9.6**

Some difficulties have been experienced where PTFE is attached to the metal backing plates by bonding alone. Ultra-violet light attacks the PTFE surface that is etched prior to bonding, and this has caused bond failures. Thus, at least two separate methods of attachment are required. Mechanical fasteners should be countersunk to avoid gouging the mating surface.

#### **C14.7.10**

Tests cannot be prescribed unless the nature of the bearing is known. In appraising an alternative bearing system, the Engineer should plan the test program carefully because the tests constitute a larger part of the quality assurance program than is the case with more widely used bearings.

In bearings that rely on elastomeric components, aspects of behavior, such as time-dependent effects, response to cyclic loading, temperature sensitivity, etc., should be investigated.

The dimensions of the bearing shall be chosen to provide for adequate movements at all times. Materials shall have sufficient strength, stiffness, and resistance to creep and decay to ensure the proper functioning of the bearing throughout the design life of the bridge.

The Engineer shall determine the tests that the bearing shall satisfy. The tests shall be designed to demonstrate any potential weakness in the system under individual compressive, shear, or rotational loading or combinations thereof. Testing under sustained and cyclic loading shall be required.

Some bearing tests are very costly to perform. Other bearing tests cannot be performed because there is no available test equipment in the United States. At the present time, the largest U.S. facility for testing bearings in combined axial load and shear is the Seismic Response Modification Device Test Facility at the University of California, San Diego constructed by Caltrans. This facility can test bearings of all kinds up to 12,000-kip axial load capacity and 2,000-kip transverse load capacity (HITEC, 2002). Nevertheless, the following test requirements should be carefully considered before specifying them (SCEF, 1991):

- Vertical loads exceeding 5,000 kips,
- Horizontal loads exceeding 500 kips,
- The simultaneous application of horizontal and vertical load where the horizontal load exceeds 75 percent of the vertical load,
- Triaxial test loading,
- The requirement for dynamic rotation of the test bearing while under vertical load, and
- Coefficient of friction test movements with normal loads greater than 250 kips.

## 14.8—LOAD PLATES AND ANCHORAGE FOR BEARINGS

### 14.8.1—Plates for Load Distribution

The bearing, together with any additional plates, shall be designed so that:

- The combined system is stiff enough to prevent distortions of the bearing that would impair its proper functioning when subjected to service and strength limit state loadings, and maximum extreme event loadings when required;
- The stresses imposed on the supporting structure satisfy the limits specified by the Engineer and Sections 5, 6, 7, or 8; and
- The bearing can be replaced within the jacking height limits specified by the Engineer without damage to the bearing, distribution plates, or supporting structure. If no limit is given, a height of 0.375 in. shall be used.

Resistance of steel components shall be determined in accordance with Section 6.

In lieu of a more refined analysis, the load from a bearing fully supported by a grout bed may be assumed to distribute at a slope of 1.5:1, horizontal to vertical, from the edge of the smallest element of the bearing that resists the compressive load.

### C14.8.1

Large forces may be concentrated in a bearing that must be distributed so as not to damage the supporting structure. In general, metal rocker and roller bearings cause the most concentrated loads, followed by pots, discs, and sphericals, whereas elastomeric bearings cause the least concentrated loads. Masonry plates may be required to prevent damage to concrete or grout surfaces.

Many simplified methods have been used to design masonry plates, some based on strength and some on stiffness. Several studies have indicated that masonry plates are less effective in distributing the load than these simplified methods would suggest, but the cost of heavy load distribution plates would be considerable (McEwen and Spencer, 1981; Saxena and McEwen, 1986). The present design rules represent an attempt to provide a uniform basis for design that lies within the range of traditional methods. Design based on more precise information, such as finite element analysis, is preferable but may not be practical in many cases.

Some types of bearings were only developed in the last 20 or 30 yr, so their longevity has yet to be proven in the field. Hence the requirement for bearing replaceability.

One common way to provide for replacement is to use a masonry plate, attached to the concrete pier head by

The use and design of bearing stiffeners on steel girders shall comply with Section 6.

Sole plate and base plate connections shall be adequate to resist lateral loads at the strength limit state. These connections shall also be adequate to resist the maximum seismic and other extreme event lateral loads unless the bearings are designed to act as fuses or sustain irreparable damage. Sole plates shall be extended to allow for anchor bolt inserts, when required.

#### 14.8.2—Tapered Plates

If, under full permanent load at the mean annual temperature for the bridge site (at the service limit state with all load factors equal to 1.0), the inclination of the underside of the girder to the horizontal exceeds 0.01 rad., a tapered plate shall be used in order to provide a level surface.

#### 14.8.3—Anchorage and Anchor Bolts

##### 14.8.3.1—General

All load distribution plates and bearings with external steel plates shall be positively secured to their supports by bolting or welding.

All girders shall be positively secured to supporting bearings by a connection that can resist the horizontal forces that may be imposed on it unless fusing or irreparable damage is permitted at the extreme event limit state. Separation of bearing components shall not be permitted at the strength limit state. Connections shall resist the least favorable combination of loads at the strength limit state and shall be installed wherever deemed necessary to prevent separation.

Trusses, girders, and rolled beams shall be securely anchored to the substructure. Where possible, anchor bolts should be cast in substructure concrete, otherwise anchor bolts may be grouted in place. Anchor bolts may be swaged or threaded to secure a satisfactory grip upon the material used to embed them in the holes.

The resistance of the anchor bolts shall be adequate for loads at the strength limit state and for the maximum loads at the extreme event limit state unless the bearings are designed to act as fuses or sustain irreparable damage.

The tensile resistance of anchor bolts shall be determined as specified in Article 6.13.2.10.2.

embedded anchors or anchor bolts. The bearing can then be attached to the masonry plate by seating it in a machined recess and bolting it down. The bridge needs then to be lifted only through a height equal to the depth of the recess in order to replace the bearing. The deformation tolerance of joints and seals, as well as the stresses in the structure, should be considered in determining the allowable jacking height.

#### C14.8.2

Tapered plates may be used to counteract the effects of end slope in a girder. In all but short-span bridges, the dead load will dominate the forces on the bearing, so the tapered plate should be designed to provide zero rotation of the girder under this condition. The limit of 0.01 rad. out of level corresponds to the 0.01 rad. component, which is required in the design rotation in Article 14.4.

##### C14.8.3.1

Bearings should be anchored securely to the support to prevent their moving out of place during construction or over the life of the bridge. Elastomeric bearings may be left without anchorage if adequate friction is available. A design coefficient of friction of 0.2 may be assumed between elastomer and clean concrete or steel.

Girders may be located on bearings by bolts or pintles. The latter provide no uplift capacity. Welding may be used, provided that it does not cause damage to the bearing or difficulties with replacement.

Uplift should be prevented both among the major elements, such as the girder, bearing, support, and between the individual components of a bearing. If it was allowed to occur, some parts of the structure could be misaligned when contact was regained, causing damage.

Anchor bolts are very susceptible to brittle failure during earthquakes or other extreme events. To increase ductility, it has been recommended in Astaneh-Asl et al. (1994) to use upset anchor bolts placed inside hollow sleeve pipes and oversized holes in the masonry plate. Thus, deformable bearing types may use the anchor bolts as the ductile element (Cook and Klingner, 1992).

Bearings designed for rigid load transfer, especially at the extreme event limit state, should not be seated on grout pads or other bedding materials that can create a sliding surface and reduce the horizontal resistance.

Seismic loading of the anchor bolts has often resulted in concrete damage, especially when they were too close to the edge of the bearing seat. Guidelines for evaluating edge distance effects and concrete strength requirements may be found in Ueda et al. (1990), among others.

The shear resistance of anchor bolts and dowels shall be determined as specified in Article 6.13.2.12.

The resistance of anchor bolts in combined tension and shear shall be determined as specified in Article 6.13.2.11.

The bearing resistance of the concrete shall be taken as specified in Article 5.7.5. The modification factor,  $m$ , shall be based on a nonuniformly distributed bearing stress.

#### **14.8.3.2—Seismic and Other Extreme Event Design and Detailing Requirements**

Sufficient reinforcement shall be provided around the anchor bolts to develop the level of horizontal forces considered at the extreme event limit state and anchor them into the mass of the substructure unit. Potential concrete crack surfaces next to the bearing anchorage shall be identified and their shear friction capacity evaluated as required.

### **14.9—CORROSION PROTECTION**

All exposed steel parts of bearings not made from stainless steel shall be protected against corrosion by zinc metalization, hot-dip galvanizing, or a paint system approved by the Engineer. A combination of zinc metalization or hot-dip galvanizing and a paint system may be used.

For global design of anchorages to concrete, refer to *Building Code Requirements for Structural Concrete* (ACI 318-05), Appendix D.

As an approximation, the bearing stress may be assumed to vary linearly from zero at the end of the embedded length to its maximum value at the top surface of concrete.

### **C14.9**

The use of stainless steel is the most reliable protection against corrosion because coatings of any sort are subject to damage by wear or mechanical impact. This is particularly important in bearings where metal-to-metal contact is inevitable, such as rocker and roller bearings. Weathering steel is excluded because it forms an oxide coating that may inhibit the proper functioning of the bearing.

When using hot-dip galvanizing for corrosion protection, several factors must be considered. Embrittlement of very high-strength fasteners, such as AASHTO M 253 ([ASTM A490](#)) bolts, may occur due to acid cleaning (pickling) before galvanizing, and quenched and tempered material, such as Grade 70W and 100W, may undergo changes in mechanical properties, so galvanizing these should be avoided (see [ASTM A143](#) on avoiding embrittlement). With good practice, commonly used steels, such as Grades 36, 50, and 50W, should not be adversely affected if their chemistry and the assembly's details are compatible (see [ASTM A385](#) on ensuring high-quality coating). Certain types of bearings, such as intricate pot or spherical bearings, are not suitable for hot-dip galvanizing.

basic steps for steel bridge	
superstructures.....	6-294
coefficient of thermal expansion .....	6-22
minimum mechanical properties by shape, strength, and thickness.....	6-24
modulus of elasticity.....	6-22
thickness of metal .....	6-22
Steel box-section flexural members.....	6-173
access and drainage .....	6-179
access holes .....	6-58
bearings .....	6-178
compact sections.....	6-189
constructibility .....	6-181
cross-section proportion limits .....	6-179
fatigue and fracture limit state .....	6-185
flange-to-web connections.....	6-178
flexural resistance—sections in negative flexure.....	6-191
flexural resistance—sections in positive flexure.....	6-189
noncompact sections.....	6-189
service limit state .....	6-184
shear connectors .....	6-197
shear resistance .....	6-196
stiffeners .....	6-198
strength limit state .....	6-187
stress determination .....	6-173
Steel dimension and detail requirements	
dead load camber .....	6-52
diaphragms and cross-frames .....	6-55
effective length of span.....	6-52
heat-curved rolled beams and welded plate girders .....	6-66
lateral bracing .....	6-60
minimum thickness of steel .....	6-54
pins .....	6-64
Steel I-girders	
See: Steel I-section flexural members	
Steel I-section flexural members	
compact sections.....	6-136, 6-141
composite sections .....	6-100
constructibility .....	6-119
cover plates.....	6-171
cross-section proportion limits .....	6-117
diaphragms or cross-frames .....	6-55
ductility requirement.....	6-140
fatigue and fracture limit state .....	6-129
flange-strength reduction factors .....	6-112
flange stresses and member bending moments .....	6-104
flexural resistance .....	6-137, 6-140
flexural resistance—composite sections in negative flexure and noncomposite sections .....	6-141
flexural resistance—composite sections in positive flexure .....	6-136
flowcharts for design .....	6-299
fundamental calculations .....	6-312
hybrid sections.....	6-102
lateral bracing .....	6-60
minimum negative flexure concrete deck reinforcement.....	6-107
moment redistribution from interior-pier I sections in straight continuous- span bridges .....	6-281
net section fracture.....	6-108
noncompact sections.....	6-139, 6-140
noncomposite sections .....	6-102
service limit state .....	6-126
shear connectors .....	6-155
shear resistance .....	6-151
stiffeners .....	6-162
stiffness.....	6-104
strength limit state .....	6-130
variable web depth members .....	6-103
web bend-buckling resistance .....	6-109
wind effect on flanges.....	4-59
Steel I-section proportioning	
flange proportions.....	6-118
web proportions .....	6-117
Steel orthotropic decks	
See: Orthotropic steel decks	
Steel piles.....	6-257
axial compression .....	6-258
buckling .....	6-258

combined axial compression and flexure .....	6-258	steel box-section flexural members .....	6-187
compressive resistance .....	6-258	steel structures .....	6-30, 6-202
maximum permissible driving stresses.....	6-259	wood structures .....	8-30
structural resistance .....	6-257, 10-119
